Transactions

of the

A.S.M.E.

SOCIETY RECORDS

(Including Indexes to Publications)

JANUARY, 1946

VOL. 68, NO. 1

Transactions

of The American Society of Mechanical Engineers

Published on the tenth of every month, except March, June, September, and December

---

Published monthly by The American Society of Mechanical Engineers. Publication office at 20th and Northampton Streets, Easton, Pa. The editorial department is located at the headquarters of the Society, 29 West Thirty-Ninth Street, New York 18, N. Y. Cable address, "Dynamic,"New York. Price $1.50 a copy, $12.00 a year; to members and affiliates, $1.00 a copy, $7.50 a year. Changes of address must be received at Society headquarters two weeks before they are to be effective on the mailing list. Please send old as well as new address. . . . By-Law: The Society shall not be responsible for statements or opinions advanced in papers or . . . printed in its publications (B13, Par. 4). . . . Entered as second-class matter March 2, 1928, at the Post Office at Easton, Pa., under the Act of August 24, 1912. . . .

Depositories for A.S.M.E. Transactions in the United States, Including Territories and Dependencies

BOUND copies of the complete Transactions of The American Society of Mechanical Engineers will be found in the libraries in the United States and other countries which are listed on the following pages.

Alabama

Auburn..........Engineering Library, Alabama Poly. Inst.
Birmingham.....Public Library
University.......Library, University of Alabama

Arizona

Tucson..........Library, University of Arizona

Arkansas

Fayetteville......Engineering Library, University of Arkansas

California

Berkeley.........Library, University of California
Long Beach......Public Library
Los Angeles......Public Library

Indexes to A.S.M.E. Papers and Publications

THIS and the following pages will serve as a guide to the current publications of the A.S.M.E.

Regular Society Publications, 1945

Mechanical Engineering, monthly (see index on page RI-91)
A.S.M.E. Transactions, monthly including the *Journal of Applied Mechanics* (see index on page RI-101)
A.S.M.E. Mechanical Catalog and Directory, 1946 edition.

Publications Issued in 1945

Bibliography on Cutting of Metals
Riveted Joints—A review of the literature covering their development, with bibliography and abstracts of the most important articles.
Sources of Information on Instruments
1943 Automotive and Oil-Engine Power Cost Reports

American Standards

Gear Tolerances and Inspection
Preferred Standards for Large 3600-Rpm 3-Phase 60-Cycle Condensing Steam Turbine-Generators
Pipe Threads
Screw Threads for High-Strength Bolting

Boiler Construction Code

1945 Addenda to:
Locomotive Boiler Code
Low-Pressure Heating Boiler Code
Power Boiler Code
Unfired Pressure Vessel Code
Specifications for Materials
Welding Qualifications

Power Test Codes

General Instructions
Definitions and Values
Part 3, Chapter 4—Resistance Thermometers
Part 20—Smoke-Density Determinations

Safety Codes

Elevator Inspector's Manual
Description and Schematic Layouts of Various Types of Undercar Safeties and Governors
Handling and Socketing of Wire Rope

How to Find Papers Presented at 1945 A.S.M.E. Meetings

THE technical programs of the meetings of the Society and of its Professional Divisions have been published in *Mechanical Engineering* and may be located by consulting the index on pages RI-91–RI-100. A majority of these papers were published, or will be published, in *Mechanical Engineering* or the Transactions (including the *Journal of Applied Mechanics*) and may be located by reference to the indexes of these publications.

Publications Developed by the Technical Committees

THE Society's technical committees, the first of which was organized many years ago and all of which have been continuously at work on codes, standards, research, and other special reports, have developed a series of publications of permanent value to the membership. The following list is presented here for record and for ready reference. This list covers the entire group of publications of these committees completed to date which are now available.

To assist members in securing copies of these publications the sale price is also given. A discount of 20 per cent is allowed to A.S.M.E. members on all publications except where otherwise noted.

A.S.M.E. AMERICAN STANDARDS

Bolt, Nut, and Rivet Proportions

Large Rivets (B18.4—1937), $0.65
Plow Bolts (B18f—1928), $0.35
Round Unslotted-Head Bolts (B18.5—1939), $0.50
Slotted-Head Proportions: Machine Screws, Cap Screws, and Wood Screws (B18c—1930), $0.45
Small Rivets (B18a—1927), $0.30
Socket Set Screws and Socket-Head Cap Screws (B18.3—1938), $0.40
Supplement to Socket Set Screws (B18.30—1944), $0.10
Tinners', Coopers', and Belt Rivets (B18g—1929), with 1942 Addendum, $0.35
Track Bolts and Nuts (B18d—1930), $0.40
Wrench-Head Bolts and Nuts and Wrench Openings (B18.2—1941), $0.65

Piping and Pipe Fittings

Air Gaps and Backflow Preventers in Plumbing Systems (A40.4—1942 and A40.6—1943), $0.45
Brass Fittings for Flared Copper Tubes (A40.2—1936), $0.35
Cast-Iron Pipe Flanges and Flanged Fittings for 25 Lb Maximum Saturated Steam Pressure (B16b2—1931), $0.40
Cast-Iron Pipe Flanges and Flanged Fittings Class 125 (B16a—1939), $0.60
Cast-Iron Pipe Flanges and Flanged Fittings Class 250 (B16b—1944), $0.45
Cast-Iron Pipe Flanges and Flanged Fittings for 800 Lb Maximum Hydraulic Pressure (B16b1—1931), $0.35
Cast-Iron Soil Pipe and Fittings (A40.1—1935), $0.65
Cast-Iron Long Turn Sprinkler Fittings for 150 and 250 Lb Maximum Saturated Steam Pressure (B16g—1929) and Addendum (B16g1—1937), $0.50
Cast-Iron Screwed Fittings for 125 and 250 Lb Maximum Saturated Steam Pressure (B16d—1941), $0.40
Cast-Iron Screwed Drainage Fittings (B16.12—1942), $0.45
Code for Pressure Piping (B31.1—1942), $2.00
Face-to-Face Dimensions of Ferrous Flanged and Welding End Valves (B16.10—1939), $0.55
Ferrous Plugs, Bushings, Lock Nuts, and Caps (B16.14—1943), $0.40
Malleable-Iron Screwed Fittings for 150 Lb Maximum Saturated Steam Pressure (B16c—1939), $0.50
Pipe Plugs (B16e2—1936), $0.35
Pipe Threads (B2.1—1945), $1.25
Scheme for the Identification of Piping Systems (A13—1928), $0.50
Steel Pipe Flanges and Flanged Fittings for 150 to 2500 Lb Maximum Steam Service Pressure (B16e—1939), $1.25
Soldered-Joint Fittings (A40.3—1941), $0.45
Steel Butt-Welding Fittings (B16.9—1940), $0.40
Threaded Cast-Iron Pipe for Drainage, Vent, and Waste Services (A40.5—1943), $0.25
Wrought-Iron and Wrought-Steel Pipe (B36.10–1939), $0.50

Letter and Graphical Symbols and Charts

Abbreviations for Scientific and Engineering Terms (Z10.1—1941), $0.35
Drawings and Drafting-Room Practice (Z14.1—1935), $0.50
Engineering and Scientific Charts for Lantern Slides (Z15.1—1932), $0.50
Engineering and Scientific Graphs for Publications (Z15.3—1943), $0.75
Graphical Symbols for Use on Drawings in Mechanical Engineering (Z32.2—1941), $0.50
Letter Symbols for Gear Engineering (B6.5—1943), $0.25
Letter Symbols for Hydraulics (Z10.2—1942), $0.35
Letter Symbols for Mechanics of Solid Bodies (Z10.3—1942), $0.25
Letter Symbols for Heat and Thermodynamics (Z10c—1943), $0.35
Time Series Charts (Z15.2—1938), $1.25

American Standards—Miscellany

Fire-Hose Coupling Screw Threads (B26—1925), $0.25
Hose Coupling Screw Threads (B33.1—1935), $0.25
Indicating Pressure and Vacuum Gages (B40—1939), $0.40
Preferred Thickness for Uncoated Thin Flat Metals (B32.1—1941), $0.25
Rolled Threads for Screw Shells of Electric Sockets and Lamp Bases (C44—1931), $0.35
Gear Tolerances and Inspection (B6—1945), $0.65
Preferred Standards for Large 3600-Rpm 3-Phase 60-Cycle Condensing Steam Turbine-Generators (published 1945), $0.25
Shaft Couplings (B49—1932), $0.35
Spur Gear Tooth Form (B6.1—1932) $0.45

Small Tools and Machine Tool Elements

Machine Tapers (B5.10—1943), $0.60
Milling Cutters (B5c—1930), $0.75
Reamers (B5.14—1941), $0.75
Taps—Cut and Ground Threads (B5.4—1939), $1.25
Terminology and Definitions for Single-Point Cutting Tools (B5.13—1939), $0.40
Adjustable Adapters (B5.11—1937), $0.50
Chucks and Chuck Jaws (B5.8—1936), $0.45
Circular and Dovetailed Forming Tool Blanks and Holding Elements (B5.7—1943), $0.50
Shafting and Stock Keys (B17.1—1943), $0.45
Markings for Grinding Wheels (B5.17—1943), $0.25
Involute Splines, Side Bearings (B5.15—1939), $0.65
Jig Bushings (B5.6—1941), $0.35
Lathe Spindle Noses (B5.9—1936), $0.50
Spindle Noses and Arbors (B5.18—1943), $0.25
Rotating Air Cylinders and Adapters (B5.5—1932), $0.35
Tool Holder Shanks Tool Post Openings (B5.2—1943), $0.35
Tool Life Tests (B5—1945), $0.40
T-Slots, Their Bolts, Nuts, Tongues, and Cutters (B5a—1941), $0.35
Twist Drills (B5.12—1940), $0.55
Code for Design of Transmission Shafting (B17c—1927), $0.75
Shafting and Stock Keys (B17.1—1934), $0.45
Screw Threads for Bolts, Nuts, Machine Screws, and Threaded Parts (B1.1—1935), $0.60
Screw Threads for High-Strength Bolting (B1.4—1945), $0.25
Screw Thread Gages and Gaging (B1.2—1941), $0.60
Acme and Other Translating Threads (B1.3—1941), $0.45
Tolerances, Allowances, and Gages for Metal Fits (B4a—1925), $0.50
Woodruff Keys, Keyslots, and Cutters (B17f—1930), $0.35

BOILER CONSTRUCTION CODE

1943 Editions: with 1944–1945 Addenda
- Locomotive Boiler Code, $0.75
- Low-Pressure Heating Boiler Code, $0.75
- Miniature Boiler Code, $0.50
- Power Boiler Code, $2.25
- Specifications for Materials, $3.00
- Suggested Rules for Power Boilers, $1.00
- Unfired Pressure Vessel Code, $1.50
- Welding Qualifications, $0.65

Boiler Code Interpretation Service, $5.00 annually
API-ASME Code for Unfired Pressure Vessels
- 1943 Edition, with 1944 Supplement, $1.25

POWER TEST CODES AND AUXILIARY SECTIONS

Test Codes for

Atmospheric Water-Cooling Equipment (1930), $0.45
Coal Pulverizers (1944), $0.70
Displacement Compressors, Vacuum Pumps, and Blowers (1939), $0.75
Dust Separating Apparatus (1941), $0.90
Evaporating Apparatus (1941), $0.50
Feedwater Heaters (1927), $0.35
Gaseous Fuels (1944), $0.75
Gas Producers (1928), $0.55
Hydraulic Prime Movers (1938 with 1942 Addenda), $0.60
Internal-Combustion Engines (1930), $0.55
Reciprocating Steam-Driven Displacement Pumps (1927), $0.65
Reciprocating Steam Engines (1935), $0.65
Refrigerating Systems (1927), $0.55
Solid Fuels (1931), $0.55
Speed-Responsive Governors (1927), $0.45
Steam Condensing Apparatus (1938), $0.65
Steam Locomotives (1941), $0.55
Steam Turbines (1941), $2.50
Appendix to Test Code for Steam Turbines (1943), $1.50

Auxiliary Sections

General Instructions (1945), $0.45
Definitions and Values (1945), $0.80
Part 1 — General Considerations (1935), $0.35
Part 2 — Pressure Measurement
- Chapter 1, Barometers; Chapter 6, Tables, Multipliers, and Standards (1941), $0.60
- Chapter 4, Bourdon, Bellows, Diaphragm, and Deadweight Gages (1938), $0.65
- Chapter 5, Liquid Column Gages (1942), $0.75

Part 3 — Temperature Measurement
- Chapter 1, General; Chapter 5, Pyrometric Cones; Chapter 6, Liquid-in-Glass Thermometers; and Chapter 7, Bourdon-Tube Thermometers (1931), $0.75
- Chapter 2, Radiation Pyrometers (1936), $0.55
- Chapter 3, Thermocouple Thermometers or Pyrometers (1940), $0.65
- Chapter 4, Resistance Thermometers (1945), $0.80
- Chapter 8, Optical Pyrometers (1940), $0.35

Part 4 — Head Measuring Apparatus (1933), $0.35
Part 5 — Chapter 4, Flow Measurement by Means of Standardized Nozzles and Orifice Plates (1940), $2.75
Part 6—Electrical Measurements (1934), $1.25
Part 8—Measurement of Indicated Horsepower (1941), $0.75
Part 9—Heat of Combustion (1943), $0.40
Part 11—Determination of Quality of Steam (1940), $0.45
Part 12—Measurement of Time (1942), $0.40
Part 13—Speed Measurements (1939), $0.45
Part 14—Linear Measurements (1936), $0.55
Part 15—Measurement of Surface Areas (1937), $0.75
Part 16—Density Determinations (1931), $0.30
Part 17—Determination of the Viscosity of Liquids (1931), $0.45
Part 18—Humidity Determinations (1932), $0.50
Part 20—Smoke-Density Determinations (1945), $0.65
Part 21—Leakage Measurements (1942), $0.60

RESEARCH

Fluid Meters:
- Part 1—Theory and Application (1937), $3.00
- Part 3—Selection and Installation (1933), $1.50

Report of the A.G.A.-A.S.M.E. Committee on Orifice Coefficients (1935), $2.75
Tests on Electrical Equipment for Drilling Rotary Drilled Oil Wells (1933), $0.85
Tests on Steam Equipment for Drilling Rotary Drilled Oil Wells (1932), $0.85
Bibliography on Aircraft Plywood (1944), $1.00
Bibliography on Management Literature and Supplement (1903–1935), $2.75
Bibliography on Marketing Research (1935), $1.00
Bibliography on the Cutting of Metals (published 1945), $6.50
Riveted Joints—A Critical Review of the Literature Covering Their Development, with Bibliography and Abstracts of the Most Important Articles (Published 1945), $4.50
Sources of Information on Instruments (published 1945), $0.75

SAFETY CODES

Safety Code for Cranes, Derricks, and Hoists (B30.2—1943), $1.50
Safety Code for Elevators (A17.1—1937 with 1942 Supplement), $1.25
Elevator Inspectors' Manual (A17.2—1945), $1.25
Safety Code for Jacks (B30.1—1943), $0.30
Safety Code for Mechanical Power-Transmission Apparatus (B15—1927), $0.35
Compressed-Air Machinery and Equipment (B19—1938), $0.30
Description and Schematic Layouts of Various Types of Undercar Safeties and Governors (published 1945), $0.40
Handling and Socketing of Wire Rope (published 1945), $0.25

Biographies

BIOGRAPHIES issued under the sponsorship of the A.S.M.E. Biography Committee are as follows:

Autobiography of an Engineer, by W. LeR. Emmet (1940), $3.50
Autobiography of John Fritz (1940), $3.25
Biography of Fred J. Miller (1941), $1.00
Life of Henry Laurence Gantt, by L. P. Alford (1934), $5.00

Books on Special Subjects

Automotive—Diesel Engine Cost and Performance Data (1943), $0.25
Corrosion-Resistant Metals (1936), $1.25
Creative Engineering (1944), $0.50
Design Data on Strength of Materials, Book 1 (1944), $1.50
Design Data on Mechanics (1944), $1.50
Engineering's Part in the Development of Civilization (1939), $1.50
Flow of Water in Pipes and Pipe Fittings (1941), $8.00
Forging of Steel Shells (1944), $0.75
Furnace-Performance Factors (1944), $1.00
General Discussion on Lubrication (1938) (no discount), $6.50
Graphitization of Steel Piping (1943–1944), $1.50
Hydraulic Structures (1937), $18.00
I.S.A. Tolerance System (1942), $2.50
Manual on Cutting of Metals (1939), $5.00
Manual of Consulting Practice (1939), $0.40
Oil Engine Power Cost Report (1943), $1.25
Reflections on the Motive Power of Heat (1943), $2.75
Sixty Year Index to A.S.M.E. Technical Papers (1941), $3.75
Theoretical Steam Rate Tables (1937), $1.25

Regular Society Publications

*Mechanical Engineering**—Annual Subscription rate in United States $6.00; to Canada $6.75; elsewhere, $7.50
A.S.M.E. Transactions,* including *Journal of Applied Mechanics*, Annual subscription rate in United States, $12.00, elsewhere, $12.75
1946 A.S.M.E. Mechanical Catalog and Directory, $3.00 (sent gratis to members upon request)

---

*Subscription price included in A.S.M.E. membership dues.

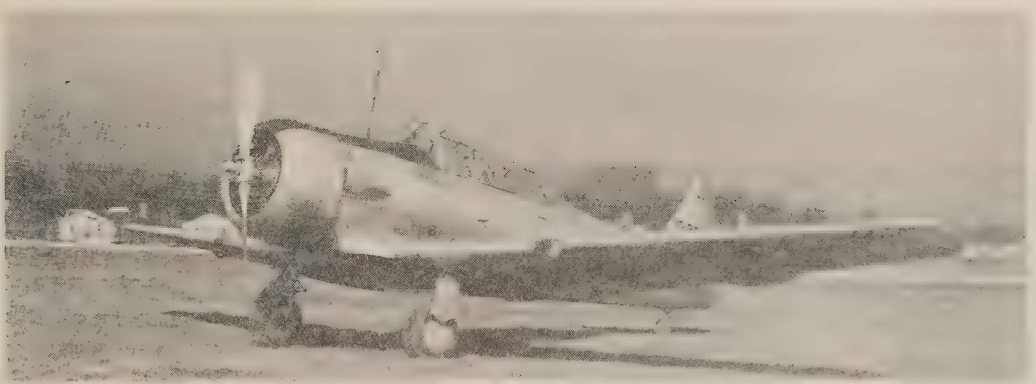

Fig. 1 North American AT-6C Airplane

The Practicability of Vibration Control in Light Aircraft

By DWIGHT C. KENNARD, JR.,[1] DAYTON, OHIO

The approach of the Air Technical Service Command to the problem of developing and evaluating a new engine-mount design is outlined, including a description of instrumentation, methods of vibration analysis, and presentation of natural-frequency formulas for elastically mounted power plants. The results of flight-vibration tests are presented for the standard engine mount, and an improved experimental engine mount installed in the North American AT-6C airplane. The results are discussed in detail showing the relative merits of the two engine installations. The test results show that the experimental engine mount, by providing natural frequencies of the mounted power plant which fall within the frequency range specified by the Air Technical Service Command, reduces appreciably the vibration of the engine and airplane structure.

Introduction

The development of successful antivibration mountings for aircraft radial engines of 1800 or more cu in. displacement has not been paralleled in the field of smaller aircraft engines. This development apparently has lagged owing to the understandable reluctance on the part of airplane manufacturers to accept what was considered to be a penalty in weight and cost in light airplane designs incorporating antivibration engine mountings. Pilots came to regard many of the light airplanes as uncomfortably "rough," and maintenance problems due to excessive vibration were looked upon as an inherent evil in such airplanes. However, the benefits of vibration control in airplanes equipped with larger engines was proving so successful that the Air Technical Service Command undertook a program of research and development directed toward attaining like benefits in light airplanes. Efforts were directed toward realizing an effective yet practical antivibration engine-mounting system for such light engine installations as are used in training, cargo, liaison, and other types of Army aircraft.

As a first step in this program, the Air Technical Service Command issued a design specification,[2] defining requirements for the antivibration provisions to be incorporated in an experimental engine mount for the Pratt and Whitney R-985 engine. Such a mount was subsequently procured[3] and thoroughly tested with an R-985 engine installed on a test stand. Upon satisfactory completion of these tests, the second step was to procure a similar engine mount for the Pratt and Whitney R-1340 engine to be installed in an AT-6C airplane.

This paper concerns the vibration tests which were conducted by the Air Technical Service Command on the AT-6C standard and experimental engine-mount installations in flight (1).[4]

Description of the AT-6C Airplane

The North American AT-6C airplane which was chosen for the test program is a two-place all-metal low-wing monoplane with monocoque fuselage and full cantilever wings, Fig. 1. The landing gear is the conventional type and is retractable. The tactical mission of the airplane is to provide a means for the advanced training of student pilots and their transition flying training to combat-type airplanes. The airplane is equipped

Contributed by the Aviation Division of The American Society of Mechanical Engineers.

[2] This specification embodied the standard AAF requirements which restrict the natural frequencies of the mounted power plant to a lower limit of 400 cycles per min and an upper limit corresponding to 45 per cent normal rated engine rpm, or 75 per cent normal rated propeller rpm, whichever has the lower value.

[3] This engine mount was designed and manufactured by the United Aircraft Corporation, Pratt and Whitney Engine Division, and the Goodyear Tire and Rubber Corporation.

[4] Numbers in parentheses refer to the Bibliography at the end of the paper.

with a Pratt and Whitney nine-cylinder single-row air-cooled radial R-1340-AN-1 engine, which drives directly a Hamilton Standard two-blade controllable-pitch constant-speed aluminum-alloy propeller, 9 ft diam. The engine has a power rating of 550 bhp at 2200 rpm and produces a maximum power for take-off amounting to 600 bhp at 2250 rpm.

Engine Mounts Tested

The engine mounting structure is the conventional welded-steel tubular-truss construction, embodying a circular ring, around the periphery of which are welded the engine attaching bosses. The nine equally spaced bosses of the standard mount are provided with elliptically shaped recesses which accommodate compression-type rubber blocks interposed between the mounting structure and the crankcase attaching bolts, Figs. 2 and 3. Experience has shown that this type of elastic mounting is not generally effective because the rubber affords insufficient elasticity when forced to act in compression.

The experimental mount tested utilizes six engine attaching points (attaching points behind cylinders Nos. 1, 4, and 7 are omitted). This arrangement provides symmetrical elastic restraint by virtue of the fact that three pairs of mounting units are equidistantly spaced about the periphery of the mounting ring, Fig. 4. The engine-mount bosses are set at an angle with circular shear type sandwich rubber bushings located on each side of the bosses. The bushings are much stiffer in a compressionwise direction than in the shear direction so that they act as directional springs tending to deflect mainly in the shear plane which is parallel to the bonded steel facing plates, Fig. 5. The bushings are held in place on each side of the mounting-ring bosses by forged angle bolts so that no metal-to-metal contact is allowed between the bolts and the bosses. The directional stiffness of the bushings is utilized by arranging the faces of the mounting-ring bosses to bear an angular relationship to the thrust line in such a way that the elastic center of the mount coincides with the center of gravity of the power-plant mass. This arrangement is termed "virtual center of gravity suspension" of the power plant. The outer bonded steel facings of the rubber bushings are eccentric with respect to each other so that when they are deflected by full engine torque, they become approximately concentric. The inner steel faces of the rubber bushings are locked to the mounting-ring bosses by mating dowel pins. The flanges of the inner faces also mate with the mounting-ring boss so as to effect a journal bearing. Shoulders on the forged angle bolt space the outer steel facings when the nut is tightened. Torque arms join adjacent angle bolts so that they cannot twist. Table 1 presents a weight breakdown for the two engine-mount assemblies tested, which shows that the experimental assembly entails an increased weight over the standard assembly amounting to only 4.5 lb.

TABLE 1 WEIGHT BREAKDOWN FOR STANDARD AND EXPERIMENTAL MOUNTING ASSEMBLIES

	Weight, lb
Experimental mounting assembly, shown in Fig. 4	43.75
Standard mounting assembly, shown in Fig. 2	39.25
Experimental mounting units, total	9.48
Rubber sandwiches, 12 required	4.02
Angle bolts, 6 required	3.96
Nuts and washers	0.50
Torque arms, 3 required	1.00
Standard mounting units, total	5.09
Rubber bushings, 18 required	0.92
Engine mount bolts, 9 required	2.52
Nuts and washers	1.10
Bushings, 9 required	0.55

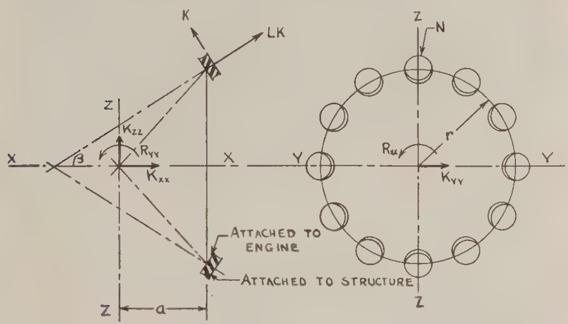

FIG. 6 SCHEMATIC ARRANGEMENT OF VIRTUAL-CENTER-OF-GRAVITY POWER-PLANT SUSPENSION

ESTIMATION OF POWER-PLANT NATURAL FREQUENCIES

It has been shown that the stiffnesses of a virtual-center-of-gravity type power-plant suspension may be expressed as follows, referring to Fig. 6 (2):

Roll about the crankshaft axis

$$R_{zz} = Nkr^2 \text{ in-lb per radian}$$

Pitching or yawing about the lateral or vertical axis

$$R_{yy} = R_{zz} = \frac{Nkr^2}{2}\left[\frac{a^2}{r^2} + L\left(\frac{a}{r}\sin\beta - \cos\beta\right)^2 + \left(\frac{a}{r}\cos\beta + \sin\beta\right)^2\right] \text{ in-lb per radian}$$

Thrustwise along the crankshaft axis

$$K_{zz} = Nk(\sin^2\beta + L\cos^2\beta) \text{ lb per in.}$$

Along the lateral or vertical axis

$$K_{yy} = K_{zz} = \frac{Nk}{2}\left[1 + (\cos^2\beta + L\sin^2\beta)\right] \text{ lb per in.}$$

where N = number of equally spaced mounting units
k = shear rate of each mounting unit, lb per in.
L = ratio of compressionwise rate to shear rate of each unit
r = radius of mounting units, in.
a = distance between plane of mounting units and virtual point of suspension, in.
β = angle made by the compression axis of mounting units with respect to thrust line, deg

It can be shown that the point of virtual suspension may be expressed as

$$a = \frac{1}{2}\,\frac{r\sin 2\beta}{\dfrac{2}{L-1} + \sin^2\beta} \text{ in.}$$

Neglecting the effect of gyroscopic forces and structural coupling, the natural frequencies may be determined by the well-known relationships

$$F = \frac{60}{2\pi}\sqrt{\frac{\text{Angular stiffness}}{\text{Moment of inertia}}} = \frac{60}{2\pi}\sqrt{\frac{R}{I}} \text{ cycles per min.}$$

or

$$F = \frac{60}{2\pi}\sqrt{\frac{\text{Translational stiffness}}{\text{Mass}}} = \frac{60}{2\pi}\sqrt{\frac{K}{M}} \text{ cycles per min.}$$

Applying these equations to the experimental mount under consideration

$N = 3 \times 2 = 6$
$k = 1250$ lb per in.
$L = 12.7$
$r = 12.2$ in.
$a = 10.75$ in.
$\beta = 35$ deg

Power-plant moment of inertia about the thrust axis (minus propeller inertia) = 240 lb-in. sec²
Power-plant moment of inertia about the vertical or lateral axis (including maximum propeller inertia) = 355 lb-in. sec²
Weight of power plant (including propeller) = 996 lb

Roll about the crankshaft axis
Stiffness = $6 \times 1250 \times 12.2^2$ = 1,120,000 in-lb per radian

$$\text{Natural frequency} = \frac{60}{2\pi}\sqrt{\frac{1{,}120{,}000}{240}} = 645 \text{ cycles per min}$$

Pitching or yawing about lateral or vertical axis

$$\text{Stiffness} = \frac{6 \times 12.2^2 \times 1250}{2}\left[\frac{10.75^2}{12.2^2} + 12.7\left(\frac{10.75}{12.2}\sin 35^\circ - \cos 35^\circ\right)^2 + \left(\frac{10.75}{12.2}\cos 35^\circ + \sin 35^\circ\right)^2\right]$$
$$= 1{,}170{,}000 \text{ in-lb per radian}$$

$$\text{Natural frequency} = \frac{60}{2\pi}\sqrt{\frac{1{,}170{,}000}{355}} = 547 \text{ cycles per min}$$

Thrustwise along the crankshaft axis
Stiffness = $6 \times 1250\,(\sin^2 35^\circ + 12.7\cos^2 35^\circ)$ = 66,500 lb per in.

$$\text{Natural frequency} = \frac{60}{2\pi}\sqrt{\frac{66{,}500}{996} \times 386} = 1520 \text{ cycles per min}$$

Laterally or vertically

$$\text{Stiffness} = \frac{6 \times 1250}{2}\left[1 + (\cos^2 35^\circ + 12.7\sin^2 35^\circ)\right]$$
$$= 21{,}750 \text{ lb per in.}$$

$$\text{Natural frequency} = \frac{60}{2\pi}\sqrt{\frac{21{,}750}{996} \times 386} = 876 \text{ cycles per min}$$

Distance of elastic center from plane of mounts

$$a = \frac{1}{2}\,\frac{12.2\sin 70^\circ}{\dfrac{2}{12.7-1} + \sin^2 35^\circ} = 11.5 \text{ in.}$$

Distance of elastic center ahead of center of gravity = 11.5 − 10.75 = 0.75 in.

INSTRUMENTATION FOR FLIGHT TESTS

The Air Technical Service Command has standardized on the use of Sperry-M.I.T. instrumentation for flight measurements of engine vibration and associated vibration of the aircraft structure. This equipment comprises velocity-type vibration pickups

which are fed into integrating amplifiers. The amplifier outputs actuate a four-element recording oscillograph, the traces of which indicate amplitudes which are proportional to vibratory displacement through a useful frequency range of 7 to 1500 cycles per sec.

The bridge network shown in Fig. 7 was used on the amplifier outputs so as to produce simultaneous traces on the four strings of the oscillograph which would correspond to addition, subtraction, and individual voltage outputs of a given pickup pair. The addition and subtraction traces indicated the translational and rotation components of power-plant vibratory motion.

Six pickups were suitably located to measure vibratory motion of the power plant in translation along and rotation about its three principal central axes as shown in Fig. 8. The pickup pair which measured power-plant vertical and pitching motion could not be located symmetrically with respect to the center of gravity. Hence a correction factor was applied to the vertical motion at the power-plant center of gravity. The pickup pair which measured lateral and rolling vibration was located in a plane 8 in. ahead of the center of gravity so that the lateral motion indicated contained components due to yawing vibration of the power plant about its center of gravity. A pickup was located in each cockpit to measure lateral vibration of the fuselage structure, Fig. 9. Selection of pickups was accomplished by means of a hand-operated rotary switch which fed the outputs of two pickups at a time into the amplifiers. Pickups were calibrated before and after tests by means of a mechanically driven calibrator which produces sinusoidal vibratory motion at a predetermined amplitude.

Fig. 8 Pickup Locations and Modes of Power-Plant Vibration Measured

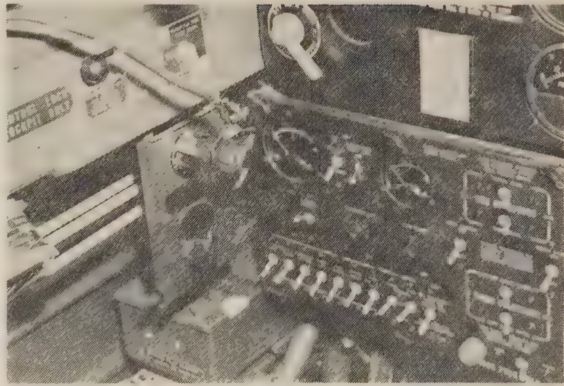

Fig. 9 Vibration Pickup Installation in Front Cockpit of AT-6C Airplane

In order to correlate the vibration frequencies with engine speeds, a pickup coil was installed on one of the spark-plug cables. The voltage induced in this coil was fed into the second stage of one of the amplifiers. This produced a mark superimposed on the vibration traces each instant the corresponding cylinder fired.

The amplifying and recording equipment was located in the rear cockpit where it could be controlled by the operator, Fig. 10. The amplifiers and oscillograph were powered by the 12-v electrical system of the airplane. The voltage input to the equipment was maintained at 12 v by means of a rheostat in series.

"Scratch plates" were installed on the three unused crankcase mounting bosses in the experimental engine-mount installation for the purpose of measuring over-all deflections of the mounted power plant. Stylii were held against the plates by means of springs in such a way that relative motion between the engine mount and crankcase resulted in scratches on the plates.

Test Procedure. The following tests were conducted in consecutive order:

1 Vibration records for the standard AT-6C engine-mount installation were taken in level flight at 8000 ft altitude throughout the operating range of engine speeds. Upon completion of this test, the standard engine mount was removed from the airplane and the experimental mount installed.

2 The test just outlined was repeated with the experimental engine-mount installation.

3 Vibration records for the experimental engine-mount installation were taken at various engine speeds while the airplane was in a 20-deg bank both to the right and to the left.

4 A series of ground tests were conducted for the purpose of checking the natural modes and frequencies of the power plant elastically suspended on the experimental mount. The natural mode in roll about the crankshaft axis was excited by running the engine on one magneto with one spark plug disconnected. This caused an excitation about the crankshaft axis at a frequency corresponding to one-half engine speed. The engine speed was

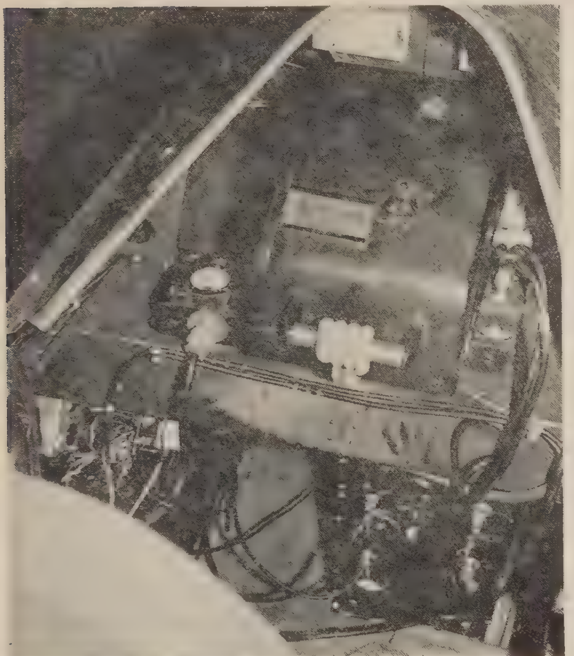

Fig. 10 Installation of Vibration-Recording Equipment in AT-6C Airplane

increased to 2200 rpm on both magnetos, at which speed the engine was switched over to the magneto having one spark plug disconnected. A vibration record of the rolling mode was then taken as the engine was throttled back to idling speed in a period of approximately 25 seconds. The spark plug was reconnected and sufficient masking tape was applied to a propeller blade to cause an unbalance of approximately 1.05 in-lb rotating at crankshaft speed. The engine speed was again raised to 2200 rpm and lowered to idling speed while vibration records of the pitching, vertical, yawing, and lateral modes were being taken.

5 A series of tests were conducted to determine the maximum movement of the engine relative to the supporting structure under various conditions by means of stylii bearing on scratch plates. The first condition investigated was that of cold idling of the engine. Stylii were allowed to bear on the scratch plates for approximately 1 min while the engine was idling in a cold condition. For the second condition, the stylii were allowed to bear on the plates while the engine was started, held at idling speed for a short time, and then shut down. The third condition consisted of an entire flight including starting, "warming up" the engine, taking off, climbing to an altitude of 8500 ft, making $4^1/_2$ turns of a right-hand spin, landing, and shutting off the engine. The stylii were allowed to bear against the plates for the entire flight.

6 In order to determine the durability of the experimental mount in service, the airplane was assigned to Headquarters, Air Technical Service Command, for postadministrative and flying duties.

Analysis of Vibration Records

Vibration records were prepared for harmonic analysis by enlarging to a 40-cm base line a section of each vibration trace included between two spark indications which mark an interval corresponding to four engine revolutions. The enlarged vibration traces were then analyzed for the five largest harmonics by means of a Coradi-type five-element rolling-sphere harmonic analyzer, Fig. 11.

The principle underlying the operation of the Coradi-type harmonic analyzer can be understood by considering the mathematical properties of the Fourier series (3). It can be shown that any periodic curve $f(t)$ can be expressed as a Fourier series, that is

$$f(t) = a_0 + a_1 \sin \omega t + a_2 \sin 2\omega t + \ldots + a_n \sin n\omega t \ldots$$
$$+ b_1 \cos \omega t + b_2 \cos 2\omega t + \ldots + b_n \cos n\omega t \ldots$$

where the function repeats itself in a period $T = \frac{2\pi}{\omega}$. The frequency of the fundamental or first harmonic is represented by ω and the frequency of the nth harmonic by $n\omega$. It can be shown, furthermore, that the amplitudes may be expressed as

$$a_n = \frac{\omega}{\pi} \int_0^{\frac{2\pi}{\omega}} f(t) \sin n\omega t dt$$

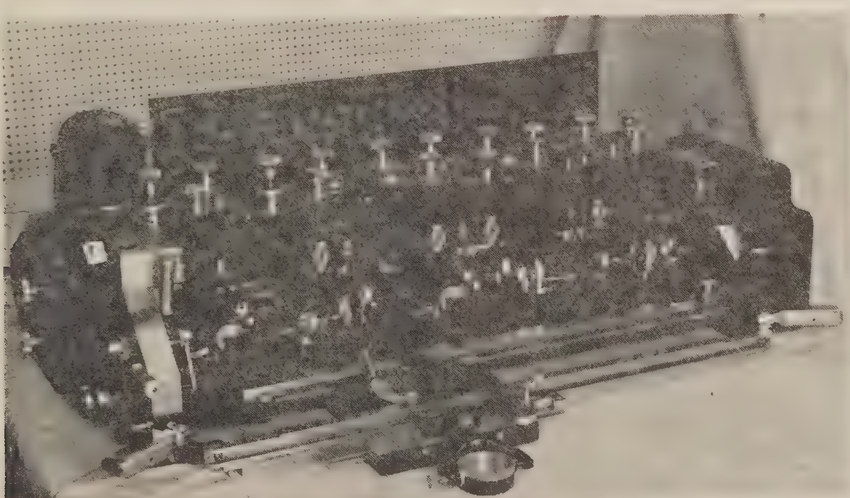

Fig. 11 Air Technical Service Command Five-Element Rollng Sphere Harmonic Analyzer

$$b_n = \frac{\omega}{\pi} \int_0^{\frac{2\pi}{\omega}} f(t) \cos n\omega t dt$$

These definite integrals can be evaluated for a particular harmonic by determining the area included between the harmonic curve and the neutral axis. The Coradi-type harmonic analyzer measures these areas by applying the principles utilized in the ordinary planimeter. Each integrator head is geared to revolve about a vertical axis n times as the curve follower moves on a lead screw across a span of 40 cm which represents the period of the first harmonic $\frac{2\pi}{\omega}$. On each integrator head are two planimeter wheels in vertical planes at right angles to each other, Fig. 12.

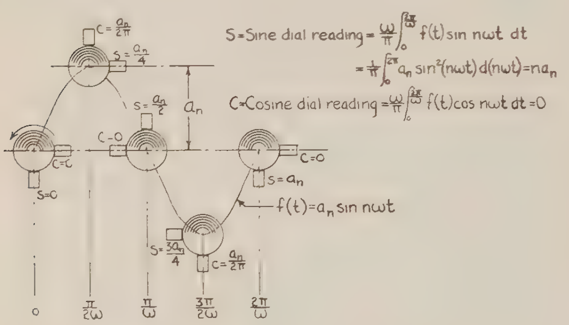

FIG. 12 ILLUSTRATION OF THE WAY IN WHICH THE CORADI-TYPE HARMONIC ANALYZER OPERATES UPON THE PERIODIC CURVE $f(t) = a_n \sin n\omega t$

(The sphere makes one complete revolution about a vertical axis in the period included between 0 and $\frac{2\pi}{\omega}$. At the end of the revolution, the sine dial registers a_n and the cosine dial registers 0, hence the amplitude $A_n = \sqrt{a_n^2 + b_n^2} = a_n$. In n periods the sine dial will read na_n.)

The planimeter wheels bear against a ground-glass sphere. The sphere in turn rides on a wheel which revolves in accordance with back-and-forth motion of the entire machine. The machine is constrained to back-and-forth motion only, and this motion is controlled by the operator in keeping the curve follower on the vibration trace as the lead screw advances the follower across the carriage. The speed of the lead screw can be controlled by a foot pedal which varies the speed of the driving motor. The planimeter wheels are calibrated to read Σa_n and Σb_n. In order to determine a_n and b_n, the planimeter readings must be divided by the harmonic being extracted, that is

$$a_n = \frac{\Sigma a_n}{n} \quad \text{and} \quad b_n = \frac{\Sigma b_n}{n}$$

The resultant amplitude is

$$A_n = \sqrt{a_n^2 + b_n^2}$$

and the phase angle may be found as

$$\tan \phi_n = \frac{b_n}{a_n}$$

The property of the analyzer which enables it to exclude all harmonics other than the nth harmonic being extracted can be understood by considering a harmonic amplitude h_0 having a frequency $m\omega$. Then

$$f(t) = h_0 \sin (m\omega t + \phi)$$

and

$$a_n = \frac{\omega}{\pi} \int_0^{\frac{2\pi}{\omega}} h_0 \sin (m\omega t + \phi) \sin n\omega t dt$$

but

$$\sin (m\omega t + \phi) = \sin m\omega t \cos \phi + \cos m\omega t \sin \phi$$

$$a_n = \frac{\omega h_0 \cos \phi}{\pi} \int_0^{\frac{2\pi}{\omega}} \sin m\omega t \sin n\omega t dt + \frac{\omega h_0 \sin \phi}{\pi} \int_0^{\frac{2\pi}{\omega}} \cos m\omega t \sin n\omega t dt = 0$$

Similarly $b_n = 0$, showing that the planimeter dials produce a zero reading over the complete cycle except for the nth harmonic.

DISCUSSION OF TEST RESULTS

The test results presented in Table 2 indicate that the experimental engine mount was very effective in attenuating that vibratory response of the power plant due to first-order forcing functions. These forcing functions, which correspond to the rotational speed of the engine crankshaft, arise from the inherent inertia forces of the articulated connecting-rod system, gas-pressure forces in the cylinders, and static, dynamic, and aerodynamic unbalances in the directly driven propeller.

On the other hand, the natural frequencies of the power plant on the standard mount were in a range where they could be excited by the first-order forcing functions, that is, the inertia and gas-pressure forces which produce alternating first-order couples about the crankshaft axis, induced resonance of the power plant on the standard mount at 1440 rpm. Inertia forces and propeller unbalances excited angular and translational modes about and along the vertical and lateral axes of the power plant. Resonances occurred in pitch about the lateral axis at 1460 and 2020 engine rpm. These peaks were reflected slightly in the measured vertical vibration and thus indicate appreciable cou-

NOTE: Double amplitudes in degrees for rotation, in inches for translation.

pling between the two modes. A resonance also occurred in yaw about the vertical axis at 1540 engine rpm which exhibited slight coupling with thrustwise vibration. A first-order lateral resonance of the power plant was measured at 1320 engine rpm.

The experimental mount eliminated all first-order resonances experienced with the standard mount. Reductions of power-plant response were attained amounting to as much as 76 per cent in roll about the crankshaft axis; 58 per cent in pitch about the lateral axis; and 84 per cent in yaw about the vertical axis. First-order lateral motion in the front cockpit also was reduced 40 to 75 per cent throughout the operating range of engine speeds. Lateral motion in the rear cockpit was not reduced but was very small for both engine-mount installations (0.0025 in. or less).

Since the natural frequencies of the power plant on the standard mount were well above the range where they can be excited by one-half order forcing functions (arising from irregularities in ignition and air-fuel induction) the corresponding power-plant responses indicated were largely due to excitation of a combined bending-torsion mode of the fuselage. This was confirmed by a lateral response in the rear cockpit which corresponded to the power-plant yawing response about the vertical axis at 2040 rpm (1020 cycles per min). A variation of this mode apparently was responsible for the magnified vertical power-plant response, coupled with roll about the crankshaft axis at 1780 to 1830 rpm (890 to 915 cycles per min).

The experimental mount did not alter appreciably the magnitude of one-half order power-plant response. Lateral response of the rear cockpit followed very closely that measured for the standard mount.

First-order crankshaft unbalance forces are largely compensated by the counterweight in a radial engine but this compensation introduces transverse second-order forces of appreciable magnitude because the center of mass of the rotating and articulating system travels in an oval rather than in a circular path, as does the center of mass of the counterweight. The frequency of the second-order forces is above the natural frequencies of the mounted power plant by a sufficient amount to result in approximately the same power-plant and cockpit response for either the standard or the experimental mount. Since the second-order unbalance forces act in the transverse plane, a comparatively low magnitude of vibration was measured in all modes of power-plant motion other than lateral or vertical. The second-order response of the cockpits probably was largely due to propeller-blade-passage impulses in the slip stream which impinged upon the canopy.

Because the moment of inertia of the power plant about a given transverse axis varies from a maximum to a minimum twice during each revolution of a two-blade propeller, second-order gyroscopic couples result during a bank and turn due to rotation of the airplane about its vertical axis. In order to check this effect for the experimental engine-mount installation, vibration records were taken at various engine speeds during a 20-deg bank and turn both to the right and to the left. Examination of the records revealed no important increase of second-order response of the power plant or the cockpit structure.

Two $3^1/_2$-order peak responses were indicated in the angular modes about the vertical and lateral axes at 1430 rpm (5000 cycles per min) and 1830 rpm (6410 cycles per min) which were the result of so called "conical whirls." In this particular case the whirls were largely independent of the dynamics of both engine mounts because they were generated by $4^1/_2$-order (frequency of cylinder firing) torsional vibration of the crankshaft combined with crankshaft bending. This mode of crankshaft vibration energized a propeller-bending mode which was symmetrical in the plane of rotation but asymmetrical perpendicular to the plane of rotation, that is, the propeller tips were moving out of phase in a thrustwise direction but in phase in the transverse plane. In such a condition, transverse reactions are imposed upon the thrust bearing due to the symmetrical vibration of the propeller blades in the plane of rotation, and moments about transverse axes are imposed upon the propeller shaft due to asymmetrical propeller-blade vibration perpendicular to the plane of rotation. These forces and moments cause a conical whirl of the engine at a frequency of $\left(n - \frac{P}{N}\right)$, where n is the harmonic order of propeller vibration, N is the engine speed, and P is the propeller speed (4).

In the case under consideration, the whirling frequency was $3^1/_2$-order ($4^1/_2$—1) although $4^1/_2$-order vibration of the power plant was negligible. This mode was also apparent in the indication of the lateral pickups which were located in a plane ahead of the power-plant center of gravity so that they responded to a yawing component of motion. Since there was no $3^1/_2$-order response vertically, it is apparent that the power plant underwent a conical whirl with a node in the vicinity of the power-plant center of gravity.

The engine run-down tests with one cylinder not firing, as conducted on the experimental engine mount, indicated that the power-plant natural frequency in roll about the crankshaft axis was 680 cycles per min (645 cycles per min calculated). The natural frequencies excited by unbalancing the propeller 1.05 in. lb were 850 cycles per min for the vertical-pitching mode and 865 cycles per min for the lateral-yawing mode. The calculated natural frequency for the vertical and lateral modes was 875 cycles per min and for the pitching and yawing modes, 547 cycles per min. The engine could not be run slow enough to produce a satisfactory excitation of the pitching-yawing natural modes, however. The foregoing natural frequencies are sufficiently low to provide adequate vibration isolation for the important forcing functions. Resonance with one-half order couples about the crankshaft axis is possible at 1360 rpm (680 cycles per min), but under the conditions of the flight tests, the response indicated was small.

The results of scratch-plate records indicating relative motion between the crankcase and mounting ring for the experimental mount are given in Table 3. The mounting elements are manufactured 0.140 in. eccentric in order to offset engine torque. The scratch-plate records show a deflection of 0.156 in. at take-off power. This means that full engine torque deflects the mounting elements 0.016 in. beyond the concentric configuration which is not considered to be excessive. No metal-to-metal contact in the mounts is likely to occur.

TABLE 3 SCRATCH-PLATE RECORDS OF RELATIVE MOTION BETWEEN CRANKCASE AND MOUNTING RING

Condition	Indicated deflection, in. Right	Left	Top	Remarks
Engine idling prior to warm-up	$^1/_8$	$^1/_8$	—	Deflection on clockwise side of neutral position due to torque reaction

Conclusion

The principles embodied in the design of the experimental engine mount herein described are applicable for the control of vibration in many types of aircraft where lightweight and simplicity of design are important factors. Vibration control need be limited no longer to the larger aircraft-engine installations.

On the contrary, development of this type of engine mount suggests new opportunities for attaining greater flying comfort and added serviceability in light airplanes without attendant design penalties. It will be an increased pleasure to fly in the light airplanes of tomorrow!

Gasoline Explosion Pressures

By M. S. PLESSET[1] and F. R. GILMORE,[2] SANTA MONICA, CALIF.

A numerical method is outlined which permits the calculation of the temperatures and pressures obtained when mixtures of air and aviation-gasoline vapor are exploded in a closed chamber. The calculations use basic thermodynamic data to determine the final equilibrium state of the air and gasoline mixtures after combustion. Similar calculations have been carried out previously by other investigators, but only for a limited range of mixture ratios. Experimental measurements of the explosion pressures were made using an explosion bomb with a strain-gage pressure pickup. The measured pressures were of the same order of magnitude as the calculated pressures, but in general were somewhat above the theoretical values. Some possible explanations for this trend are discussed in the text.

Introduction

The investigation covered by this paper was initiated so that some conception could be formed of the temperatures and pressures developed in aviation combustion heaters under the assumption that an explosion takes place. No general solution of the problem applicable to all mixture ratios was found so that an analysis based on fundamental physico-chemical principles was necessary.

An estimate was also desired of the ignition limits of gasoline-air mixtures at various temperatures and pressures. These limits have an important bearing on the problem of combustion-heater ignition.

Theoretical Considerations

The pressures which are produced when a mixture of air and fuel vapor explodes in a closed chamber can be calculated from basic chemical principles, provided the assumption is made that all chemical reactions reach equilibrium at the high explosion temperature, and provided that sufficient thermodynamic data on the reaction products are available.

If aviation gasoline is assumed to have the average molecular composition, C_8H_{16}, the combustion of 1 mole of a gasoline-air mixture can be represented by the following total reaction:

$$X\, C_8H_{16} + 0.2095\,(1-X)\, O_2 + 0.7809\,(1-X)\, N_2 + 0.0093\,(1-X)\, A + 0.0003\,(1-X)\, CO_2 \rightarrow a\, CO_2 + b\, CO + c\, H_2O + d\, H_2 + e\, O_2 + f\, N_2 + g\, NO + h\, NO_2 + i\, CH_4 + j\, OH + k\, H + m\, O + n\, O_3 + q\, C\,(\text{graphite}) + r\, C_2\,(\text{gas}) + s\, C(\text{gas}) + t\, NH_3 + 0.0093\,(1-X)\, A$$

In this X is the mole fraction of gasoline vapor present before the explosion. The composition of dry air, according to Humphreys (1)[3] is used. Although argon does not take part in the chemical reaction, it has been included in the equation because its thermal capacity enters into the heat-balance equation. The seventeen letters a to t represent unknown coefficients which are to be determined. Some possible products of the reaction, such as CH and CH_2, have been omitted because thermodynamic data on these compounds are not available; it is believed that this omission should not appreciably affect the results. Other possible products, such as C_2H_6, C_2N_2, etc., can be shown to be entirely negligible.

The requirement that the foregoing reaction equation be balanced yields four equations for the unknown coefficients

$$a + b + i + q + 2r + s = 8X + 0.0003\,(1-X) \quad [1]$$

$$2c + 2d + 4i + j + k + 3t = 16X \quad [2]$$

$$2a + b + c + 2e + g + 2h + j + m + 3n = 0.4196\,(1-X) \quad [3]$$

$$2f + g + h + t = 1.5618\,(1-X) \quad [4]$$

The remaining thirteen equations necessary for the evaluation of the seventeen constants are derived from a consideration of the various reactions which are assumed to be in equilibrium at the explosion temperature; for example, the carbon monoxide can react with the oxygen to form carbon dioxide

$$CO + {}^1/_2O_2 \rightleftharpoons CO_2$$

For this reaction, there is a certain equilibrium constant

$$K_1 = \frac{p_{CO}\sqrt{p_{O_2}}}{p_{CO_2}}$$

where p_{CO}, p_{O_2}, and p_{CO_2} are the partial pressures of the carbon monoxide, oxygen, and carbon dioxide, respectively. If the explosion has taken place at constant volume, then b moles of carbon monoxide, e moles of oxygen, and a moles of carbon dioxide are occupying the same volume at the explosion temperature T_m that one mole of the mixed gases occupied at the initial temperature T_0 and pressure P_0. From the perfect-gas law, it follows that

$$p_{CO} = b\,\frac{T_m}{T_0}\,P_0$$

$$p_{O_2} = e\,\frac{T_m}{T_0}\,P_0$$

$$p_{CO_2} = a\,\frac{T_m}{T_0}\,P_0$$

The expression for the equilibrium constant then becomes

$$K_1 = \frac{p_{CO}\sqrt{p_{O_2}}}{p_{CO_2}} = \frac{b}{a}\sqrt{e\left[\frac{T_m}{T_0}\,P_0\right]} \quad [5]$$

In a similar manner, twelve other equations can be derived

$$K_2 = \frac{p_{H_2}\sqrt{p_{O_2}}}{p_{H_2O}} = \frac{d}{c}\sqrt{e\left[\frac{T_m}{T_0}\,P_0\right]} \quad [6]$$

$$K_3 = \frac{p_{NO}}{\sqrt{p_{N_2}p_{O_2}}} = \frac{g}{\sqrt{fe}} \quad [7]$$

[3] Numbers in parentheses refer to the Bibliography at the end of the paper.

Contributed by the Aviation Division and presented at the Aviation War Conference, Los Angeles, Calif., June 11–14, 1945, of The American Society of Mechanical Engineers.

$$K_4 = \frac{p_{NO}\sqrt{p_{O_2}}}{p_{NO_2}} = \frac{g}{h}\sqrt{e\left[\frac{T_m}{T_0}P_0\right]} \quad [8]$$

$$K_5 = \frac{\sqrt{p_{H_2}{}^3 p_{N_2}}}{p_{NH_3}} = \frac{\sqrt{d^3 f}}{t}\left[\frac{T_m}{T_0}P_0\right] \quad [9]$$

$$K_6 = \frac{p_{OH}\sqrt{p_{H_2}}}{p_{H_2O}} = \frac{j}{c}\sqrt{d\left[\frac{T_m}{T_0}P_0\right]} \quad [10]$$

$$K_7 = \frac{p_H{}^2}{p_{H_2}} = \frac{k^2}{d}\left[\frac{T_m}{T_0}P_0\right] \quad [11]$$

$$K_8 = \frac{p_O{}^2}{p_{O_2}} = \frac{m^2}{e}\left[\frac{T_m}{T_0}P_0\right] \quad [12]$$

$$K_9 = \frac{p_{O_3}}{\sqrt{p_{O_2}{}^3}} = \frac{n}{\sqrt{e^3}}\sqrt{\frac{T_0}{T_m P_0}} \quad [13]$$

$$K_{10} = \frac{\sqrt{p_{O_2}}}{p_{CO}} = \frac{1}{b}\sqrt{e\left[\frac{T_0}{T_m P_0}\right]},\ (q > 0) \quad [14]$$

$$K_{11} = \sqrt{p_{C_2\,(gas)}} = \sqrt{r\left[\frac{T_m}{T_0}P_0\right]},\ (q > 0) \quad [15]$$

$$K_{12} = \frac{p_{H_2}{}^2}{p_{CH_4}} = \frac{d^2}{i}\left[\frac{T_m}{T_0}P_0\right],\ (q > 0) \quad [16]$$

$$K_{13} = p_{C(gas)} = s\left[\frac{T_m}{T_0}P_0\right],\ (q > 0) \quad [17]$$

The values of these equilibrium constants at various temperatures are given in Appendix 1 (Table 3). A sufficient number of algebraic relations have now been obtained to permit the calculation of the amount of each gas present after combustion, provided the temperature can be determined.

The explosion temperature T_m is calculated by equating the energy of combustion of the fuel at constant volume to the energy required to heat the products of combustion to the temperature T_m plus the energy required to cause the dissociation which occurs at this temperature. The energy of complete combustion of 100-octane gasoline vapor can be taken to be 18,700 Btu per lb (for the liquid) plus 140 Btu per lb (energy of vaporization; see Appendix 1). The internal energies of various gases at different temperatures, using as base values (zero internal energy) the energy of CO_2, H_2O, O_2, and N_2, and A, are given in Table 2.

The solution of these relations to obtain the explosion temperature and pressure involves successive approximation. For a particular mole-fraction of fuel vapor X, and particular initial temperature and pressure T_0 and P_0, a value for the explosion temperature T_m is guessed, and the values for the equilibrium constants, $K_1, \ldots, K_{13}$, at the temperature T_m are interpolated from the table in Appendix 1. The values for T_0, T_m, P_0, $K_1, \ldots, K_{13}$ can now be substituted in the equilibrium equations. These equations are then solved for the unknown coefficients, $a, \ldots, t$, by the method of successive approximation. Thus, the chemical composition of the mixture after combustion has been calculated. The energy balance is then checked by comparing the energy evolved in the complete combustion of the fuel with the energy change associated with the heating of the reaction products from T_0 to T_m accompanied by the change in chemical composition from CO_2, H_2O, N_2, and O_2 to the composition just calculated. If the energy does not balance, a new value of T_m must be estimated and the whole process repeated.

After the temperature and composition of the mixture after explosion are found in this manner, the explosion pressure is readily calculated from the formula

$$P_m = P_0 N_m \frac{T_m}{T_0} \quad [18]$$

where N_m is the number of final moles of gas per unit initial mole and is therefore equal to $a + b + c + \ldots + t$.

An example of the calculation of explosion temperatures and pressures by this method is given in Appendix 2.

For five particular mixture ratios, corresponding to five values of X, thermodynamic charts were available which greatly simplified the problem of calculating the explosion temperatures and pressures. These charts are not reproduced here because they are as yet restricted in distribution.

Apparatus and Tests

In order to check the calculations of explosion pressures experimentally, a spherical explosion bomb was constructed by modifying a 9-in. aluminum pressure accumulator. A pair of strain gages was cemented to the outside surface of the bomb. The pressure pickup system is shown in Fig. 1, and a block diagram of the electrical circuit is given in Fig. 2.

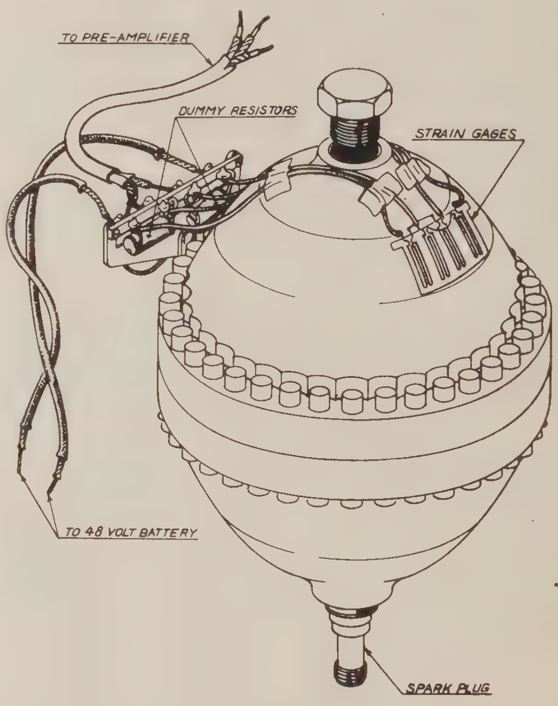

Fig. 1 Explosion Bomb and Pressure Pickup

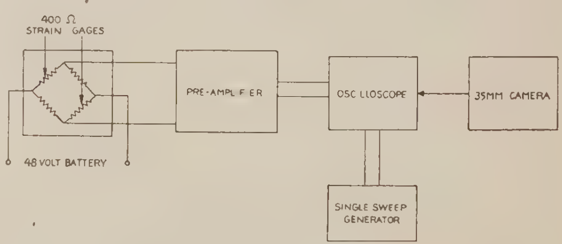

Fig. 2 Electrical Circuit of the Pressure Pickup

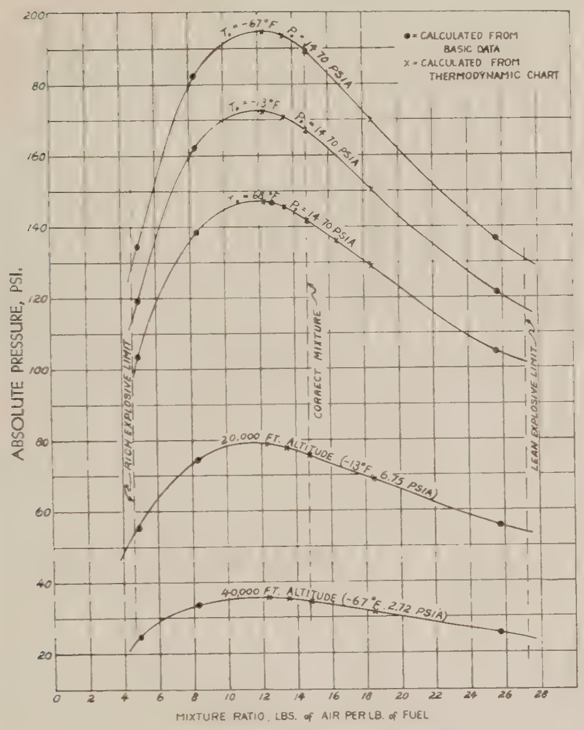

Fig. 3 Theoretical Explosion Pressures

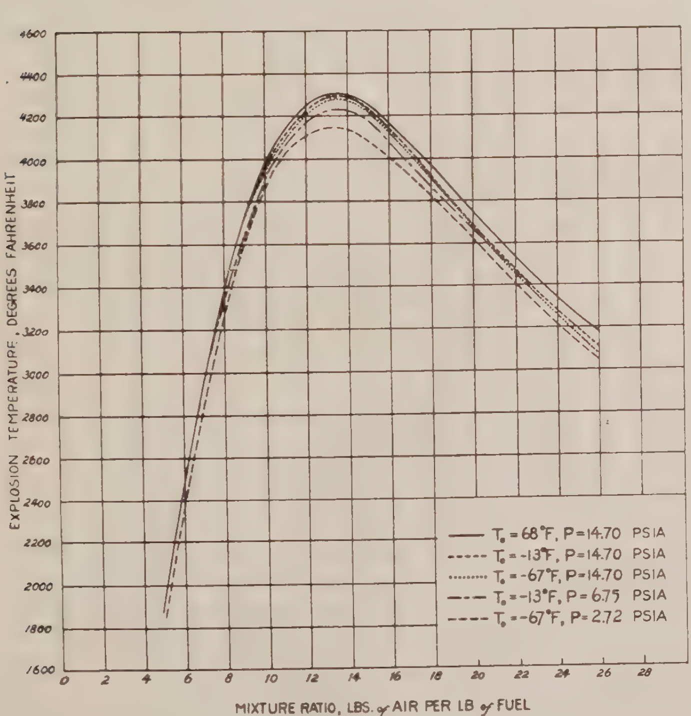

Fig. 4 Theoretical Explosion Temperatures

The two strain gages used to measure the pressure were made opposite legs of a balanced Wheatstone bridge. Pressure inside the bomb caused the surface of the bomb, and hence the gages, to be strained, which increased the resistance of the gages and produced a voltage difference across the vertical plates of an oscilloscope. A single-sweep voltage pulse was simultaneously applied to the horizontal plates.

In the tests, the bomb was charged by injecting measured amounts of 100-octane gasoline into it. The bomb was agitated manually, then allowed to stand for 15 or 20 min to permit complete vaporization. The pressure of the gasoline-air mixture immediately before the explosion was therefore 1 atm plus the partial pressure of the gasoline vapor. The mixture was exploded by a spark, and the pressure rise was shown visually by the oscilloscope. The oscilloscope trace was simultaneously photographed. To determine the actual explosion pressure, the oscilloscope trace deflection shown on the photographic film was measured and compared with the deflections produced by charging the bomb with compressed air under known pressures.

Results Obtained

Theoretical. The temperatures and pressures that should result when various mixtures of air and 100-octane gasoline are exploded in a closed chamber, at various initial temperatures and pressures, have been calculated by the method described in the section discussing theory. Sample calculations are given in Appendix 2. The results are presented graphically in Figs. 3 and 4.

The results have been related to the conventional mixture ratio M_R, which is defined as the ratio of the weight of air to the weight of gasoline vapor. It should be noted that

$$M_R = \frac{\text{Vol per cent of air}}{\text{Vol per cent of gasoline vapor}} \times \frac{28.98}{112.2} = 0.2583\,(1 - X)/X$$

Experimental. The results of the explosion pressure measurements made with the spherical bomb are given in Table 1. These results are also compared graphically with the theoretical curve in Fig. 5.

Discussion of Results

Theoretical. It can be seen from Figs. 3 and 4, that very good agreement is obtained between the algebraic method of calculation developed in this paper and the method based on thermodynamic charts.

Except for very rich mixtures, these theoretical calculations should be quite accurate. The gasoline has been rather arbitrarily assigned the average composition C_8H_{16}, which is equivalent to specifying a hydrogen-carbon ratio of 2, and an average molecular weight of 112. The hydrogen-carbon ratios for aviation gasolines are known to be very close to 2; moreover, a considerable variation of the ratio affects the calculated pressures only slightly (for example, use of the charts of reference (2) calculated for a hydrogen-carbon ratio of 2.25, gives for M_R = 14.76 a pressure 0.7 per cent lower). The molecular weight enters into the problem only in the determination of the amount of air displaced by the fuel vapor. A 10 per cent error in the estimated molecular weight would change the final results by only 0.5 per cent for X = 0.05.

† Numbers indicate first five explosions in the bomb, showing decrease of pressure readings as inside of bomb becomes coated with carbon and other explosion products.

The error due to inaccuracies in the values for the internal energy of the gases (Appendix 1) should be less than 0.5 per cent. Inaccuracies in the values of the equilibrium constants would probably affect the results by less than 1 per cent. The possible errors caused by nonequilibrium conditions, radiation losses, and other minor effects[4] are presumably small, since calculations by Lewis and von Elbe[5] for explosion pressures of lighter gases (H_2, CO, C_2H_2) agree with the experimentally measured pressures within 3 per cent. (These lighter gases contain the same elements as gasoline, and the composition of the hot burned mixture depends only on the elements present and the temperature, not on the original compounds present.)

When very rich mixtures are exploded, radicals such as CH and CH_2 can be expected to take part in the reaction. No thermodynamic data on such radicals are available, so their presence has been perforce neglected in the calculations for this paper. The error thus introduced is probably not large, since the calculations show that the related molecule CH_4 is present only in a minor amount. However, at the lower explosion temperatures which occur with rich mixtures, the assumption that all chemical reactions reach equilibrium may be in appreciable error. Moreover, the presence of finely divided free carbon may greatly increase the radiation losses. For these reasons, that part of the theoretical curves to the left of $M_R = 8$ should be considered as approximate only.

Experimental. A graphical comparison of the explosion-pressure calculations with the experimental measurements is presented in Fig. 5. As was explained in the "Apparatus and Tests"

[4] Such as the nonuniform final temperature distribution (reference (3), pp. 167, 175–176, 293–299), and the "excitation lag" due to the greater rapidity with which energy flows into the translational and rotational rather than the vibrational degrees of freedom (reference (3), p. 306).

[5] Reference (3), pp. 301–308.

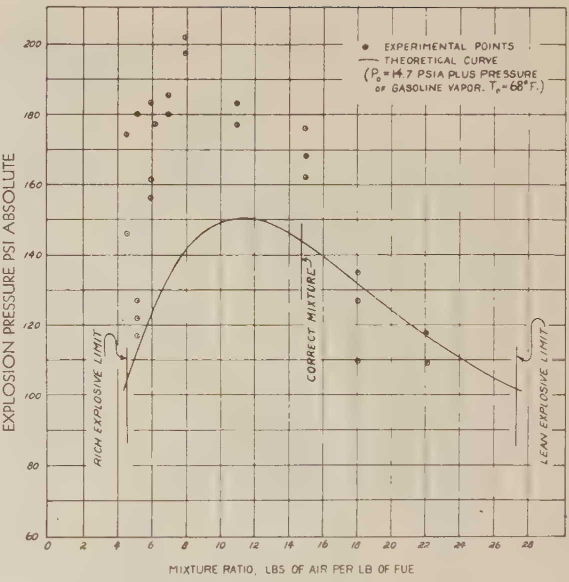

FIG. 5 COMPARISON OF THEORETICAL AND EXPERIMENTAL EXPLOSION PRESSURES

section, the initial pressures for the bomb explosions were slightly higher than 1 atm, and the initial temperature assumed in the calculation of the theoretical curve was 68 F.

The experimental points fall generally above the theoretical curve and also show much scatter among themselves. A number of factors probably contribute to these discrepancies. Perhaps the most important factor is the incomplete vaporization and mixing of the fuel. The theoretical calculations assume that the gasoline is completely vaporized and the vapor uniformly mixed with the air. Under the conditions of the tests, it is very possible that the heavier fractions of the gasoline remained unvaporized. Since the lighter hydrocarbons in the gasoline have higher heats of combustion, the actual explosion pressures would be above the calculated values. This agrees with the experimental measurements. Furthermore, for mixtures richer than the maximum-pressure mixture, the experimentally measured pressures would appear to be too high because the mixtures are actually leaner than would be supposed from the amount of gasoline injected. The large variations in pressures for repeated explosions of mixtures having supposedly the same mixture ratio can be attributed to variations in the degree of vaporization of the fuel and in the homogeneity of the explosive mixture.

A possible cause of error in the strain-gage pressure measurements is the thermal strain produced by the contact of the hot gases with the inner surface of the bomb wall. If the wall were uniformly heated, the temperature of the gages would rise simultaneously, and the error introduced would be small, since the gages are practically temperature-compensated for aluminum. However, only the inside surface of the bomb is heated by the gases. If the temperature at the outer surface remains constant, while the temperature increases toward the inner surface such that the average temperature increase throughout the shell is 1 C, it can be shown that the thermal strain causes a rise in the apparent pressure reading of about 85 psi, while the heat loss from the gas mixture reduces the actual pressure about 30 psi, leaving a net apparent increase in pressure of 55 psi. It is difficult to determine how high a temperature rise in the shell of the bomb should be expected during the short time between sparking

and attainment of maximum pressure, but a 1-deg C average rise might not be unreasonable. It might be expected that the layer of carbon and other materials deposited on the inner surface of the bomb after several charges have been exploded would reduce the amount of heat conducted to the walls and therefore reduce the apparent pressure readings. The experimental data, which designate the first five charges fired, appear to confirm this hypothesis (see Table 1).

An estimate has been made of the gasoline temperature as a function of air pressure which gives the lean-explosive-limit mixture with gasoline vapor saturation. This estimate is shown in Fig. 6, where air pressure has been converted into altitude by the standard atmospheric table. The gasoline vapor pressure as a function of temperature was taken from work of the Cooperative Fuel Research Committee.[6] As long as the rich explosive limit is not exceeded, the region above this curve is the region of true ignitibility, assuming that the lean-limit-mixture ratio is a constant independent of temperature and pressure. The latter assumption implies that the kinetics of the chain reactions involved in ignition do not change appreciably within the temperature and pressure range. Such an assumption can only represent an approximation and most likely is optimistic in that the air-gasoline lean-limit mixture will tend to decrease with temperature. The true ignition-limit curve would thus most likely be above the curve in Fig. 6.

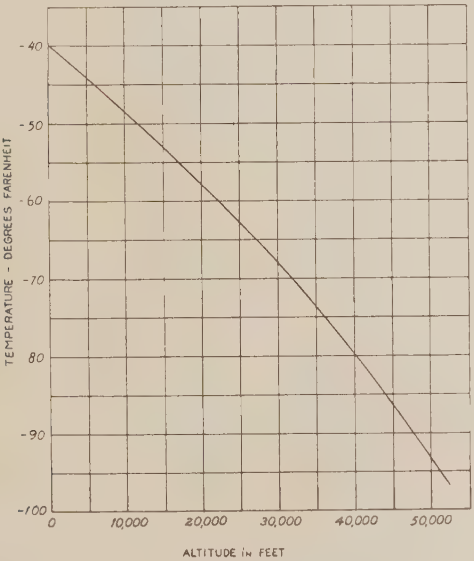

Fig. 6 Estimated Lean-Explosive-Limit Temperatures for Saturated Gasoline-Air Mixtures
(Standard atmospheric conditions assumed.)

Conclusions

A method is developed which permits the calculation of the temperatures and pressures attained when mixtures of air and aviation-gasoline vapor are exploded in a closed chamber. For a few mixture ratios, calculations may be made by the use of thermodynamic charts. Calculations by the two methods show close agreement. The results for various initial temperatures and pressures are presented graphically.

Experimental measurements of the explosion pressures were made using an explosion bomb with a strain-gage pressure pickup. The measured pressures were of the same order of magnitude as the calculated pressures, but in general were somewhat higher than the theoretical values. Possible explanations for this trend are incomplete vaporization of the fuel, incomplete attainment of chemical equilibrium at the explosion temperature, and errors in the pressure measurements caused by temperature gradients.

An estimate of the lower ignition-temperature limit as a function of altitude, for standard atmospheric conditions, is also given.

Appendix 1

Thermodynamic Data

The internal energy of combustion (i.e., heat of combustion at constant volume) of gasoline vapor is equal to the energy of combustion of liquid gasoline plus the energy of vaporization of gasoline. A minimum net calorific value of 18,700 Btu per lb is specified[7] for 100-octane gasoline (liquid). No data have been found for the energy of vaporization of 100-octane gasoline, but Holcomb and Brown (5) give the heat of vaporization of normal octane at room temperature as 140 Btu per lb. Since this figure does not affect the total greatly, the approximation that the energy of vaporization of aviation gasoline equals 140 Btu per lb will be used. The energy of combustion of the gasoline vapor is therefore 18,700 + 140 = 18,840 Btu per lb. If the gasoline has an average molecular weight of 112.21, this value is equivalent to 1,174,400 cal per g-mole.

Values for the thirteen pertinent equilibrium constants at various temperatures are given in Table 2 and plotted in Fig 7. The values are taken from Lewis and von Elbe (3), except the values for log K_5, which are derived from an expression for the free energy of NH_3 given by Thacker, Folkins, and Miller (6).

Table 3 shows the internal energy per gram-mole of the various gases present after combustion, as a function of temperature. For the gases usually present in large amounts, exact energy values at various temperatures, taken from (2), are given. For gases present only in small amounts, approximate equations for the energy as a function of the absolute temperature are given. These expressions have been derived[8] from values of C_p; and from values of the energies of reaction.[9] The quantities are expressed in terms of gram-moles and degrees Kelvin (deg C + 273.2) rather than in the usual engineering units. In all cases, the zero energy level is taken as the internal energy of CO_2, H_2O, O_2, N_2, and A at 300 K, but corrections are given for changing to a base level of 20 C (68 F), —25 C (—13 F), or —55 C (—67 F)

Appendix 2

Example of Algebraic Calculation of Explosion Pressures

As an example of the method of calculating explosion pressures and temperatures as described in the section, "Theoretical Considerations," consider the problem with the particular initial conditions $P_0 = 1$ atm, $T_0 = 68$ F (20 C), and $X = 0.0300$.

Substitution of this value of X in Equations [1] to [4], inclusive, yields

$$a + b + i + q + 2r + s = 0.2403 \quad [19]$$

$$2c + 2d + 4i + j + k + 3t = 0.4800 \quad [20]$$

$$2a + b + c + 2e + g + 2h + j + m + 3n = 0.4070 \quad [21]$$

$$2f + g + h + t = 1.5150 \quad [22]$$

* Interpolated values.
NOTE: These equilibrium constants are defined in the Theory section. All pressures are in standard atmospheres.
These values are derived from Ref. (2), Table 2, p. 382, except the values for log K_5, which are derived from the values of free energy for NH_3 given in Ref. (6), p. 587.
Some of these values are plotted in Fig. 7, for convenience in interpolation.

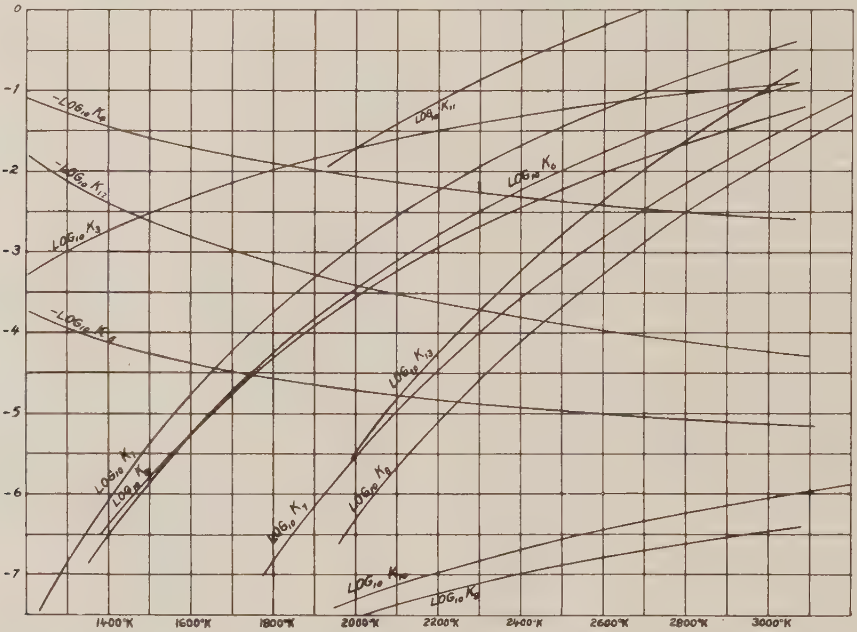

FIG. 7 LOGARITHMS OF EQUILIBRIUM CONSTANTS AT VARIOUS TEMPERATURES
(From Table 2.)

The next step in the calculation is to guess a value for the explosion temperature T_m, which value will be checked at the conclusion of the calculations. Suppose the value $T_m = 2200$ deg K is chosen. The values of the pertinent equilibrium constants $K_1, K_2, \ldots, K_{13}$, are found in Table 2. When these values and the values of T_0 and T_m are substituted in Equations [5] to [17], inclusive, the following equations result

$$\frac{b}{a}\sqrt{e} = 2.34 \times 10^{-3} \quad [23]$$

$$\frac{d}{c}\sqrt{e} = 4.49 \times 10^{-4} \quad [24]$$

$$\frac{g}{\sqrt{fe}} = 0.0332 \quad [25]$$

$$\frac{g}{h}\sqrt{e} = 55.5 \quad [26]$$

$$\frac{\sqrt{d^3 f}}{t} = 9{,}220 \quad [27]$$

$$\frac{j}{c}\sqrt{d} = 6.64 \times 10^{-4} \quad [28]$$

$$\frac{k^2}{d} = 5.02 \times 10^{-6} \quad [29]$$

NOTE: Precise energy values (in upper part of Table) taken from Ref. (2), Table 5A, p. 423. Approximate expressions in lower part of table (for gases present in small amounts) derived from values of C_p given in Ref. (6), p. 586, and Ref. (7), p. 75, and values of thermal energies and energies of reaction given in Ref. (3), pp. 378–385. T = temperature in degrees Kelvin (°C + 273.2).

$$\frac{m^2}{e} = 1.08 \times 10^{-6} \quad [30]$$

$$\frac{n}{e^{3/2}} = 3.07 \times 10^{-7} \quad [31]$$

$$\frac{1}{b}\sqrt{e} = 1.65 \times 10^{-7}, (q > 0) \quad [32]$$

$$\sqrt{r} = 2.9 \times 10^{-2}, (q > 0) \quad [33]$$

$$\frac{d^2}{i} = 550, (q > 0) \quad [34]$$

$$s = 8.18 \times 10^{-6}, (q > 0) \quad [35]$$

It should be noted that the last four equalities hold only when q is greater than zero, that is, when solid carbon is present. Although, with this particular gasoline-air mixture, not enough oxygen is present for complete combustion of the fuel to CO_2 and H_2O, more than sufficient oxygen is present to burn the fuel to CO and H_2O. Therefore, it might be supposed that the carbon atoms in the mixture are so completely oxidized that the free carbon remaining is so small in amount as to be completely vaporized, or, in other words, $q = 0$. In working the problem, this assumption will be made and then checked before the calculation is completed.

If $q = 0$, Equations [32] to [35], inclusive, must be replaced by the corresponding inequalities

$$\sqrt{e} > 1.65 \times 10^{-7}\, b, \quad (q = 0) \quad [36]$$

$$\sqrt{r} < 2.9 \times 10^{-2}, \quad (q = 0) \quad [37]$$

$$i < d^2/550, \quad (q = 0) \quad [38]$$

$$s < 8.18 \times 10^{-6}, \quad (q = 0) \quad [39]$$

These inequalities permit only upper limits to be set on the values of r, i, and s. However, in many instances, these upper limits are sufficiently small to show that r, i, and s are negligible. For mixture ratios which give moderately large upper limits, the exact values of r, i, and s can be calculated by transforming Equations [32], [33], [34], and [35] for equilibriums involving solid carbon into similar equations involving gaseous carbon, by the fundamental chemical principle that, in equilibriums involving a solid, the solid may be replaced by the corresponding vapor, at a pressure equal to the vapor pressure of the solid, without disturbing the equilibrium.

If it is assumed that $q = 0$ and that r, i, and s can be neglected, the problem is reduced to the solution of thirteen nonlinear simultaneous equations, Equations [19] through [31], in thirteen unknowns. These simultaneous equations cannot be solved explicitly, so the method of successive approximation must be used. Perhaps the simplest way to begin is to guess a value of a and follow through the evaluation of the other unknowns until all the equations check. Suppose the value $a = 0.0416$ is tried. Since i, q, r, and s are assumed negligible, Equation [19], becomes

$$a + b = 0.2403$$
$$b = 0.2403 - a = 0.1987 \quad [40]$$

From Equation [23]

$$e = (2.34 \times 10^{-3}\, a/b)^2$$
$$= 2.40 \times 10^{-7} \quad [41]$$

From Equation [24]

$$c = \frac{d\sqrt{e}}{4.49 \times 10^{-4}}$$
$$= 1.092\, d \quad [42]$$

From Equation [28]

$$j = 6.64 \times 10^{-4} \frac{c}{\sqrt{d}}$$
$$= 7.25 \times 10^{-4}\sqrt{d} \quad [43]$$

From Equation [29]

$$k = 2.24 \times 10^{-3}\sqrt{d} \quad [44]$$

From Equation [27]

$$t = 1.085 \times 10^{-4}\sqrt{d^3 f} \quad [45]$$

If the assumption is made that g, h, and t are fairly small, it follows from Equation [22] that $f = 0.757$. Therefore, from Equation [45]

$$t = 9.44 \times 10^{-5}\sqrt{d^3} \quad [46]$$

If the values of c, j, k and t from Equations [42], [43], [44], and [46] are substituted in Equation [20] that equation becomes

$$4.184d + 2.97 \times 10^{-3}\sqrt{d} + 2.83 \times 10^{-4}\sqrt{d^3} = 0.4800$$

whence

$$d = 0.1144 \quad [47]$$

It follows, from Equations [42], [43], and [44], that

$$c = 0.1249$$
$$j = 2.45 \times 10^{-4}$$
$$k = 7.58 \times 10^{-4}$$

Equation [25] can be rewritten

$$g = 0.0322\sqrt{fe}$$
$$= 1.63 \times 10^{-5}\sqrt{f} \quad [48]$$

If Equation [25] is divided by Equation [26], the result is

$$\frac{h}{e\sqrt{f}} = 5.98 \times 10^{-4}$$
$$h = 5.98 \times 10^{-4}\, e\sqrt{f}$$
$$= 1.44 \times 10^{-10}\sqrt{f} \quad [49]$$

The value of d from Equation [47] can be substituted in Equation [45] to give

$$t = 4.20 \times 10^{-6}\sqrt{f} \quad [50]$$

An equation for f results when the values for g, h, and t from Equations [48], [49], and [50] are substituted in Equation [22]

$$2f + 2.05 \times 10^{-5}\sqrt{f} = 1.5150$$
$$f = 0.7575$$

whence

$$g = 1.42 \times 10^{-5}$$
$$h = 1.25 \times 10^{-12}$$
$$t = 3.66 \times 10^{-6}$$

From Equations [30] and [31], using the value of e from Equation [41]

$$m = \sqrt{1.08 \times 10^{-6}\, e}$$
$$= 5.11 \times 10^{-10}$$

$$
\begin{aligned}
n &= 3.07 \times 10^{-7}\, e^{3/2} \\
&= 3.66 \times 10^{-17}
\end{aligned}
$$

All of the unknowns have now been evaluated using an estimated value of a, and twelve of the thirteen equations. To check the estimated value of a, use is made of the remaining equation, Equation [21]. Substitution of the values of the unknowns in the left side of Equation [21] yields the near equality

$$0.4071 = 0.4070$$

It remains to confirm the initial assumption that q, r, i, and s are negligible. The values of b and e calculated previously are such that

$$\sqrt{e} = 2.48 \times 10^{-3}\, b$$

Comparison of this with inequality [36]

$$\sqrt{e} > 1.65 \times 10^{-7}\, b, \ (q = 0)$$

shows that q does equal zero. The ratio of the pressure of the carbon vapor actually present to the vapor pressure of carbon at the explosion temperature is $1.65 \times 10^{-7}/2.48 \times 10^{-3} = 6.65 \times 10^{-5}$. Inequalities [37], [38], and [39] can then be converted into the following equations

$$\sqrt{r} = (6.65 \times 10^{-5})\,(2.9 \times 10^{-2}) = 1.9 \times 10^{-6}$$

$$i = \frac{6.65 \times 10^{-5}\, d^2}{550} = 1.21 \times 10^{-7}\, d^2$$

$$s = (6.65 \times 10^{-5})\,(8.18 \times 10^{-6}) = 5.44 \times 10^{-10}$$

Evaluation of r and i yields

$$
\begin{aligned}
r &= 3.6 \times 10^{-12} \\
i &= 1.58 \times 10^{-9}
\end{aligned}
$$

Thus the assumption that q, r, i, and s can be neglected is verified.

The calculations thus far have shown the equilibrium composition of the gasoline-air mixture at 2200 K. It must still be demonstrated that the heat evolved by the reaction is just sufficient to raise the temperature of the gas mixture to the assumed value of 2200 K.

The heat energy evolved at room temperature by the complete constant-volume combustion of 0.030 mole of gasoline vapor to H_2O (vapor) and CO_2 is (1,174,400) (0.030) = 35,232 cal (see Appendix 1).

The energy required to raise the temperature from 293 K to 2200 K and cause the dissociation which occurs at the latter temperature is calculated by using the coefficients $a, b, \ldots, t$ already calculated, and the internal energy per mole of the various gases at 2200 K above the energy of O_2, N_2, H_2O, and CO_2 at 293 K, values of which are given in Table 2.

The calculation may be conveniently presented as in Table 4.

The last two columns of Table 4 show the rate of change of energy with temperature and will be used to estimate how much the actual explosion temperature differs from 2200 K. The

TABLE 4

Gas	No. moles	ΔE per mole[a]	ΔE per react.	$\frac{d(\Delta E \text{ per mole})}{dT}$	$\frac{d(\Delta E \text{ per react.})}{dT}$
a CO_2	0.0416	21089	878	12.2	0.51
b CO	0.1987	78880	15670	6.8	1.35
c H_2O	0.1249	15950	1991	10.5	1.31
d H_2	0.1144	68041	7783	6.4	0.73
f N_2	0.7575	11402	8630	6.71	5.14
j OH	0.00025	45461	11	....	....
k H	0.00076	85998	65	....	....
A	0.0090	5680	51	....	....
Total	1.2471		35079		9 04

[a] Refer to Table 3.

difference between the energy evolved and the energy at 2200 K is 35,232 — 35,079 = 153 cal. The actual temperature is, therefore, approximately 153/9.04 = 16.9 deg above 2200 K. This is not different enough from 2200 K to change the equilibrium constants significantly, so the value T_m = 2217 K (1944 C) may be taken as accurate. The explosion pressure P_m can be calculated from Equation [18]

$$
\begin{aligned}
P_m &= P_0 N_m T_m / T_0 \\
&= (1.000)\,(1.2471)\,(2217)/293.2 \\
&= 9.42 \text{ atm} = 138.5 \text{ psia}
\end{aligned}
$$

It should be noted that if the energy-balance calculation shows that the temperature is considerably different from the estimated temperature which was used to calculate the unknown coefficients, the entire calculations must be repeated using the equilibrium constants at the newly estimated temperature. However, if the difference between the two temperatures is not too great, the recalculation may be greatly simplified by neglecting the coefficients which the previous calculation has shown are negligible. In fact, for all mixture ratios, more than one half of the seventeen coefficients can be neglected; however, the coefficients which may be neglected are different for different mixture ratios. In the calculations presented, the precise value of every coefficient has been given so that there will be no question as to which coefficients are negligible.

Heat Transfer in Annuli

By C. Y. CHEN,[1] G. A. HAWKINS,[2] and H. L. SOLBERG[3]

A survey of the literature reveals that few data are available relative to heat transfer in annular spaces for the case of laminar flow. This paper presents data acquired in an experimental study[4] of the heat-transfer coefficients at the inner wall of four different annuli for the case of laminar flow of water. Both heating and cooling tests were conducted. The experiments were performed over a range of Reynolds numbers from 200 to 2000. The accompanying dimensionless equation was

$$\frac{hD}{k} = 1.02\left(\frac{VD\rho}{\mu_a}\right)^{0.45}\left(\frac{c_p\mu_a}{k}\right)^{1/3}\left(\frac{\mu_a}{\mu_w}\right)^{0.14}\left(\frac{D}{L}\right)^{0.4}\left(\frac{D_1}{D_2}\right)^{0.8}\cdot\left(\frac{D^3\rho^2\beta g\Delta t}{\mu_a^2}\right)^{0.05}$$

found to correlate both the heating and the cooling data for all four annuli with an average deviation of ±6.6 per cent and a maximum deviation of ±14.1 per cent. This equation may be used for computing the heat-transfer coefficient on the inner wall of an annulus for laminar flow of water for Reynolds numbers in the range of 200 to 2000.

Nomenclature

The following nomenclature is used in the paper:

a = constant
A = area, sq ft
b = constant
c_p = heat capacity at constant pressure, Btu/(lb$_{mass}$)(deg F)
d = constant
D_1 = outer diameter of annulus, ft
D_2 = inner diameter of annulus, ft
D = equivalent diameter of annulus, ft
D_e = characteristic dimension of annulus, ft
e = constant
f = constant
g = gravitational acceleration, ft/hr^2
h = surface coefficient of heat transfer, Btu/(hr)(sq ft)(deg F)
k = thermal conductivity, Btu/(hr)(ft)(deg F)
L = characteristic linear dimension, ft
L = heating or cooling length of an annular section, ft
m = constant
m = hydraulic radius, ft
q_r = heat transferred by radiation, Btu/hr
t = temperature, deg F
T = absolute temperature, deg R
V = velocity, fph
α = constant
ϵ = emissivity of surface for radiation
β = coefficient of cubical expansion, (deg F)$^{-1}$
ρ = density, (lb$_{mass}$)/cu ft
μ = dynamic (absolute) viscosity, (lb$_{mass}$)/(hr)(ft)
μ_w = dynamic (absolute) viscosity at the surface temperature, (lb$_{mass}$)/(hr)(ft)
μ_a = dynamic (absolute) viscosity evaluated at bulk-fluid temperature, (lb$_{mass}$)/(hr)(ft)
Δ = difference

Introduction

The double-pipe heat exchanger is frequently used in engineering work to transmit heat from one fluid to another. The design of this type of heat exchanger requires a knowledge of the heat-transfer coefficient in the annular space. Designing engineers have long felt the need for a single heat-transfer correlation which could be used for determining the coefficient for the case of an annular space for either a heating or a cooling process. In an annular space, heat transfer may take place either at the inner surface of the annulus or at the outer surface or both.

A survey of the literature reveals that in the last decade a number of successful investigations have been made on the heat transfer in annular spaces for the case of turbulent flow. However, very little has been done for the case of laminar flow in annular spaces. Jakob and Rees (1)[5] presented a mathematical theory of heat transfer between the walls of an annulus and a fluid passing through it in laminar flow for the cases of uniform heating or cooling from outside, inside, or from both sides at the same time.

In a recent paper, Davis (2) suggested a tentative dimensionless equation for determining heat-transfer coefficients in annuli for the case of laminar flow. Since there were no experimental data available, the constants of the equation were left as unknowns.

The criterion of flow is the Reynolds number $\frac{VD\rho}{\mu}$. In case of flow in an annular space, usually an equivalent diameter is used for D. There are two methods of calculating the equivalent diameter of an annulus. In the first of these methods, a value of 4 times the hydraulic radius m is used for the equivalent diameter. The hydraulic radius may be expressed as follows

$$m = \frac{\frac{\pi}{4}(D_1^2 - D_2^2)}{\pi(D_1 + D_2)} = \frac{D_1 - D_2}{4}$$

The equivalent diameter in this case is therefore $(D_1 - D_2)$.

In the second method, the heated perimeter is used. Where heat transfer takes place at the inner wall the equivalent diameter is

$$D = \frac{4 \times \frac{\pi}{4}(D_1^2 - D_2^2)}{\pi D_2} = \frac{D_1^2 - D_2^2}{D_2}$$

This was the first suggested by Jordan (3) and later by Nusselt (4).

[5] Numbers in parentheses refer to the Bibliography at the end of the paper.

Although both of these equivalent diameters have been used for correlating data dealing with heat transfer in annular spaces, the one based on 4 times the hydraulic radius was used in this investigation to compute the Reynolds number.

For flow in a round pipe, it has been established that the lower critical Reynolds number occurs at about 2300. The lower critical Reynolds number for flow in an annular space has not been completely ascertained. Using an annular cylinder having a ratio of radii of 0.818 to 1, Page (5) found a value of 2400 as the lower critical Reynolds number. Researchers (6, 7) on fluid friction in annular spaces have shown that there is no abrupt change in friction factor for Reynolds number below 2000. It is therefore believed that the lower critical Reynolds number for flow in annular spaces must be about 2000.

In the present experiments, the range of Reynolds number investigated was from 200 to 2000. A few cases of abrupt increase in the heat-transfer coefficient occurred near a Reynolds number of 2000. This was taken as an indication that the critical Reynolds number had been reached and these data were discarded. None of the tests were conducted at a Reynolds number less than 200, owing to the difficulty of regulating the flow with the available equipment.

Theoretical Considerations

The problem of forced convection has long defied mathematical solution. Only for the simplest cases and corresponding simplified assumptions has the mathematical solution been successful. In the present cases, because of geometrical complications, variable temperature gradients, and heat exchange, dimensional analysis was used to correlate the test data. By using general dimensionless groups which have been used in other correlations, the following equation was selected as a first approximation

$$\frac{hD_c}{k} = \alpha\left(\frac{VD_c\rho}{\mu_a}\right)^a\left(\frac{c_p\mu_a}{k}\right)^b\left(\frac{L}{D_c}\right)^d\left(\frac{D_1}{D_c}\right)^e\left(\frac{\mu_w}{\mu_a}\right)^f \ldots\ldots [1]$$

where D_c is some characteristic dimension of the annulus. Since the criterion of flow is the Reynolds number based on the equivalent diameter D, it is logical to use this equivalent diameter for D_c throughout the correlation.

The factor $(D_1/D_c)^e$ expresses the effect of geometric proportion of different annuli. Inasmuch as the equivalent diameter D is a function of D_1 and D_2, it will simplify computations to use the factor $(D_1/D_2)^e$ directly rather than to use an equivalent or some other form.

For the case of laminar flow of fluids of low viscosities such as water, natural convection sometimes plays a prominent part. When dimensional analysis is applied to problems dealing with natural convection, the Grashof number, $\frac{L^3\rho^2\Delta t\beta g}{\mu^2}$ appears. Introducing the Grashof number, Colburn (8) has correlated the data for water, air, and petroleum oil for the case of laminar flow in round pipes by use of the following multiplying factor:

$$(1 + 0.015\mathbf{G}^{1/3})$$

It has been pointed out by Martinelli and his associates (9) that for fluids of low viscosities the Grashof number appears in the general equation as a constant multiplier. Thus the effect of free convection which is represented by the Grashof number does not decrease as the Reynolds number becomes larger, but remains a constant multiplier.

In this work attempts were made to express the free convection effect as a function of the Reynolds number, the product of the Grashof and Prandtl numbers, and other dimensionless groupings. However, for the data obtained in these experiments the most satisfactory correlation was found using the factor $K(\mathbf{G}/\mathbf{R})^r$, where K is a constant. By use of this relation in Equation [1], it is possible to combine the equation constant and K and the various Reynolds numbers. Hence in the final equation the Grashof number appears as a multiplying factor.

It is recognized that this procedure is open to question. Other correlations may be possible, which would make the equation suitable for use beyond the range of the experimental data reported.

Since D, the equivalent diameter, is to be used in Equation [1], in the Reynolds number, it is desirable to use this same D as the characteristic dimension L in the Grashof number. There seems to be no universally accepted method of evaluating viscosity in the Grashof number. Colburn (8, 10) used the viscosity at the film temperature but there is some uncertainty as to how this film temperature should be computed. The viscosity at the bulk fluid temperature μ_a therefore was used in the computation of the Grashof number in this correlation.

Hence Equation [1] becomes

$$\frac{hD}{k} = \alpha'\left(\frac{VD\rho}{\mu_a}\right)^{a'}\left(\frac{c_p\,\mu_a}{k}\right)^b\left(\frac{L}{D}\right)^d\left(\frac{D_1}{D_2}\right)^e\left(\frac{\mu_w}{\mu_a}\right)^f\left(\frac{D^3\rho^2\,\Delta t\beta g}{\mu_a^{\,2}}\right)^m . [2]$$

For both the laminar and the turbulent flow in round pipes, Sieder and Tate (11) and Colburn (8, 10) used an exponent for the Prandtl number equal to $^1/_3$. For heat transfer at the inner wall of the annuli with turbulent flow, Monrad and Pelton (12), and Davis (2) correlated the data with a dimensionless equation, in which the exponent of $^1/_3$ was used for the Prandtl number. Based on these results, a value of $b = ^1/_3$ was used in correlating the experimental data.

The use of $(\mu_w/\mu_a)^f$ in the heat-transfer correlation was first introduced by Sieder and Tate (11). For flow inside round pipes they used —0.14 for f. This factor accounts for the effect of the increased or decreased velocity gradients at a heated or cooled wall and may hold even if another wall is placed opposite to it as in an annulus. The 0.14 power is valid in crossflow according to Sieder. It seems probable that the presence of another wall would not affect appreciably the velocity gradient at the heated or cooled wall. Davis (2) used this power to correlate the data for heat transfer at the inner wall of the annuli with turbulent flow, and $f = -0.14$ was also used to correlate the data in this investigation. All of these assumptions can be justified only in the light of additional experimental data.

Description of Apparatus

Fig. 1 is a schematic diagram of the complete setup of the equipment. Letter A designates a large water tank equipped with a suitable overflow. The heating device consisted of copper coils connected to a steam pipe. A mechanical stirrer was used to maintain a uniform temperature.

From tank A water was pumped to the test section. A valve and a by-pass were inserted to control the flow. The inlet temperature to the annular section was measured by a thermometer inserted through a cork plug at one end of a tee. The temperature was measured at a point where the leading pipe made a turn which was located at a considerable distance from the entrance to the test section. The location of the thermometer was selected in order to eliminate unnecessary turbulence near the entrance. The leading pipe was suitably insulated.

Water flowed through the annular section into the mixing chamber where the outlet temperature was measured by means of thermometers. From the mixing chamber, the water flowed either to the weighing tank or to the drain. Water flowing in the inner pipe followed a somewhat similar path, as shown in Fig. 1.

The test section consisted of two brass pipes, one inside the other. Fig. 2 shows a part of the test section. The inner pipe

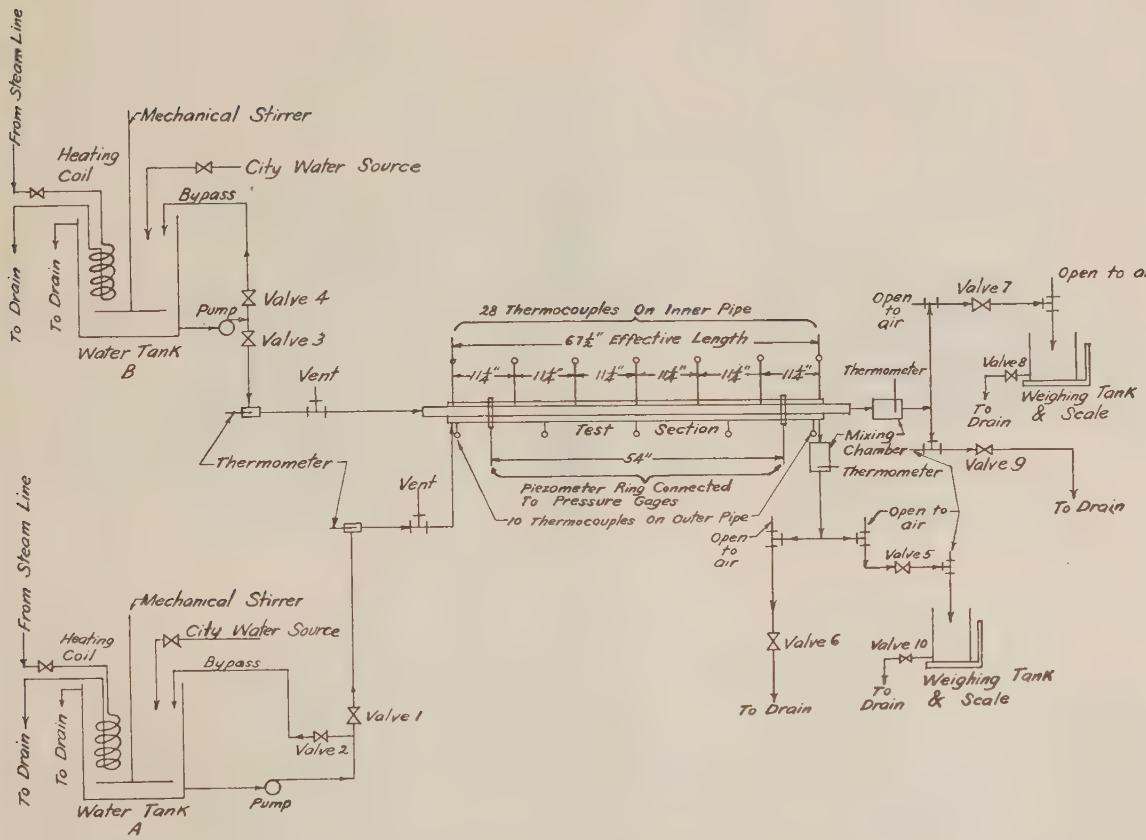

Fig. 1 Schematic Diagram of Complete Setup

was 7 ft in length. It was connected to the inlet pipe by a bronze sleeve, threaded on one end and soldered to the inner pipe at the other end. The outer pipe was $66^1/_2$ in. long. Both of its ends were slipped into the ends of two cast-iron pieces and the joints soldered. These two cast-iron pieces served as the entrance and exit pieces and were designed to have the flow area in the section leading to the inlet and outlet of the annular section approximately equal to the cross-sectional area of the annular space, thus eliminating rapid changes in the flow areas. Wooden plugs screwed into these cast-iron pieces were designed to permit smooth entrance to and from the annulus, and to serve as heat insulation. Steel packing glands were used to prevent leakage.

A total of $67^1/_2$ in. effective internal heating or cooling length was used in all tests. No calming section was used owing to construction difficulties. Water was led into and out of the test section in a horizontal direction.

The following brass pipes were used:

Pipe	Outside diameter, in.	Inside diameter, in.
A	$2^1/_4$	2
B	$1^1/_2$	$1^3/_8$
C	1	$^7/_8$
D	$^3/_4$	$^1/_2$

Four combinations were tested. These were *A-C*, *A-D*, *B-C*, and *B-D*. The inner pipe was centered inside the outer pipe by the wooden plugs and steel packing glands, and was strong enough to prevent sagging.

The temperatures of the outside surface of the inner pipe were measured along the pipe by calibrated 28-gage copper-constantan thermocouples. Seven sets of couples located $11^1/_4$ in. apart were spaced over the effective length. Each set of couples consisted of 4 pairs of couples placed around the section at 90-deg intervals so as to give an average temperature of the section. The first and last sets were placed near the ends of the wooden plugs.

The thermocouples were attached to the pipe wall by a modified method suggested by Colburn and Hougen (13). Longitudinal slots 3 in. long, $^1/_{16}$ in. wide, and $^1/_{16}$ in. deep were cut on the outside surface of the inner pipe. The cotton-covered insulation on the wires was first impregnated with a water-resistant varnish. After welding the junction, the insulated wires were twisted together and pressed into the slot. A drop of solder was placed over the welded ends of wires to form a rigid connection between the thermocouple and the pipe. The soldered joint was then polished with fine emery cloth in order to get a surface flush with the pipe surface. Waterproof varnish was applied to the wires in the slots in order to make the surface of the slot flush with the pipe surface.

The thermocouples were led out vertically from the inner pipe surface through $^1/_8$-in. holes drilled in the outer pipe and through a small packing gland to the outside. These small packing glands were screwed into seats which were soldered to the outside surface of the outer pipe. All the thermocouple wires were led downstream except the last group which was brought upstream because of space limitations. In this case a fine copper wire was

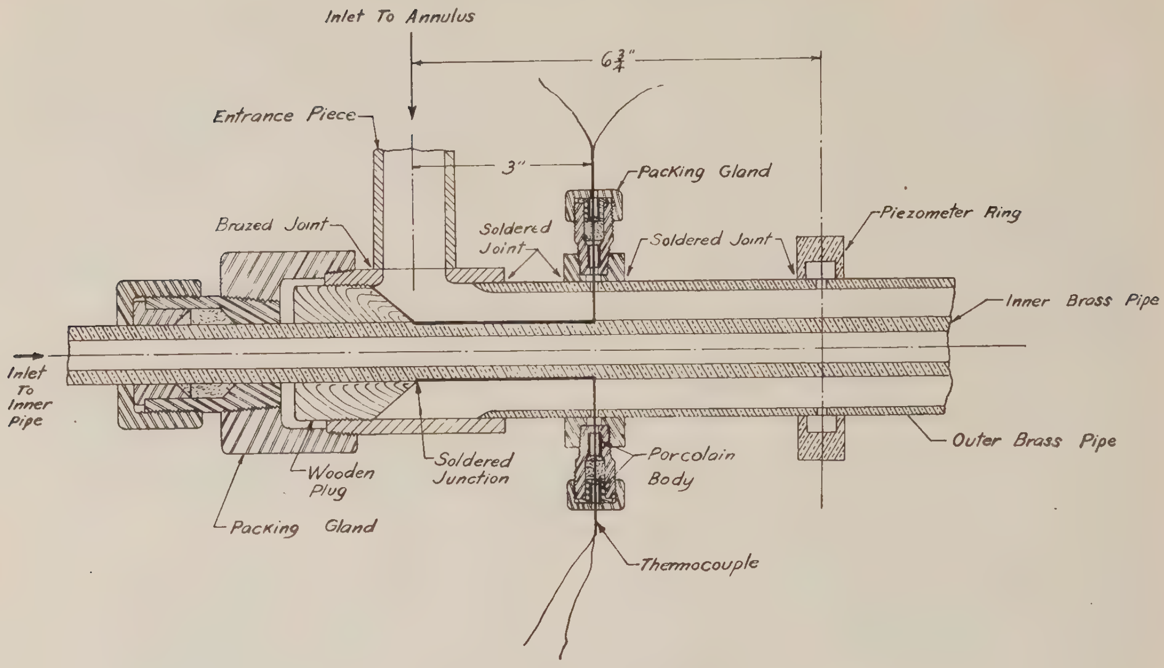

FIG. 2 ENTRANCE SIDE OF TEST SECTION

wound around the ends to prevent them from becoming loose. This prevented the couples from being moved out of the slot by the flowing fluid. After the tests the couples were all inspected and were found to be practically in the same condition as they were when first placed in the slots.

The outer pipe was cut into three sections to simplify the operation of installing the thermocouple wires. After all the couples were installed and checked, the outer pipe sections were joined by two sleeves and soldered. The surfaces at the sections were faced smoothly so that when the sections were joined together in the sleeve, they would closely match each other and thus prevent turbulence.

The short lengths of thermocouple wire leading from the inner pipe surface through the holes in the outer pipe surface and through the glands, were impregnated with waterproof varnish. Since 28-gage thermocouple wires were used, it is believed that the wires caused very little disturbance to the flow. The accuracy obtained from averaging the temperatures around the section should more than offset the small additional turbulence caused by the thermocouples.

Five sets of thermocouples were soldered on the outside surface of the outer pipe. Each set consisted of two pairs of couples, one at the top and the other at the bottom. These gave the outer-wall temperature gradient along the pipe.

Piezometer holes $^1/_8$ in. diam were drilled at two sections on the outer pipe 54 in. apart, spaced equally from the two ends. At each section the four openings were connected to a brass piezometer ring. The pressure readings from a Wahlen gage and an inclined draft gage served as a check as to whether laminar flow existed in the annular space.

The mixing chambers, Fig. 3, were made of 4-in. standard galvanized pipe and were fitted with half-moon baffles on the inside to promote mixing. In order to obtain the outlet temperature, two thermometers were inserted through the rubber stoppers at the top of the mixing chamber with their bulbs widely spaced at two different heights in the chamber. The exact check of the two thermometer readings indicated the efficiency of the mixing chamber. A short glass tube inserted through one of the rubber stoppers and connected to a glass stopcock served as a vent for the air to escape from the chamber when the fluid started to flow. The results of temperature measurements made on the mixing chamber during preliminary calibration tests did not show any evidence of stratification.

The outside surface of the outer pipe and the mixing chambers were heavily insulated.

The test section was mounted horizontally with a slight inclination to enable air to escape from the vent at the exit end.

From the mixing chamber, water was led to the weighing tank and the drain through separate pipe lines and valves. As shown in Fig. 1, two tees were placed in the flow paths before the valves. The tees were open to the atmosphere at one end to stabilize the flow.

After the tests had been completed on each combination of pipes, the inner pipe was taken out and examined. The outer wall of the inner pipe was found to be slightly fouled. When the inner pipe was used again, in a different combination, its outer surface was carefully polished.

TEST PROCEDURE

All thermometers were calibrated. The thermocouples were checked against each other by running water at the same temperature through both the inner pipe and the annular section. Only parallel flow was employed and both heating and cooling runs were made. Water was used in both the annulus and the inner pipe.

To start a test, the sources of water were turned on and the mechanical stirrer set into operation. Cooling tests were conducted first. Valves nos. 1 and 2, Fig. 1, were adjusted to give the flow corresponding to the Reynolds number. Valves nos. 3 and 4 on the inner pipe side were adjusted to give a flow such that

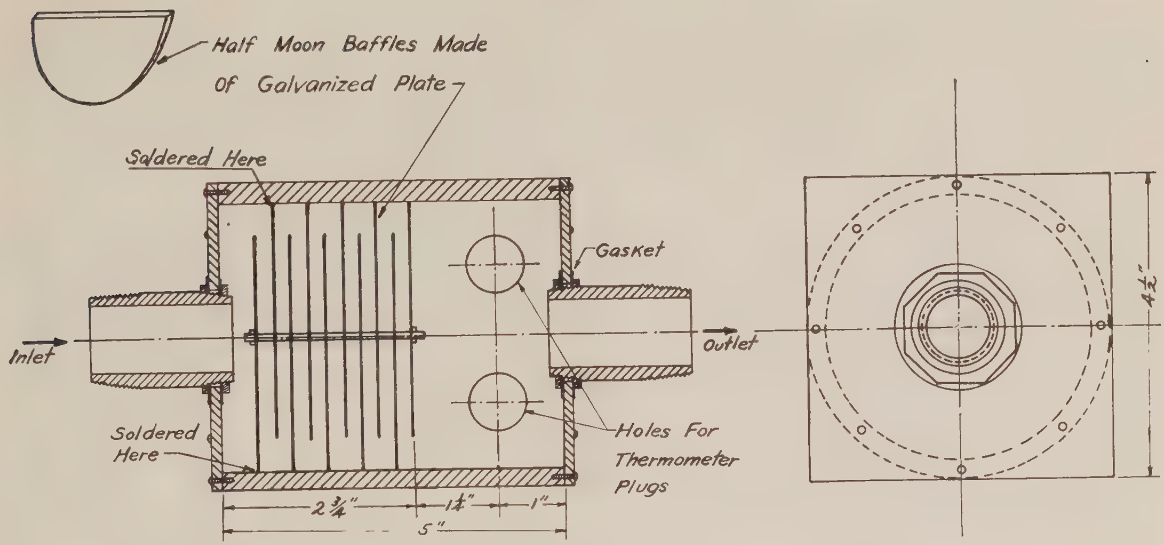

FIG. 3 MIXING CHAMBER

the drop in temperature of the fluid in the annular section would be as small as practical but large enough to give a suitable temperature between water flowing out from the annulus and water flowing out from the inner pipe. Valves nos. 5 and 7 were kept open while valves nos. 6 and 9 were closed. Water flowed into the two weighing tanks during the test except for a brief instant when the initial tank readings were taken.

The various temperature and pressure readings were taken at regular intervals. After these readings had remained constant for about 1 hr, thermal equilibrium was reached and a set of readings was taken, which included the inlet and outlet temperatures of water in both the annulus and the inner pipe, the pipe-wall temperatures, and the weight rate of flow in both the annulus and the inner pipe.

Check tests were conducted on different days to ascertain whether or not the surfaces were becoming contaminated by dirt or other substances. In every case these test results agreed.

Experimental Results and Conclusions

The original experimental data together with computations are presented in Tables 1, 2, 3, and 4. In computing the data the average fluid temperature in the annulus was taken as the arithmetic average of the inlet and outlet temperatures. The heat transferred was based on readings on the inner pipe. The heat-transfer coefficient was based on the arithmetic-mean temperature difference. The inner pipe-wall temperature was the average of the 28 thermocouple readings. Values of μ, c_p, and k were based on those given by Dorsey (14). The coefficients of cubical expansion of water at different temperatures were based on Kopp's data on the relative volumes of water at different

temperatures as listed in Kent's Mechanical Engineers' Handbook.

In making the correlation, an exponent of $-^1/_3$ was assumed for the L/D factor in Equation [2], and four sets of cooling-test data for the different annular combinations were selected with approximately equal Reynolds numbers. The function

$$\left(\frac{hD}{k}\right)\left(\frac{c_p\mu_a}{k}\right)^{-1/3}\left(\frac{\mu_a}{\mu_w}\right)^{-0.14}\left(\frac{D}{L}\right)^{-1/3}$$

was plotted against (D_1/D_2) values for these four sets on logarithmic paper. Different straight lines were drawn to join the four points. The slopes of the lines were found to vary from 0.8 to 1, the majority being in the neighborhood of 0.8. As a result, it was decided to use a value of 0.8.

The function

$$\left(\frac{hD}{k}\right)\left(\frac{c_p\mu_a}{k}\right)^{-1/3}\left(\frac{\mu_a}{\mu_w}\right)^{-0.14}\left(\frac{D}{L}\right)^{-1/3}\left(\frac{D_1}{D_2}\right)^{-0.8}$$

was plotted against

$$\left(\frac{D^3\rho^2\beta g\,\Delta t}{\mu_a^2}\right)\left(\frac{\mu_a}{VD\rho}\right)$$

on logarithmic paper for eight sets of cooling and heating tests on the four combinations with approximately equal Reynolds numbers. A straight line was drawn to join the points and a slope of 0.05 was found for the line.

The function

$$\left(\frac{hD}{k}\right)\left(\frac{c_p\mu_a}{k}\right)^{-1/3}\left(\frac{\mu_a}{\mu_w}\right)^{-0.14}\left(\frac{D}{L}\right)^{-1/3}\left(\frac{D_1}{D_2}\right)^{-0.8}\left[\left(\frac{D^3\rho^2\beta g\,\Delta t}{\mu_a^2}\right)\left(\frac{\mu_a}{VD\rho}\right)\right]^{-0.05}$$

was plotted against $\frac{VD\rho}{\mu}$ on logarithmic paper for all 74 runs. The plotted points fell within a strip on the graph, showing the definite existence of a correlation; however, the spread of the data was rather large.

Finally the exponent of (D/L) was changed to -0.4 and the function

$$\left(\frac{hD}{k}\right)\left(\frac{c_p\mu_a}{k}\right)^{-1/3}\left(\frac{\mu_a}{\mu_w}\right)^{-0.14}\left(\frac{D_1}{D_2}\right)^{-0.8}\left[\left(\frac{D^3\rho^2\beta g\,\Delta t}{\mu_a^2}\right)\left(\frac{\mu_a}{VD\rho}\right)\right]^{-0.05}$$

was plotted against $\frac{VD\rho}{\mu}$. A satisfactory correlation resulted.

Combining the Reynolds number, the function

$$\left(\frac{hD}{k}\right)\left(\frac{c_p\mu_a}{k}\right)^{-1/3}\left(\frac{\mu_a}{\mu_w}\right)^{-0.14}\left(\frac{D}{L}\right)^{-0.4}\left(\frac{D_1}{D_2}\right)^{-0.8}\left(\frac{D^3\rho^2\beta g\,\Delta t}{\mu_a^2}\right)^{-0.05}$$

was plotted against the Reynolds number as shown in Fig. 4.

A close examination shows that the slope of a line drawn through the cooling data is slightly steeper than a similar line for the heating data. The difference between the two is so small that it can be neglected.

The equation of the single line in Fig. 4 was found to be

$$\left(\frac{hD}{k}\right)\left(\frac{c_p\mu_a}{k}\right)^{-1/3}\left(\frac{\mu_a}{\mu_w}\right)^{-0.14}\left(\frac{D}{L}\right)^{-0.4}\left(\frac{D_1}{D_2}\right)^{-0.8}\left(\frac{D^3\rho^2\beta g\,\Delta t}{\mu_a^2}\right)^{-0.05} = 1.02\left(\frac{VD\rho}{\mu_a^2}\right)^{0.45}$$

Solving for the Nusselt number gives

$$\frac{hD}{k} = 1.02\left(\frac{VD\rho}{\mu_a}\right)^{0.45}\left(\frac{c_p\mu_a}{k}\right)^{1/3}\left(\frac{\mu_a}{\mu_w}\right)^{0.14}\left(\frac{D}{L}\right)^{0.4}\left(\frac{D_1}{D_2}\right)^{0.8}\left(\frac{D^3\rho^2\beta g\,\Delta t}{\mu_a^2}\right)^{0.05}$$

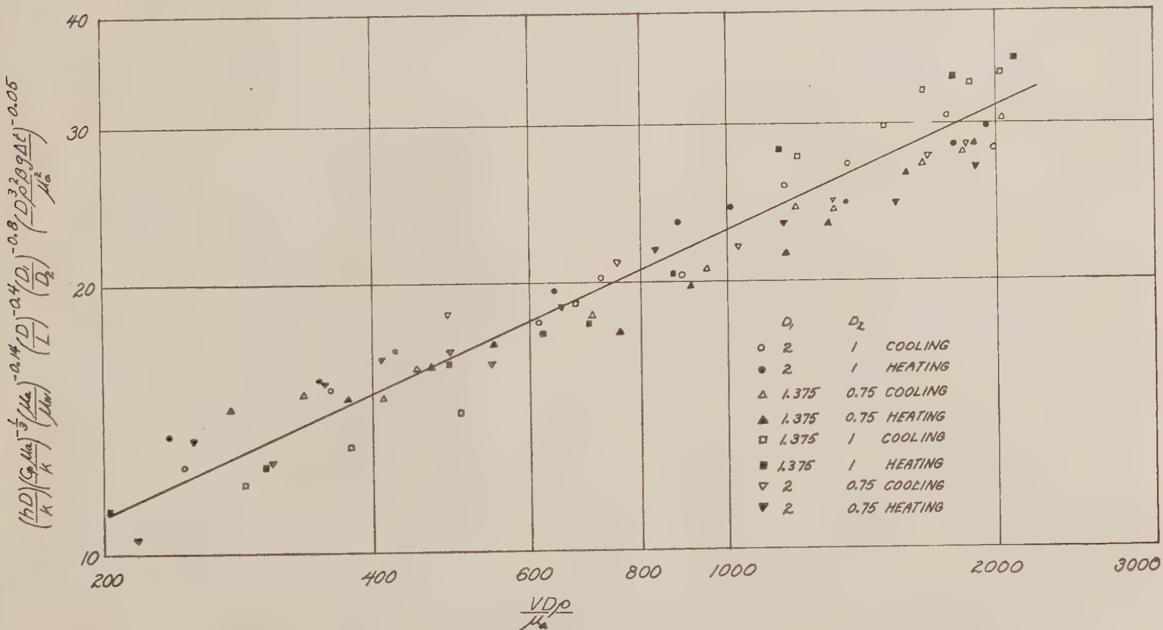

Fig. 4 Recommended Correlation of Data for Heating and Cooling Tests

Equation: $\left(\frac{hD}{k}\right)\left(\frac{C_p\mu_a}{k}\right)^{-1/3}\left(\frac{\mu_a}{\mu_w}\right)^{-0.14}\left(\frac{D_1}{D_2}\right)^{-0.8}\left(\frac{D}{L}\right)^{-0.4}\left(\frac{D^3\rho^2\beta g\,\Delta t}{\mu_a^2}\right)^{-0.05} = 1.02\left(\frac{DV\rho}{\mu_a}\right)^{0.45}$

Discussion and Conclusion

The following equation

$$\frac{hD}{k} = 1.02\left(\frac{VD\rho}{\mu_a}\right)^{0.45}\left(\frac{c_p\mu_a}{k}\right)^{1/3}\left(\frac{\mu_a}{\mu_w}\right)^{0.14}\left(\frac{D}{L}\right)^{0.4}\left(\frac{D_1}{D_2}\right)^{0.8}\left(\frac{D^3\rho^2\beta g\,\Delta t}{\mu_a{}^2}\right)^{0.05} \quad \ldots\ldots [3]$$

was found to correlate the test data with an average deviation of ± 6.6 per cent and a maximum deviation of $+14.1$ per cent. In view of the variables encountered in such a problem and the difficulty of making precise temperature measurements, it is considered satisfactory and is recommended for computing the heat-transfer coefficient at the inner wall of an annulus for laminar flow. Since the tests were conducted over a range of Reynolds number from 200 to 2000, the relation is only valid for this range of Reynolds number. However, as the effects on heat transfer in the laminar region should be the same for all Reynolds numbers below the lower critical value, as is the case for flow in round pipes, it can be reasonably expected that the equation may also hold for Reynolds numbers smaller than 200.

It should be noted that the exponent for (**P**) was assumed to be $^1/_3$. The Prandtl number is connected solely w th the properties of the fluid. As water was the only fluid used, the exponent for (**P**) was not verified for all fluids. Nevertheless, it is safe to presume that this exponent should be somewhere around $^1/_3$, as this was the exponent used successfully in the correlation of the heat-transfer data for both laminar and turbulent flow in round pipes, and for turbulent flow in annuli.

The Grashof number (**G**) in Equation [3] accounts for the effect of natural convection. This effect should decrease with an increase in the flow rates or Reynolds number. This was proved qualitatively by the temperature-distribution data.

The temperature at any section was found to be the highest at the top and the lowest at the bottom. In 1931 Drew and Ryan (15) studied the distribution of heat about the circumference of a pipe in a stream of fluid flowing across the pipe. Baker and Mueller (16) investigated the temperature variation around the perimeter of a tube when pure and mixed vapors were condensing. They found that the top surface attained the highest temperature and the bottom the lowest. Since only four temperature readings were obtained at each section, no quantitative analysis can be made.

The percentage of difference between temperatures at the top and bottom of any one section decreased with an increase in the Reynolds number. This means that the effect of natural convection decreased for a given increase of the Reynolds number.

The end effect constitutes a variable, the influence of which could not be determined quantitatively from the experimental results. It is felt that the end effect on the heat-transfer rate is very small for these experiments. The (L/D) ratio for the four annular combinations varies from 179.8 to 54. However, the test data fell into a satisfactory correlation. This should indicate that the end effect for different (L/D) ratios within this range were of the same order of magnitude at the same Reynolds number.

The difference between the heat loss or gain for the water flowing in the annulus and the heat loss or gain for the water flowing in the inner pipe was used as a relative index of the heat balance. Due to the facts that the area of the external insulation surface was not known accurately, and that the temperature differences between the outer insulation surface and the air were small, no effort was made to compute the heat-transfer loss by convection and radiation from the insulation surface. Approximate computations could be made for this loss, which when taken into account would decrease the difference between the heat gained or lost by the fluid in the annular space and the heat gained or lost by the fluid in the inner pipe. It was felt that the difference between the heat gained or lost by the water in the annular space and that in the pipe would serve as an index of the reliability of the tests. The average difference for all of the tests was approximately 5.8 per cent. The results obtained on the first test conducted showed a difference of 31.6 per cent. The data for one other test checked to within 16.9 per cent. The differences for seventy-two tests were less than 11 per cent, the average for these tests being 5.22 per cent.

The heat-transfer coefficients for the inner pipe were computed in order to check the experimental values. These data correlated in a satisfactory manner with those already published.

Heat Transfer in the Locomotive Boiler

By LAWFORD H. FRY,[1] NEW YORK, N. Y.

It is shown that the total heat absorption in a locomotive boiler for any assumed rate of heat release and weight of gases of combustion can be predicted with all of the accuracy practically necessary. The over-all heat transfer is considered as taking place in two separate operations which can be represented by two formulas, a fourth-power equation of the usual type for the radiation in the firebox, and a double logarithmic equation for the convection in the flues. This form of equation was suggested by Fessenden (1),[2] and its usefulness has been extended by the coefficients developed by the present author. It may not represent the exact physical reactions of the process of heat transfer, but it has the pragmatic sanction of giving practically accurate results under many different conditions. Actually that is all that can be claimed for any other heat-transfer formula even if it uses the Reynolds number. Fessenden pointed out, "It should be noted that the apparently rational idea that the rate of heat transfer is directly proportional to the temperature difference is, after all, only an assumption that has been accepted for so long that it has come to be regarded as an axiomatic statement of fact."

THE locomotive boiler with its water-enclosed firebox and its fire-tube barrel still follows the lines laid down by George and Robert Stephenson when they built the *Rocket* in 1829. This survival is sometimes criticized by advocates of other forms of motive power who think that we should be modern at all costs. Actually the retention of the locomotive-type boiler is the result of hard common sense supported by the inherent advantages of the arrangement. Change in design is not necessarily good engineering. Retention of a circular form for a wheel is still good practice.

Study of the details of operation of the locomotive boiler leads inevitably to recognition of the fact that in its modern form the locomotive boiler is an extremely compact and effective mechanism for the production of steam. Some efficiency of combustion is deliberately sacrificed to obtain the high rate of heat release necessary. It must be remembered that the boiler is part of a mobile power plant capable of running at 100 mph and able to pass through the restricted limits of a railroad loading gage. Evaporative capacities of over 100,000 lb of superheated steam per hr are obtained, and heat-release rates up to 300,000 Btu per hr per cu ft of firebox volume may be reached at maximum outputs. It is obvious that such rates of heat release are not compatible with high combustion efficiencies. The efficiency of heat absorption with which this paper is chiefly concerned is, however, generally satisfactory.

In studying the processes by which part of the heat released in the firebox is transferred to the boiler heating surfaces and taken up by the water and steam, the action may be considered as taking place in two major and individual operations. In the firebox, part of the heat released is taken up by direct radiation, while the remainder is carried into the tubes and flues by the gases of combustion. Of this gas-carried heat, part is transferred to the evaporative and to the superheating surfaces by convection while the remainder is lost through the smokebox as sensible and latent heat in the gases of combustion.

The purpose of this paper is to present formulas which represent the two processes of heat transfer and to show how they can be combined for use in estimating the amount of heat that will be taken up by a boiler of given dimensions under any known or assumed operating conditions.

In applying the formulas the boiler design is characterized by the area of the firebox heating surface, and by the number, diameters, and lengths of the flues, tubes, and superheater pipes. The operating conditions are characterized by the rate of heat release and by the weight of gases of combustion produced per hour. These dimensions and conditions are necessary and sufficient for determining the rate at which the boiler will take up heat to be used in producing and superheating the steam.

Over-All Heat Transfer

Computation of the over-all heat transfer falls into two parts. In the first the rate of heat release, the rate of gas production, and the area of the firebox surface are used to find the so-called "equilibrium temperature" of the firebox. This is the temperature at which the sum of the heat radiated direct to the firebox surface and of the sensible heat carried by the gases at that temperature is just equal to the total available heat released by combustion.

In the second part of the computation the gases are assumed to enter the flue bundle at the equilibrium temperature and to lose temperature at a rate given by the double logarithmic formula, Equation [2]. This equation takes into account the rate of gas flow, the gas-swept perimeter and the free gas area of the flue bundle, the temperature of the receiving surface, and the length of the flues.

Details of the formulas and of their application in practice are given later. Attention is here directed to the results obtained by applying the formulas to four different locomotive boilers of the dimensions shown in Table 1, for which extensive boiler test results are available. Outlines of two of the boilers are shown in Fig. 1. Two boilers have Type A superheaters with 4 pipes in each flue, while the other two boilers have Type E superheaters

with 2 superheater pipes in each flue. Representative arrangements of the superheater flues and the tubes are shown in Fig. 2. Computations for heat transfer have been carried out for twenty-seven tests taken largely at random. The test data for rate of heat release and weight of gases of combustion have been used, and the rates of heat transfer in firebox and in flues and the resulting smokebox temperatures have been computed by means of the formulas. The results are given in Tables 2 and 3 for comparison with the measured values. Agreement between measured and computed values is generally satisfactory, as the greatest divergence is hardly greater than the element of uncertainty in the measured values.

Heat Distribution

Table 2 includes the experimental data to which the formulas are applied and gives the computed and measured firebox and smokebox temperatures. The relation between measured and computed temperatures is also shown in Figs. 3 and 4.

Table 3 is based on the same data, measured and computed, that are contained in Table 1, but the data are organized to show how the heat released in the firebox is distributed. It may be noted that rates of firing range from the low rate of 35 lb of dry coal per sq ft of grate area per hr up to the high rate of 242 lb per sq ft per hr. Column 4 gives the computed equilibrium temperature, and column 5 the corresponding rate of radiation per square foot of firebox heating surface. This rate of radiation is given in column 5 in terms of Btu per hour and in column 6 is translated into equivalent evaporation in pounds of water per hour from and at 212 F per square foot of firebox surface. These values run up to 126 lb per sq ft per hr at the maximum firing rates. At normal working rates they are about 90 to 100 lb per sq ft per hr. There is no direct method of checking these

figures with evaporations actually obtained, but they are in line with values usually accepted.

Columns 7, 8, 9, 10 split up heat released into percentages representing, respectively, in column 7 the heat radiated to the firebox at equilibrium temperature, in column 8 the heat taken up by the evaporative and superheater surface of the tube bundle in cooling the gases from equilibrium to smokebox temperature, in column 9 the heat lost in sensible heat of gases at smokebox temperature, and in column 10 the heat lost in latent heat of the vapor. Except for high values at the very low firing rates, the distribution of the heat shows no great variation with the rate of firing and is very similar for the boilers of Series B, C, and D. The boiler of Series A with shorter flues shows a slightly lower percentage of heat absorbed in the flues.

Mean Firebox Equilibrium Temperature

The "mean equilibrium temperature" is defined as the temperature at which the amount of heat carried by the combustion gases, together with the amount radiated to the firebox surface, is just equal to the quantity of heat released by combustion. Its value in any given case can be found by using Table 4 or Fig. 5, provided that the experimental data furnish information as to the rate of available heat released in the firebox as well as the weight of the gases of combustion. Table 4 covers temperatures from 1400 F to 2800 F by steps of 10 deg F and for each temperature gives the sensible heat carried by the gas as well as the rate in Btu per square foot per hour at which radiated heat will be taken up by the firebox heating surface. The sensible heat in Btu above 32 F carried by 1 lb of gas is derived from the values given by Heck (6) for the products of combustion of coal with 20 per cent excess air. The original data show that the percentage of excess air has little effect on the specific heat of the mixed gases of combustion and that the figures of Table 4 are satisfactory in practice for any gas composition encountered in a coal-burning locomotive.

The values for radiated heat absorbed by the firebox heating surface are derived from the so-called Stefan-Boltzmann fourth-power equation

$$H_R = 1600\ [(T/1000)^4 - (t/1000)^4] \quad \ldots\ldots\ldots [1]$$

where

H_R is heat absorbed by radiation, in Btu per hour per square foot of firebox surface

T is absolute temperature of flame in firebox, in degrees Rankine

t is absolute temperature of receiving surface, in degrees Rankine. The temperature of the firebox surface is taken to be the temperature of the water back of the firebox surface.

Table 4 is computed for a water temperature of 380 F (200 psi) and can be used for any pressures normally encountered in locomotive practice. An increase of temperature to 600 F (1600 psi) would reduce the tabular values by 1000 Btu per sq ft per hr, which is negligible except for the lowest transmitting temperatures.

The Stefan-Boltzmann fourth-power relation is generally accepted as representative of radiation heat transfer and the factor 1600 has been found to give satisfactory results for the conditions encountered in locomotive fireboxes.

Fig. 5 has been plotted to answer graphically any question as to the mean equilibrium temperature for any combination of heat available and weight of gas per square foot of heating surface per hour.

In using Table 4 and Fig. 5, computations must be based not on total heat released, but on heat available, exclusive of the latent heat of the vapor. Usually the value given in the experimental data for heat released will be based on the upper calorific value of the fuel and will therefore include the heat involved in vaporizing the H_2O produced by combustion. The latent heat of this vapor is not available for radiation and is not included in the values for gas-carried heat in Table 4. It must therefore be deducted from the heat released to find the "heat available." Each pound of hydrogen burned produces 9 lb of vapor which will account for 8730 Btu of latent heat. Consequently, for each per cent of hydrogen in the fuel, 87.3 Btu must be deducted from the total heat released per pound of fuel to find the "net available heat" to be used in computing the equilibrium temperature.

For example, in test No. 1439 in Series A with 288 lb of gas pro-

[a] If the temperature of the receiving surface is increased to 600 F, the tabulated figures should be reduced by 1000 Btu.

NOTE: The "radiation factor" represents, for each temperature, the rate at which heat measured in Btu per hour is taken up by each square foot of firebox surface.

The "heat-content factor" gives the amount of sensible heat carried by each pound of the mixed gases of combustion. Latent heat is not included.

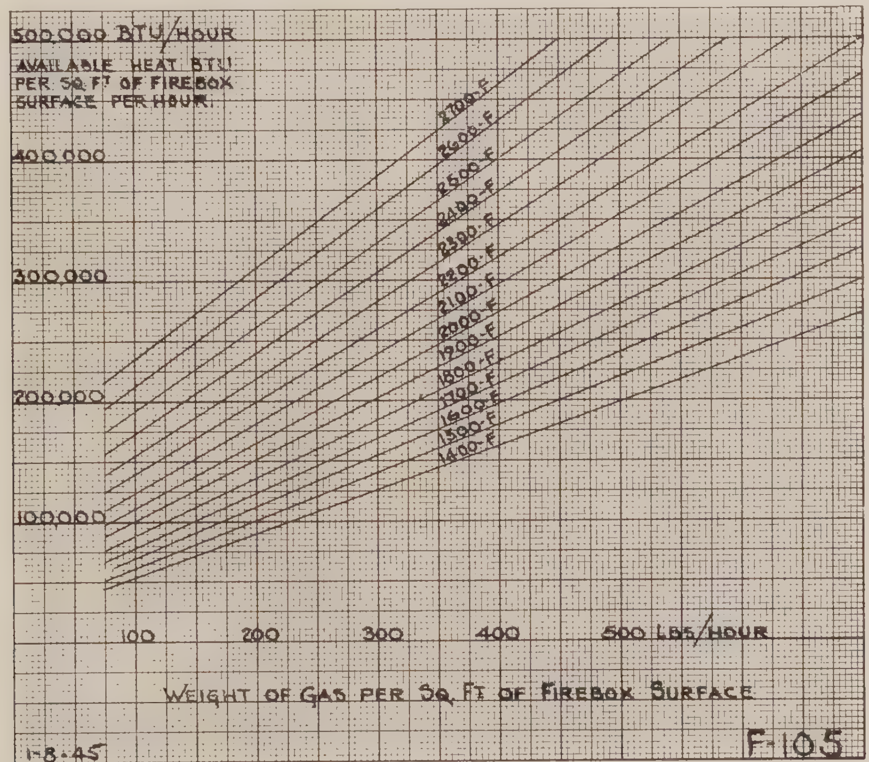

FIG. 5 EQUILIBRIUM TEMPERATURE IN RELATION TO HEAT AVAILABLE AND WEIGHT OF GAS

duced and 271,000 Btu released per sq ft of firebox heating surface per hr, the latent heat accounts for 13,000 Btu per sq ft per hr, leaving 258,000 Btu available. Inspection of Fig. 5, followed by check with Table 4, shows that at a temperature of 2230 F the heat released per hour per square foot of firebox surface will be accounted for as follows:

	Btu
Heat radiated at 2230 F	83000
Sensible heat in 288 lb of gas at 612 Btu per lb	175000
Heat available	258000
Latent heat	13000
Heat released	271000

On this basis the mean equilibrium temperature is taken to be 2230 F. It may be noted that the experimental data and the type of computation do not justify an attempt to determine the equilibrium temperature to a value closer than the nearest 10 deg F.

In test No. 1439 just quoted, the measured firebox temperatures were 2566 F at the center and 1858 F at the flue sheet. On the basis of radiation proportional to the fourth power of the absolute temperature, the mean between 2566 F and 1858 F is 2280 F, which is close to the computed mean equilibrium temperature of 2230 F. The measured values for the firebox temperatures are not sufficiently reliable to allow any final conclusions to be drawn, but it is of interest to note that where the measured values seem to be most consistent there is quite close agreement between the mean fourth-power absolute temperature and the computed equilibrium temperature. This supports the view that radiation at the mean equilibrium temperature, as given in Table 4, corresponds to the heat actually taken up by the firebox. It should be noted that the drop in firebox temperature between center and flue sheet is not due in any large degree to transfer of heat by convection. The hydraulic depth of the firebox is too large to provide any effective rate of heat transfer. The lower final temperature is due to the lower rate of heat release. With a firing rate of 100 lb of dry coal per hr, the hourly supply of combustible may be represented by 78 lb of carbon, 5 lb of hydrogen, and 248 lb of oxygen. These combustible elements are diluted by 920 lb, which is 2.8 times their weight, of inert nitrogen. As they pass through the firebox they combine until when the flue sheet is reached the combustible elements may be reduced to 16 lb of carbon and 63 lb of oxygen, diluted by 14 times their weight of inert gas consisting of nitrogen and the products of combustion. It is obvious that as these final conditions are approached the rate of heat release will be much slower than that at the center of the firebox.

Heat Transfer by Convection in Flue Bundle

The heat taken up by the flues from the gases of combustion as they pass from firebox to smokebox is found by computing the drop in temperature of the gases. The double logarithmic formula shown as Equation [2] is used for this purpose.

This form of equation, by which heat transfer is measured in temperature drop and not by the rate of transfer per square foot of surface per degree of temperature difference per hour, is due to Fessenden (1, 3, 4) who showed that it could be applied to represent satisfactorily a variety of experimental data. The author has carried the application a step further and shown (2, 5) that if the coefficient M were related to the rate of gas flow and to the hydraulic depth of the flue by Equations [3], [4a], and [4b], given later in this paper, the formula had a remarkably wide range of usefulness. It has been shown to be applicable to flues ranging in diameter from $^1/_2$ in. to 4 in. and of circular and of annular cross section, with gas temperatures ranging from room temperature up to 2500 F, and with heat transmission either from a hot gas to a cooler liquid surrounding the flue or to a cooler gas from a hot liquid. As the formula covers a broad territory with an accuracy sufficient for all practical purposes, it has useful possibilities even if its pedigree is not entirely unimpeachable from the standpoint of theoretical physics.

Fessenden pointed out that the real justification of the formula rests not so much upon the rationality of its development, as upon the manner in which it satisfies the experimental data gathered from many different sources. The fundamental assumption leading to Equation [2] might be stated in a number of ways, but the simplest is that the loss of heat from an element of gas passing along a tube takes place in accordance with the exponential formula for a damped process. This leads to the equation

$$dQ = C \cdot e^{-m.x} \qquad [1]$$

where

dQ is heat lost by element of gas traversing flue length x.

Hedrick and Fessenden (1) show that this can be developed into the form

$$\text{lolog } (T_2/t) = \text{lolog } (T_1/t) - M_x \qquad [2]$$

where

lolog means "the logarithm of the logarithm of"
T_1 is absolute equilibrium temperature in degrees Rankine
T_2 is absolute smokebox temperature in degrees Rankine
t is absolute mean effective temperature of receiving surface in degrees Rankine
x is length of flues in feet
M is coefficient depending only on mean hydraulic depth of tube bundle and on rate of gas flow per inch of perimeter of receiving surface

Using data from many sources, the author has found that the coefficient M is linked with the rate of gas flow and with the flue dimensions by the equation

$$\log M = B - m \log W/p \qquad [3]$$

where

W is total weight of gases of combustion in pounds per hour
p is total perimeter of receiving surface, including flues, tubes and superheater pipes, in inches

The auxiliary coefficients B and m depend only upon the ratio of (p), the gas-swept perimeter of the flue through which the gas flows to (a), the free area of this flue. The ratio of perimeter to area is of course the reciprocal of the hydraulic depth. It has been used as a parameter instead of the hydraulic depth because it varies in the same direction as the heat-absorbing value of a flue. A high value of the p/a ratio corresponds to a flue with a high capacity for heat absorption.

With values of p in inches and of a in square inches, values of the coefficients B and m, corresponding to the various values of the ratio p/a, are given in Table 5. These values are derived from the equations

$$\log (B - 1.3) = 9.384 - 0.54 \log (p/a) \qquad [4a]$$

$$\log m = 9.583 - 0.37 \log (p/a) \qquad [4b]$$

Equation [2] involves t the absolute temperature of the receiving surface of the flue. Experience shows that for work with locomotive boilers a satisfactory mean value can be obtained by adding to the mean value of the steam or water surface of the flue a differential which varies with the heat offered per linear inch of the gas-swept perimeter of the flue, as shown in Fig. 6.

In the case of the evaporative surface of the flues, the water temperature is that of the saturated steam. In the superheater the steam temperature varies from saturated to the final superheat, and for the whole superheater surface an arithmetic mean may be taken. When evaporative and superheater surfaces are taken together a weighted mean is taken, allowing for the surface and temperature of both surfaces. In the present work both surfaces have been taken together and only the final smokebox temperature has been computed. The earlier paper referred to shows that the equations can be applied to the evaporative and superheating surfaces separately and a step-by-step computation used to find the progressive temperature drop along the flue, and to determine separately the respective amounts of heat taken up by the evaporative and by the superheating surface.

The smokebox temperatures reported in Table 2 have been obtained by taking the combined perimeter and area and the mean temperature for evaporative and superheating surface, and by assuming that the gases entered the flues at the equilibrium temperature. Agreement between the computed and the measured values meets practical requirements.

The widest deviation is found in test No. 13 F, Series B, with a smokebox temperature of 620 F computed and 693 F measured. This represents a difference of 19 Btu of sensible heat per lb of gas, and as the gas flow is 374 lb for a heat release of 394,000 Btu per hr per sq ft of firebox surface, the difference amounts to 1.8 per cent of the heat released. This is hardly greater than the factor of uncertainty in the measured values. Agreement in the three other series of tests is considerably closer so it is felt that the proposed method can be used with confidence in predicting the over-all heat-absorbing capacity of a locomotive boiler. It should be noted that in the computation the gases of combustion are assumed to leave the firebox and to enter the flues at the equilibrium temperature, while in reality the gases at the flue sheet are probably from 100 to 200 deg F below the equilibrium temperature. The justification for this is that the formula as set up gives satisfactory results and that, in estimating the heat transfer, the equilibrium temperature can be computed while the actual flue-sheet temperature is not known.

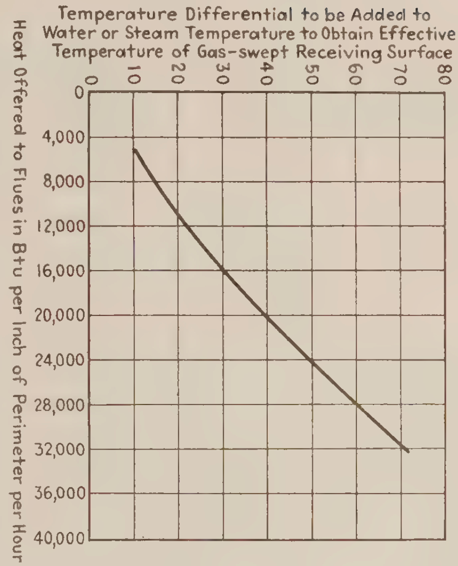

FIG. 6 TEMPERATURE DIFFERENTIAL FOR FULL LENGTH FLUES

If a close study of the heat transfer in the flues were to be made, it would be desirable to adjust the differential given in Fig. 6, so that it would correspond to heat transfer from the exact initial flue-gas temperature. This would require an increase of about 60 per cent in the values of the temperature differential given in Fig. 6.

The Influence of Tube Shape on Heat-Transfer Coefficients in Air to Air Heat Exchangers

By F. H. Green[1] and L. S. King,[1] Los Angeles, Calif.

Heat-transfer coefficients are reported for air passing through round tubes, through partially flattened tubes, and through partially flattened tubes which have also been dimpled. It was found that flattened tubes maintained fully turbulent flow and, consequently, a higher heat-transfer coefficient at lower Reynolds number values than did round tubes. The addition of dimples to the flattened tubes maintained fully turbulent flow from the transition point and increased the heat-transfer coefficient substantially. The addition of the dimples also improved the relation between heat transfer and pressure drop in the flattened tubes.

Nomenclature

The following nomenclature is used in the paper:

A = tube internal cross section area, sq ft
A_i = total area of inside surface of tubes in unit, sq ft
A_0 = total area of outside surface of tubes in unit, sq ft
D_H = hydraulic diameter, ft
D_0 = outside diameter of tube, ft
E_i = effectiveness on air inside tubes $= \dfrac{t_1 - t_2}{t_1 - t_3}$
E_0 = effectiveness on air outside tubes $= \dfrac{t_4 - t_3}{t_1 - t_3}$
G = mass velocity, lb/(hr)(sq ft)
h_i = coefficient of heat transfer inside tubes, Btu/(hr)(sq ft)(deg F)
h_0 = coefficient of heat transfer outside tubes, Btu/(hr)(sq ft)(deg F)
i_1 = enthalpy of steam, Btu per lb
i_2 = enthalpy of condensate, Btu per lb
k = thermal conductivity of fluid, Btu/(hr)(sq ft)(deg F per ft)
L = length of tube or tube section, ft
$\mathbf{N}$ = Nusselt number $= \dfrac{hD_H}{k_{avg}}$
$\mathbf{R}$ = Reynolds number $= \dfrac{D_H\, G_{max}}{\mu_{avg}}$
$\sigma \Delta P$ = air pressure drop corrected to standard conditions at center of unit, in. H_2O
q = rate of heat transfer, Btu per min
T = absolute temperature, deg F + 460
Δt = temperature change, deg F
Δt_m = log-mean temperature difference, deg F
t_1 = inlet temperature of air inside tubes, deg F
t_2 = outlet temperature of air inside tubes, deg F
t_3 = inlet temperature of air outside tubes, deg F
t_4 = outlet temperature of air outside tubes, deg F
U = over-all heat-transfer coefficient, Btu/(hr)(sq ft) (deg F)
w_a = mass rate of air flow, lb per min
w_s = mass rate of steam flow, lb per min
μ = absolute viscosity, lb/(hr)(ft)

Introduction

Aircraft-engine supercharger intercoolers are designed to reduce the temperature of the air leaving the supercharger before it enters the carburetor. These intercoolers use cooling air obtained from the outside air and forced through the intercooler by the ram pressure created by the forward motion of the airplane. The first units manufactured by the authors' company were constructed with round aluminum tubes about $^1/_4$ in. diam with the supercharged air flowing through the tubes while the cooling air flowed across the tubes. This type is satisfactory, however, only for certain limited types of installations. In order to maintain a sufficient temperature difference between the average cooling air and the average supercharged air, it is necessary to have a fairly high rate of flow of cooling air. The actual amount of cooling air required for a given intercooler effectiveness of course depends also on the over-all heat-transfer coefficient. However, at high air flows, the pressure drop outside the tubes becomes excessive in a round-tube unit. Since the drag imposed on the airplane by the intercooler is a function of the product of the pressure drop of the cooling air by the amount of cooling air required and since the drag which is required for operating the intercooler increases substantially at high altitudes, it became necessary to develop an improved form of low-drag intercooler for modern high-altitude high-speed airplanes.

The first step in this development was to partially flatten the tubes so that their axes would be parallel to the cooling-air-flow direction. This permitted a greater flow of cooling air at the same pressure drop and reduced the cooling-air drag. Although the outside film coefficient was probably reduced in many cases, the inside coefficient, which with round tubes had been smaller than the outside coefficient, was raised by the decrease in the internal cross section of the tube. The net result was an increase in over-all heat-transfer coefficient for a given horsepower without reduction in surface per tube. Also, flattening the tubes allowed them to be placed closer together, thus forming a lighter-weight and more compact unit.

In an attempt to reduce still further the cooling-air drag horsepower, the flattened tubes were dimpled with small creases about $^1/_2$ in. apart running crosswise on the flattened portion of the tubes. At the same time, the outside dimension perpendicular to the flattened portion of the tube was increased to avoid increasing the pressure drop of the supercharged air inside the tubes too greatly by the introduction of the dimples.

The net result of this dimpling was greater than anticipated. In one typical case the cooling-air flow was reduced 30 per cent at an increase in pressure drop of only 25 per cent, resulting in a net saving of 12.5 per cent in horsepower required. Since the reduced cooling-air flow required resulted in a log-mean temperature difference only 87 per cent as great as before, it was apparent that this change had made a substantial increase in heat-transfer coefficient, most of which was estimated to be an increase in the coefficient for the air flowing inside the tube, since the air flow

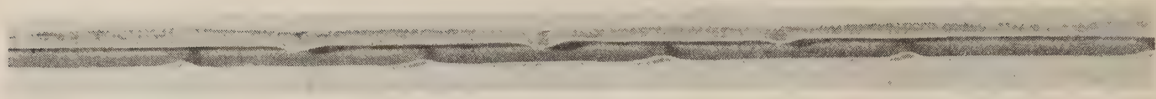

Fig. 1 Longitudinal Cross Section of Dimpled Tube

outside had been reduced. The tests to be described were performed in an attempt to obtain information which would correlate these results with the usual methods of computing heat-transfer coefficients.

Apparatus Used in Tests

The apparatus tested consisted of three tubular-type aircraft-engine intercoolers of approximately the same external dimensions. One unit was constructed with round tubes, one with partially flattened tubes, and one with partially flattened and dimpled tubes. The flattened and flattened dimpled tubes had the same flattening dimension and were placed with a no-flow clearance or cooling-air passage which was the same clearance as the diagonal clearance used in the round-tube unit. Major dimensions of the test units are given in Table 1. A longitudinal cross section of a portion of a dimpled tube is shown in Fig. 1.

TABLE 1 MAJOR DIMENSIONS OF TEST UNITS

	Round	Flattened	Dimpled
Tube length, net, in.	12	12	12
Tube outside diameter at headers, in.	0.247	0.247	0.247
Dimension perpendicular to flats, in.	....	0.1215	0.1215
Depth of dimple, in.	....	....	0.030
Dimple spacing, in.	....	....	0.5
Minimum space outside tubes, in.	0.0885	0.0885	0.0885
Hydraulic diameter inside, ft	0.0192	0.0136	0.0105
Hydraulic diameter outside, ft	0.0144	0.0144	0.0144
Number of active tubes	567	659	652
Surface area inside tubes, sq ft	34.3	39.8	39.4
Surface area outside tubes, sq ft	36.7	42.6	42.1

For the first tests the units were mounted as shown in Figs. 2 and 3, with air being blown through the tubes while steam condensed around the tubes. The steam was fed at low pressure and slightly superheated to provide complete dryness and allow determination of its enthalpy from measurements of temperature and pressure alone. A small portion of the steam was bled off the bell at the bottom of the unit in order to keep a steady flow of steam past the tubes and prevent the accumulation of water in the lower passages. The condensate ran to a pipe coil in which it was subcooled slightly and then passed to the weighing bucket. A sight glass was used to keep a constant water level in the lower part of the apparatus and thus prevent loss of steam. The inlet steam temperature and pressure were measured with a mercury-in-glass thermometer and a mercury manometer.

The air inlet temperature was measured with two thermometers in the inlet duct just ahead of the unit. The outlet temperature was measured with four thermometers in the outlet duct just beyond the unit. The outlet air temperature was also measured after the air had passed through a baffled mixing box. It was found that when the temperature at the outlet of the mixing box was corrected for the experimentally determined drop of temperature in the mixing box, this corrected temperature agreed very well with the average of the four outlet thermometers placed immediately after the unit.

Most of the air flows were measured with a flat-plate sharp-edged orifice in a duct following the mixing box. The largest air flows were computed from the pressure drop across the unit under test by extrapolation of the pressure drop versus flow curve drawn from the runs where the flow was determined by the orifice. The apparatus was thoroughly insulated with glass wool at all parts where needed.

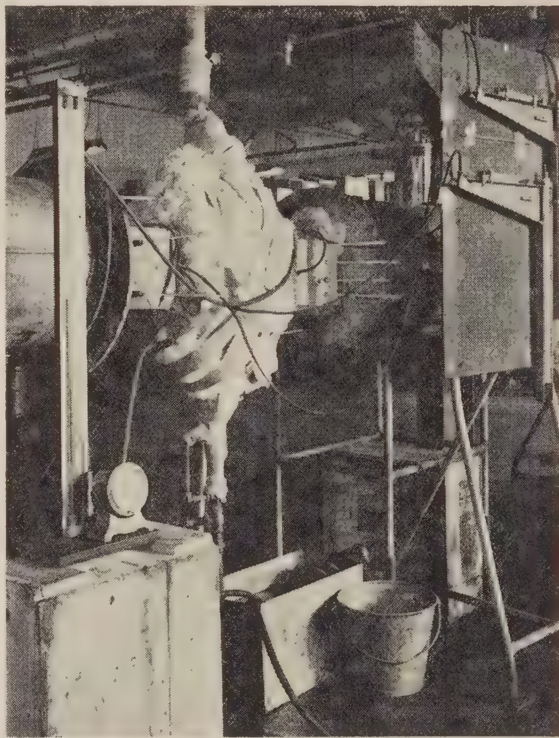

Fig. 2 Setup for Steam-Air Test

For the other series of tests the units were mounted as shown in Fig. 4. Hot air was used inside the tubes while room-temperature air was passed outside the tubes. Inlet air temperatures were measured with one thermometer on the cooling-air side and with three thermometers on the hot-air side. Outlet air temperatures were measured after the air had passed through the mixing boxes, and the temperatures were corrected for the known loss in the boxes. The air flows were measured with orifice plates for the lower air flows and were determined from unit pressure drops for the higher air flows. Because of the relatively high resistance of the unit as compared with that of the duct, a uniform flow distribution was obtained in both the cooling air and the hot paths.

Experimental Procedure

The first series of tests was run to determine the heat-transfer coefficient to air passing inside the tubes. Each of the three units was treated in the same manner. Air was passed through the tubes at a range of velocity to give values of **R** ranging from approximately 1400 to the highest available with the fan used as shown in Table 2. Steam was supplied to the unit under approximately 2 psig pressure and with approximately 10 deg F superheat. The air flow and steam temperature and pressure were kept constant within very close limits, and the system was allowed to balance thoroughly before readings were taken. Readings of all quantities except condensate flow rate were then

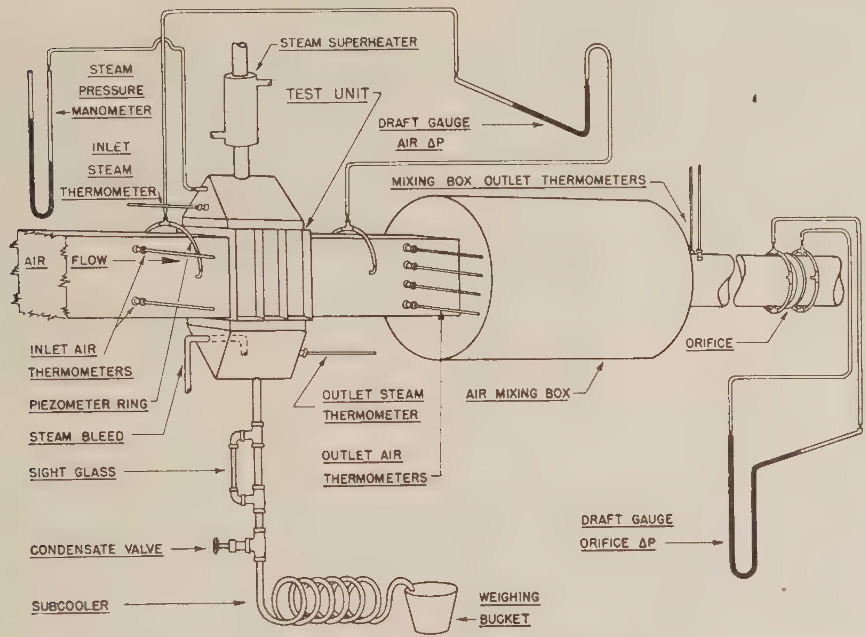

Fig. 3 Setup for Steam-Air Test

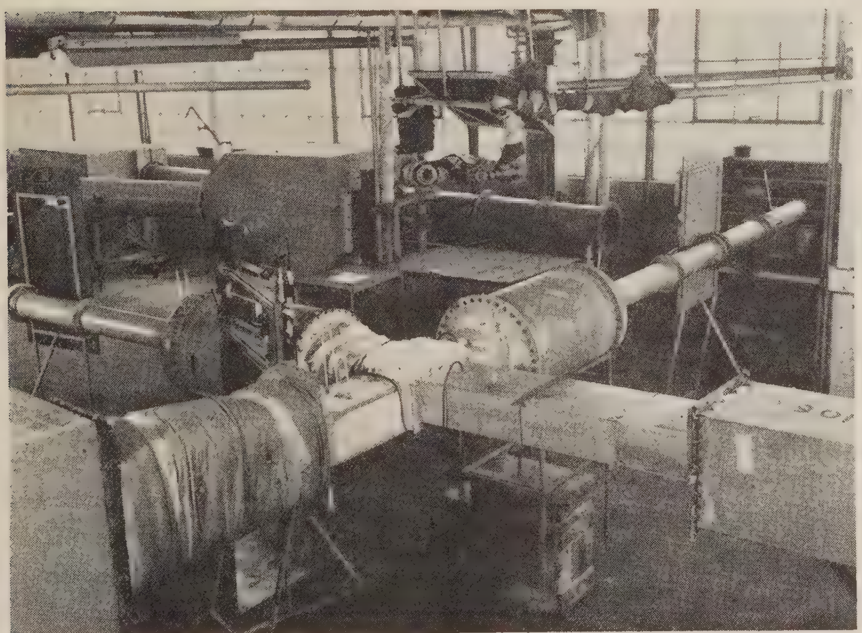

Fig. 4 Setup for Air-Air Test

taken every 2 min for a period of 10 min. At the end of this period,the condensate was weighed. Since the condensate level was kept constant in the sight glass during the run, it was possible to determine from the amount of adjustment necessary in the condensate valve whether the condensate rate was constant. The heat balances obtained on the higher air-flow points show some discrepancies due to the necessity for bleeding steam from the outlet header at these points in order to keep the condensate blown off the tubes and to obtain the highest heat transfer to the air inside the tubes. The extensive experience of the laboratory of the authors' company in measuring air heat gains and losses indicates that the errors involved in these measurements did not exceed 3 per cent. For this reason, all computations of heat-transfer coefficients have been based on the air-side heat gains.

To determine heat-transfer coefficients to air outside the tubes, the units were operated as intercoolers with hot air inside the tubes and cool air outside the tubes. The air flows were varied throughout the range of the apparatus as shown in Table 2. The flows were maintained until steady conditions were observed at all points and then all instruments were read as rapidly as possible by three observers. This procedure was repeated until there were two sets of readings at each point which agreed within an effectiveness of 0.01 with each other. At least 30 such points were taken on each unit.

Method of Calculation

In the steam test the enthalpy of the entering steam was determined from the readings of temperature and pressure by reference to the steam tables (1).[2] It was assumed that the tube-wall temperature would be the same as the condensing temperature of the steam. This assumption probably leads to much less error than would have been introduced if thermocouples had been used to determine tube-wall temperatures in the small thin-wall tubes. The enthalpy of the condensate was determined from the condensing temperature of the steam and the steam tables. By experiment it was determined that the heat loss through the insulation of the unit in the steam tests was approximately 7 Btu per min, therefore the net heat loss of the steam was determined as

$$q = w_s(i_1 - i_2 - 7) \qquad [1]$$

Air inlet and outlet temperatures were computed by taking the arithmetic average of the respective thermometer readings. Air flows were determined from pressure-drop and temperature readings at the orifice and were computed from graphs based on reference (2). The air-side heat gained was therefore

$$q = 0.244\, w_a \Delta t \qquad [2]$$

The over-all heat-transfer coefficient U was determined from the inside surface area of the tubes, from the log-mean temperature difference based on the condensing temperature of steam at the observed pressure and the inlet- and outlet-air temperatures and from the air-side heat gain as determined from Equation [2]. The over-all heat-transfer coefficient was therefore

$$U = \frac{60\, q}{A_i \times \Delta T_m} \qquad [3]$$

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

Since the steam-side coefficient was probably of the order of 2000 Btu/(hr)(sq ft)(deg F) very slight error was introduced by assuming that the air-side coefficient was equal to the over-all coefficient. Also this error had the effect of giving a slightly lower inside coefficient which was desirable for design purposes. A plot of the air-side coefficient inside the tubes of the three units versus Reynolds number is shown in Fig. 5. A plot of the Nusselt number versus Reynolds number for the three units is shown in Fig. 6. In computing Reynolds number and Nusselt number the hydraulic diameters were based on the minimum cross section of the tube, that is, in the dimpled-tube unit the

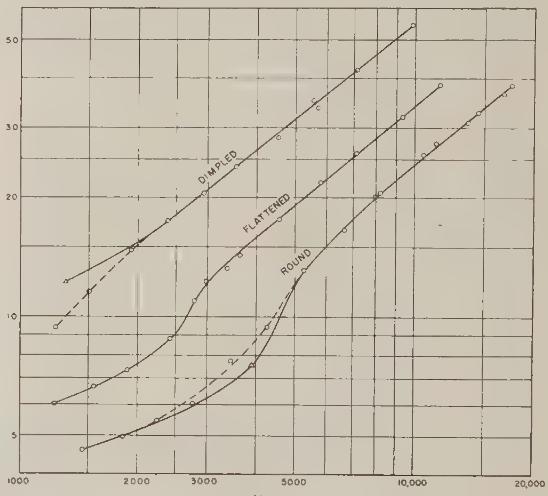

Fig. 5 Comparison of Experimental Heat-Transfer Coefficients for Air Inside Tubes

(Dashed lines show steam-air test results which were modified by air-air test results shown by triangles.)

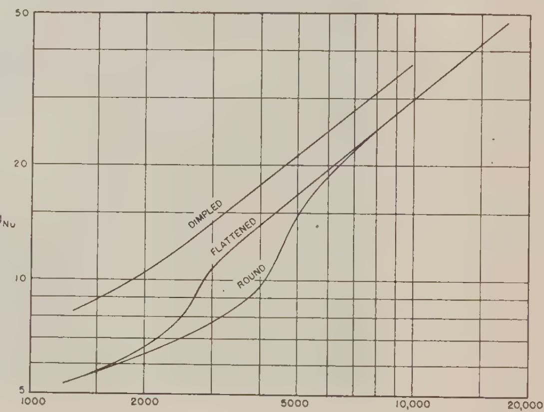

Fig. 6 Comparison of Experimental Values of Nusselt Number for Air Inside Tubes

internal cross section was determined under the dimple. The hydraulic diameter was then computed as

$$D_H = \frac{4A}{P} \qquad [4]$$

The mass velocity G was computed from the same minimum cross section and the conductivity and viscosity of the air were taken as 0.0155 Btu/(hr)(sq ft)(deg F/ft) and 0.047 lb/(hr)(sq ft), respectively, at an assumed average temperature of 140 F.

In the intercooler test the air temperatures and air flows were measured in the same manner as in the steam test. The air heat gains and losses were also determined in a similar manner in order to check the heat balance. The over-all heat-transfer coefficient in the intercooler test was determined from the log-mean temperature difference corrected for crossflow (4). The amount of heat transfer was assumed to be the average of the computed heat gained and heat lost. The surface area used was the average of the internal and external surfaces. The external heat-transfer coefficients were then determined from the following equation

$$\frac{1}{h_0 A_0} = \frac{2}{U(A_i + A_0)} - \frac{1}{h_i A_i} \qquad [5]$$

These outside coefficients are plotted in Figs. 7 and 8.

Correlation of Test Results

Fig. 6, which shows Nusselt number versus Reynolds number for flow inside the tubes, indicates that for the round tubes fully turbulent flow is not established until the Reynolds number

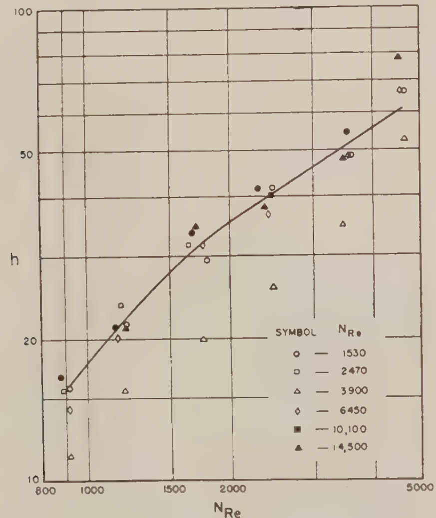

Fig. 7 Experimental Heat-Transfer Coefficients for Air Outside Round Tubes, Showing Results With Various Values of Reynolds Number Inside the Tubes

reaches 8000 and that laminar flow appears to continue up to a Reynolds number of about 2500. In contrast, it is noted that turbulent flow in the flattened tubes starts at approximately 3500 Reynolds number. The dimpled tubes appear to maintain fully turbulent flow from a Reynolds number of 2000.

The graph shows good correlation between the round tubes and flattened tubes tested in both the fully turbulent and fully laminar flow regions. This curve lies only slightly below the average curve given by McAdams (3). The position of this curve seems confirmed by other experiments with very small hydraulic diameters (5).

Both the dimpled-tube curve and the common curve for round and flattened tubes have approximately the same slope in the fully turbulent-flow regions, namely, 0.82.

It will be noted that the curve for dimpled tubes lies 26 per cent above the curve for flattened tubes. A suggested explanation of this is as follows:

Schack (6) states that the heat-transfer coefficient should vary with the length of the pipe, the exponent expressing this variation being —0.05. A recalculation of his figures shows that this exponent should have been stated as —0.07. Now, a dimpled tube might be considered as consisting of a series of short tubes with a new one starting at each dimple. Since, in the unit tested there are 21 dimples per tube, therefore 22 short tubes are represented. The Nusselt number for the dimpled-tube unit was found to be 26 per cent higher than for nondimpled tubes, thus

$$\left(\frac{1}{22}\right)^n = 1.26 \qquad [6]$$

where n is the exponent expressing the effect of tube length. Solving, n equals —0.07 which checks with the recalculation of Schack's result. Thus a logical justification may be established for use of the minimum cross-sectional area in determination of hydraulic diameter and mass velocity in dimpled tubes.

Fig. 5 shows the film coefficient inside the tubes for all three units. In drawing Fig. 6, the lines in Fig. 5 which pass through the points marked by triangles were used to determine the Nusselt number. The method of obtaining these points is explained as follows:

Fig. 7 shows the heat-transfer coefficients outside of round tubes. In this plot Reynolds number has been based on the hydraulic diameter of the diagonal passes between the tubes instead of on the tube diameter, in order to provide a more direct comparison with the results of the tests on the dimpled-tube unit in which the Reynolds number is also based on the passage available. It may be noted that the points plotted for a value of **R** of 3900 inside the tubes fall consistently below the average of all the other test points. It was therefore assumed that the steam-test points at values of **R** of 3450 and 4300 inside the tubes were in error since these were based on two runs, whereas the intercooler result is based on ten runs. By assuming outside coefficients at each of the cooling-air flows as read from the average line in Fig. 7, the inside coefficients were recalculated and averaged, and this average was plotted as the intercooler test point at a value of **R** of 3900 shown in Fig. 5. The same procedure was used in obtaining the intercooler test

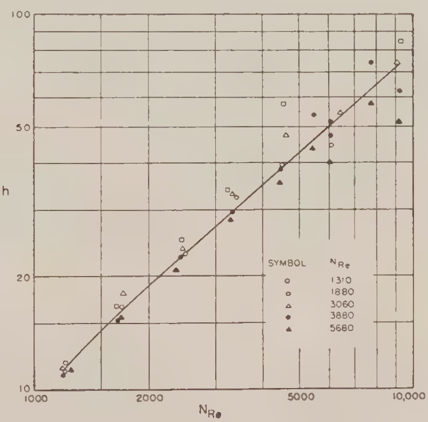

Fig. 8 Experimental Heat-Transfer Coefficients for Air Outside Dimpled Tubes, Showing Results With Various Values of Reynolds Number Inside the Tubes

point for the dimpled-tube unit shown at a value of **R** of 1300 in Fig. 5.

For heat-transfer coefficients outside round tubes, Fig. 7, extrapolation of Grimison's (7) values gives the following estimated equation for a no-flow spacing of 2.4 D_0 and a cooling-air spacing of 0.6 D_0 as used in the test unit

$$h = \frac{0.296\, k\, G_{max}^{0.61}}{\mu^{0.61}\, D_0^{0.39}} \qquad [7]$$

The test results in Fig. 7 average 27 per cent above the values given by Equation [7] in the region where **R** is greater than 2000.

Fig. 8 shows heat-transfer coefficients versus Reynolds number for air outside the dimpled-tube unit. In this case the arrangement of the dimpled tubes is such that an approximately straight passage of rectangular cross section is provided for air outside the tubes. The hydraulic diameter of this passage was determined from Equation [4]. It will be noted that the slope of the line in the turbulent-flow region is approximately 0.8 as compared to a slope of approximately 0.6 with the round-tube unit. This would seem to indicate that with this type of construction heat-transfer coefficients outside the tubes should be computed on the same basis as for flow inside the tubes.

There is seen to be a rather large spread of points in the higher values of **R** in Fig. 8. However, this spread does not indicate a very large experimental error. If heat-transfer coefficients outside the tubes are read from the curve in Fig. 8, and heat-transfer coefficients inside the tubes are read from Fig. 5, and the over-all coefficient U is computed for each of the test points, it is found that the computed U has an average variation of ± 5 per cent from the values of U obtained in the intercooler test. It is probable that these coefficients for air outside dimpled tubes are too high and it is hoped that further work can be done on this subject.

Fig. 9 shows heat-transfer coefficients inside the tubes plotted against the air pressure drop corrected to a standard density of 0.07651 pcf at the center of the unit. This air pressure drop is

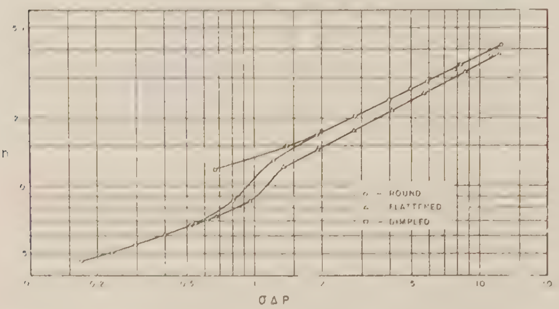

Fig. 9 Comparison of Experimental Heat-Transfer Coefficients and Pressure Drop for Air Inside Tubes

the over-all pressure drop as measured by static fittings located on the sides of the ducts 4 in. upstream and 4 in. downstream of the test unit, as shown in Fig. 3.

Conclusions

1 The transition from laminar to turbulent flow extends over the range **R** = 2000 to **R** = 8000 for small round tubes. If the tubes are flattened the transition region extends only from **R** = 2000 to **R** = 3500 while if the flattened tubes are dimpled the transition takes place at **R** = 2000.

2 For any given Reynolds number, flattening a round tube increases the heat-transfer coefficient substantially, while dim-

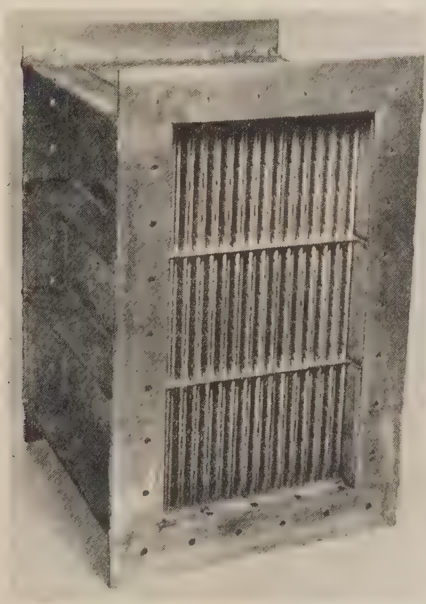

FIG. 10 TEST UNIT WITH DIMPLED TUBES

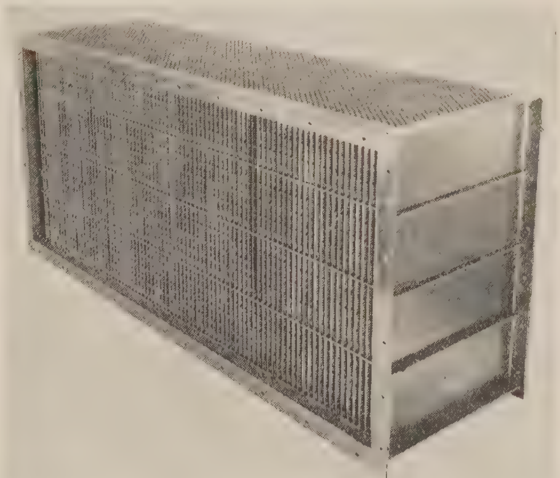

FIG. 11 LARGE AIRCRAFT INTERCOOLER WITH DIMPLED TUBES

pling the flattened tube increases the heat-transfer coefficient to an even higher value. This statement also applies to equal weight flows of air, since the Reynolds number for a tube of given perimeter at a given weight flow is not varied by flattening the tube or by dimpling it.

3 For the same air-pressure drop, dimpled tubes have the same or higher heat-transfer coefficient than round tubes, while plain flattened tubes have a lower heat-transfer coefficient, except at very low air-pressure drops.

4 The use of dimpled tubes in intercoolers permits a reduction in the amount of cooling air required and therefore leads to a lower drag on the airplane.

Acknowledgments

The authors express their appreciation to Mr. Robert W. Wagner and Mr. Harry H. Beckwith of their company for assistance in the performance of the tests and in the compilation of the report.

Heat Transfer From a Cylindrical Surface to Air in Parallel Flow With and Without Unheated Starting Sections[1]

By MAX JAKOB[2] and W. M. DOW,[3] CHICAGO, ILL.

The present investigation sponsored by the Illinois Institute of Technology, Armour Research Foundation, and Institute of Gas Technology, deals with the heat transfer of air in parallel flow to a surface, a process of great practical importance which, for instance, occurs with all kinds of fins or on the skin of an airplane in flight. Previous knowledge of that process was based on a few sets of experiments which were performed with plane surfaces and led to a considerably higher heat transfer than a reliable theory, due to H. Latzko. In particular, the influence of nonheated starting sections seemed to require a new investigation. Compared with the use of plane plates by previous investigators, the use of an electrically heated cylindrical specimen has the following advantages: A cylinder can be easily placed in the center of an air jet and is free of the edge losses of a plate; for both reasons, air jets of moderate diameter can be used. Uniform heating is easier to provide, heat losses to the back are easier to control, and noses of different shape and cylindrical starting sections can readily be used for studying the behavior of the so-called boundary layer of the fluid which is developing along the surface, first streamlined and then turbulent, and in which all resistance against heat transfer is concentrated. The experiments were performed with specimens of 1.3 in. diam and 9 to 20 in. total length, the ratio of the heated length to the total length being varied from 40 to 90 per cent. Spherical, ellipsoidal, and conical nosepieces were used. The air velocity was varied from 10 to 150 fps and it is assumed that the results can be theoretically extrapolated above sound velocity, using the principle of similarity.

Nomenclature

The following nomenclature is used in the paper:

A = area of heating surface, sq ft
b = thickness of boundary layer, ft
C, C_0, C_1, C_2, C_3 are constant factors
c_p = specific heat at constant pressure of air, B $\mathrm{lb_m}^{-1}$ F^{-1}
$F = N/M$ = correction factor
H = velocity head in feet of air, ft
H_w = velocity head, in. of water
h = coefficient of heat transfer by convection (mean taken over heating length, L_{th},) B hr^{-1} ft^{-2} F^{-1}
h_x = local coefficient of heat transfer by convection at distance x from leading edge, B hr^{-1} ft^{-2} F^{-1}
$h_{x,m}$ = mean of h_x, taken from $x = x_1$ to $x = x$, B hr^{-1} ft^{-2} F^{-1}
J = mechanical equivalent of heat, ft lb/B
k = thermal conductivity of air, B hr^{-1} ft^{-1} F^{-1}
L_{st} = hydrodynamic starting length, ft
L_{th} = thermal or heating length, ft
L_{tot} = total length, ft
M, N are integrals, defined in text, sq ft/sec
m and n are constant exponents
$N_{Nu} = \dfrac{hL_{tot}}{k}$ = Nusselt number (total mean)
$(N_{Nu})_{max}$ = Nusselt number, corresponding to q_{max}
$(N_{Nu})_{min}$ = Nusselt number, corresponding to q_{min}
$(N_{Nu})_0$ = Nusselt number for $L_{st}/L_{tot} = 0$
$(N_{Nu})_x = \dfrac{h_x x}{k}$ = local Nusselt number
$(N_{Nu})_{x,m} = \dfrac{h_{x,m} x}{k}$ = mean Nusselt number for distance x from leading edge
$N_{Nu}' = \dfrac{h(L_{tot} - x_0)}{k}$
$N_{Pr} = \dfrac{\rho c_p \nu}{k}$ = Prandtl number
$N_{Re} = \dfrac{v_a L_{tot}}{\nu}$ = Reynolds number with L_{tot} as characteristic length
$(N_{Re})_{cr}$ = critical Reynolds number
$(N_{Re})_x = \dfrac{v_a x}{\nu}$ = Reynolds number with x as characteristic length
$N_{Re}' = \dfrac{v_a(L_{tot} - x_0)}{\nu}$
$(N_{Re}')_x' = \dfrac{v_a x'}{\nu}$
q = rate of heat flow, B/hr
q' = rate of heat transferred by convection over length $x - x_1$ and unit width, B/hr
q_c = rate of heat transferred by convection from cylindrical surface, B/hr
q_i = rate of heat input, B/hr
q_l = sum of heat losses, B/hr
q_{max} = rate of heat transferred for certain values of L_{tot} and L_{st}, B/hr
q_{min} = rate of heat transferred for the same L_{tot}, but L_{st} = 0, B/hr

q_p = rate of heat transferred by convection from plane surface, B/hr
r = radius of cylinder, ft
t = air temperature at distance y from surface, °F
t_a = temperature of bulk of air stream, °F
t_f = $(t_a + t_s)/2$ = film temperature, °F
t_i = $t_a + \theta_i$ = impressed temperature of unheated surface, °F
t_s = average surface temperature, °F
v = air velocity at distance y from surface, ft/sec
v_a = velocity of bulk of fluid (air), ft/sec
v_b = air velocity at distance b from surface, ft/sec
W = width of flat surface, ft
x = distance from leading edge, general, ft
x_0 = distance from leading edge, defined by Fig. 1, ft
x_1 = L_{st} (see this symbol), ft
x_{cr} = distance from leading edge where critical Reynolds number occurs, ft
x' = $x - x_0$, ft
y = perpendicular distance from surface, ft
θ = $t - t_a$ = temperature excess at distance y from surface, F
θ_{ad} = temperature increment by frictionless adiabatic stopping of flow, F
θ_i = temperature increment by adiabatic stopping of flow, including effect of friction, F
θ_s = $t_s - t_a$ = temperature difference between heating surface and bulk of air stream, F
ν = kinematic viscosity of fluid (air) at bulk temperature t_a, sq ft/sec
ν_f = kinematic viscosity of air at film temperature t_f, sq ft/hr
ρ = density of air, lb_m/cu ft
$\varphi(N_{Pr})$ = function of N_{Pr}

Introduction

While the heat transfer between a cylindrical surface and a fluid has been abundantly studied for the flow in a tube and across a cylinder, no experiments seem to have been done for the parallel flow on the surface of a cylinder on the outside of a tube, and only a few sets of experiments have been performed concerning the free stream parallel to a plane heating surface. As a consequence, the numerous correlations of heat transfer for flow inside of tubes and channels and across cylinders have a much better foundation than the few correlations known for the flow parallel to a heating or cooling surface when the fluid is not bounded by the walls of a tube or channel.

The present experimental investigation was undertaken to secure and correlate data of heat transfer for this sort of flow, including transition-state conditions and the influence of hydrodynamic starting sections.

Referring to Fig. 1, it may be remembered that at the leading edge the fluid is suddenly caused to adhere to the solid surface. As a result a thin layer is formed in which the viscosity forces of the fluid bring about a change of velocity. As the stream moves over the surface, the retarding effect of the viscosity forces gradually penetrates deeper and deeper into the surrounding fluid so that the boundary layer increases in thickness. For some distance the flow in that layer is laminar; in a transition range it gradually becomes turbulent; in the turbulent stage, finally, the thickness of the layer increases more rapidly than it did in the laminar range. Within the boundary layer, however, still a very thin laminar film exists next the surface, being a permanent feature of any fully established flow.

The boundary layer of a free stream parallel to a surface can be characterized by a dimensionless Reynolds number xv_a/ν,

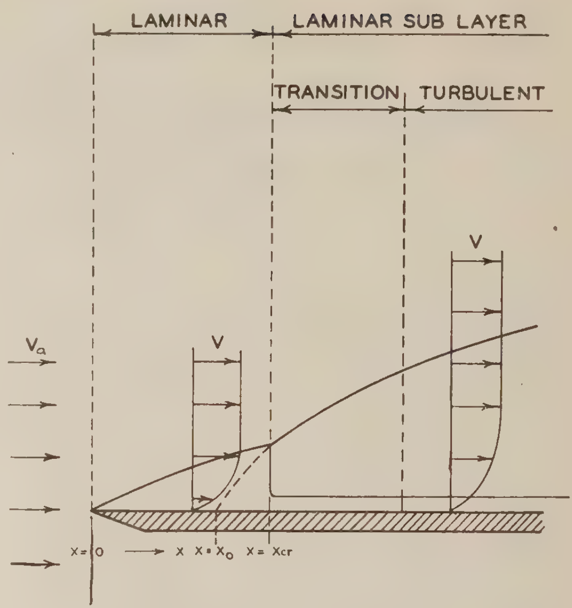

Fig. 1 Boundary-Layer Development Along a Flat Plate

where x is the distance from the leading edge ($x = 0$ in Fig. 1), v_a is the unaltered velocity, and ν is the kinematic viscosity of the fluid. The transition from laminar to turbulent flow is not sharp; it depends on original disturbances in the turbulent stream ahead of the surface, the shape of the leading edge, and the roughness of the surface. Critical Reynolds numbers, determining the place, $x = x_{cr}$, where laminar flow ceases in the layer, have been measured from 100,000 to 500,000, depending on the starting conditions, 300,000 being the ordinary value according to van der Hegge Zijnen (1)[4] and Hansen (2). With blunt leading edges, however, turbulent boundary layers have been obtained straight from the start (3),[5] $x = 0$.

Due to the well-known analogy between momentum transfer and heat transfer, the mode of heat transmission depends on whether the flow in the boundary layer is laminar or turbulent. A difference in the coefficient of heat transfer by convection can also be expected if heating does not begin at the leading edge, but is preceded by a hydrodynamic starting length. Whereas the development of the boundary layer and its effect on heat transfer will not necessarily be the same for cylindrical and plane surfaces, the difference will be considerable only if the radius of the surface curvature is relatively small (4).[6]

Considering the described features of flow and heat transfer along a surface, the objectives of the investigation are as follows:

1 To determine the heat transfer between a cylindrical surface and air in parallel flow, laminar or turbulent, under conditions where only a small influence of the surface curvature is to be expected.

2 To determine the effect of different hydrodynamic starting lengths on the heat-transfer coefficient.

3 To compare the results with theoretical and experimental results for plane surfaces reported in the literature.

Compared with the use of plane plates by previous investiga-

[4] Numbers in parentheses refer to the Bibliography at the end of the paper.

[6] Loc. cit., p. 249.

tors the use of a cylindrical specimen has the following advantages:

1 A cylinder can be easily placed in the center of an air jet without disturbing the uniform velocity field ahead of the apparatus.

2 With a plane plate, heat losses to the side have to be considered, and for this reason the plate must be rather wide. Such losses do not exist in a cylinder and therefore its diameter can be relatively small so that an air jet of moderate diameter can be used.

3 Uniform heating is easier to provide and losses to the backside of the heater are smaller and easier to control than with plane plates.

4 A cylindrical specimen is particularly convenient for studying the influence of the hydrodynamic starting length.

With these objectives and advantages in mind a cylindrical specimen was designed with an electric heating coil inside and thermocouples just below the outer surface to insure accurate temperature measurements without interference with the air stream. Wooden nosepieces of different shape and length served to close the upstream end of the specimen and to vary the hydrodynamic starting conditions.

In the experiments air was pressed through a channel by a blower and discharged by a nozzle into the room and against the nose of the specimen which was placed in the air stream with its axis parallel to the flow lines. Under these conditions the main air-stream velocity was measured with a Pitot tube; the heat input to the specimen was determined from the wattage of the heating coil by electric instruments; and the temperatures of the main air stream and the specimen surface were measured by thermocouples. These are the data necessary for calculating the coefficient of heat transfer by convection. Experimental runs were made at various velocities and under different hydrodynamic starting conditions. The results were correlated in graphs and formulas, discussed and compared with those of previous investigators.

Description of Apparatus

For the time being the experiments had to be restricted to one heating cylinder. In order that the results might be applicable to the case of a plane surface with reasonable approximation, a diameter of 1.3 in. seemed to be appropriate, considering the range of Reynolds numbers which could be covered by the experimental arrangement.

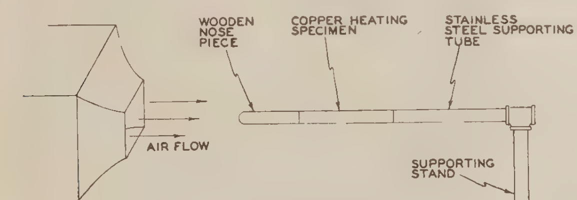

Fig. 2 General Arrangement of Apparatus

Fig. 2 is a self-explanatory sketch of the general setup of the apparatus. The nozzle indicated in this sketch had a square throat, 10 in. × 10 in. Details of the specimen with supporting assembly are given in Figs. 3 and 4. The main parts are a copper tube 8 in. long, 1.300 in. OD, 0.950 in. ID, and a stainless-steel tube 0.840 in. OD, 0.622 in. ID, on which nichrome wire, B and S gage No. 24 B (0.0201 in. diam) was wound. This heating coil was insulated by glass cloth and placed inside the copper tube.

Extreme care was taken to insure a smooth and continuous surface junction between the wooden nosepiece and the copper tube, as irregularities at this point would greatly influence the character of the boundary layer. The surface junctions were made with paper rings inserted in grooves as shown in Figs. 3 and 4. Melted paraffin was then painted on the junction and carefully scraped flush with the surface of the copper tube and the wooden nosepiece. A Pitot tube constructed according to Prandtl's design (5),[7] in connection with an inclined manometer, was provided for the velocity-head measurements.

All thermocouples used in the investigation were made of copper and constantan, B & S gage No. 28 (0.0126 in. diam). The cold junctions were placed in melting ice at 32 deg F. By means of a mercury-contact selector switch, each thermocouple could be connected to a Leeds and Northrup portable precision potentiomeeter which allowed readings of 0.001 mv.

One thermocouple served to the measurement of the air-flow temperature. It was inserted into a $^1/_8$-in-diam copper tube which was placed parallel to the air flow for a distance of 2 in. and was sealed at the upstream end.

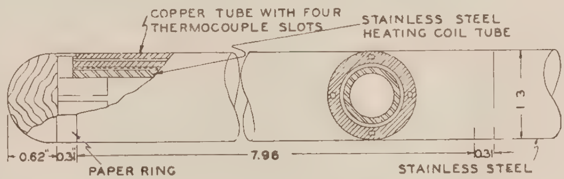

Fig. 3 Details of Copper Heating Specimen

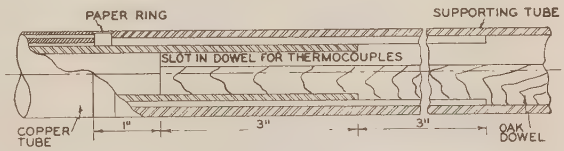

Fig. 4 Details of Supporting Assembly

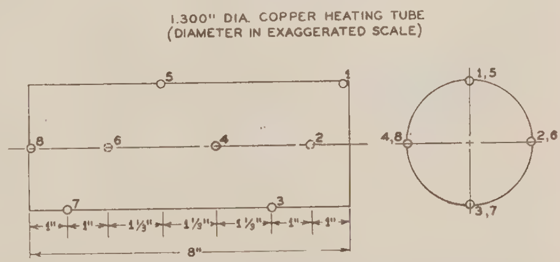

Fig. 5 Locations of Surface Thermocouples in Copper Heating Specimen

In order to avoid disturbances on the surface, the eight thermocouples serving for the measurement of the surface temperature were placed in, and brought out axially through four slots of square cross section (0.080 in. side length) in the wall of the heating tube as shown in Fig. 3. The thermocouples fitted snugly in the axial slots but were removable for ease of calibration and manipulation. Locations of the hot joints of the thermocouples are shown in Fig. 5.

Thermocouples for secondary temperature measurements were placed in the wooden nosepieces, Fig. 6, and on the rear part of the heating-coil tube, Fig. 7. Each of the latter thermocouples was wrapped around the tube once so that the wires were in an

[7] Loc. cit., p. 170.

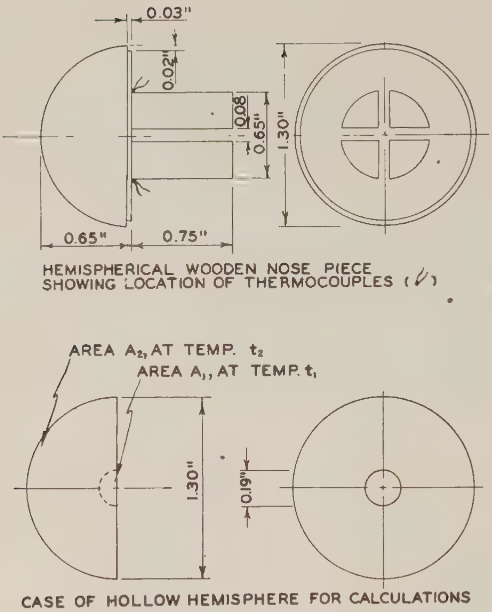

Fig. 6 Hemispherical Wooden Nose Piece

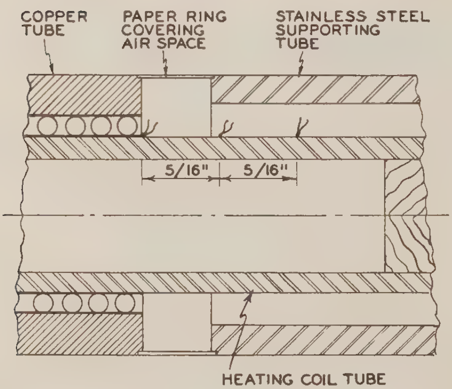

Fig. 7 Location of Thermocouple on Heating Coil Tube

isothermal zone for about 1 in. from the joint. The purpose of these thermocouples will be explained in the following section.

A hemispherical nosepiece of 0.65 in. diam is shown in Fig. 3. The six different starting pieces used in the experiments are described in Table 1.

TABLE 1 STARTING PIECES

Specification	L_{st} ft	L_{tot} ft	L_{st}/L_{tot}
Cylinder with hemispherical nose............	1.026	1.693	0.606
Cylinder with hemispherical nose............	0.689	1.356	0.508
Cylinder with hemispherical nose............	0.354	1.021	0.347
Conical piece (4 in. long)...................	0.187	0.854	0.220
Ellipsoidal nose............................	0.092	0.759	0.122
Hemispherical nose..........................	0.075	0.742	0.101

In this table L_{st} is the hydrodynamic starting length of the specimen, defined as the ratio of the surface area of the starting piece to the perimeter of the heating cylinder. The total length, L_{tot}, is defined as the sum of the starting length L_{st}, and the thermal or heating length L_{th}, of 8 in.[8]

Test Procedures

The velocities were measured by the Pitot tube, using the equation

$$v_a = \sqrt{2gH} = 18.275 \sqrt{H_w/\rho} \qquad [1]$$

where

v_a = velocity, ft/sec
H = velocity head as used in test, ft of air
H_w = velocity head, in. of water
ρ = density of air, lb_m/cu ft

H_w was read directly on the inclined manometer.

Preliminary velocity traverses through the air jet, conducted in horizontal and vertical direction, revealed that for a distance of 2 ft downstream from the nozzle, the air velocity varied less than 1 per cent within an 8-in. core. Therefore, in the main experiments the velocity of the air stream was determined at one point only, midway between the ends of the heating coil and 2 in. from the surface of the specimen.

The electromotive force of the thermocouples was checked at the water boiling point. The indications of the couples, when placed in saturated steam, were compared with the values of Keenan and Keyes's steam tables (6). The deviations from the manufacturer's calibration table were less than 0.1 F at 212°F.[9]

As the velocity of the air, also its temperature, were always taken at a point midway between the ends of, and 2 in. from the heating surface. No correction was applied for the influence of velocity on temperature measurement, which may have reached 0.7 F at the highest velocities, corresponding to about 1 per cent in the measured coefficient of heat transfer.

The measurement of the temperature of the exposed surface is a delicate operation in any heat-transfer experiment. The thermocouple wires in the axial slots below the surface parted from the junctions virtually along isothermal lines, the maximum variation of the surface temperature in axial direction being generally below and only exceptionally slightly above 1 F/in. Therefore the junctions were not sensibly affected by conduction in the axial direction. On the other hand, the influence of the slots in the copper wall on the cross-sectional temperature field had to be studied. Obviously, the length of the heat-flow path near the slots was increased and the distribution of the surface temperature around the tube was not uniform any more. In order to find the surface temperatures from the indications of the thermocouples in the slots, the temperature field in a cross section of the copper tube was determined by Lehmann's graphical method (7).[10] Fig. 8 shows the temperature field in the tube wall for the most drastic conditions encountered in the experimental work. The maximum possible deviation of the thermocouple indication from the undisturbed surface temperature was less than 0.1 F and consequently the thermocouple readings were taken as the surface temperatures.

The heat input was determined by electric-resistance and current measurements. Direct current was used in the heating coil. Its resistance was measured by a Wheatstone bridge, the slight increase of the resistance of the nichrome wire with temperature being taken from Knowlton's handbook (8). A millivoltmeter

[8] The slight difference between the sixth ratio given in Table 1, and L_{st}/L_{tot}, as calculated from the lengths given in Fig. 3, is due to some details in design not indicated in the figure.

[9] In order to distinguish temperature differences from temperatures the unit symbols F and °F, respectively, are employed in this paper. A similar procedure is recommended when the centigrade temperature scale or an absolute temperature scale is used.

[10] Loc. cit., p. 187.

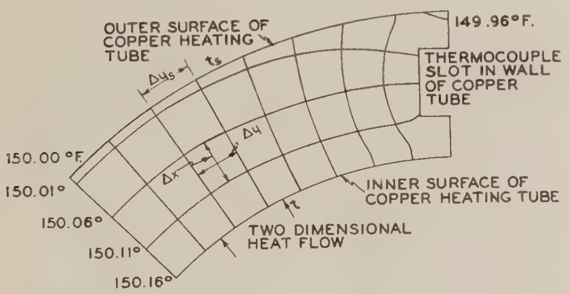

FIG. 8 TEMPERATURE FIELD IN COPPER TUBE WALL

with shunt served to determine the heating current. Voltmeter readings were also taken for each run as a check.

Any portions of the heat input which are not given up from the heating surface to the flowing air by convection will be called heat losses. They might be due to the following:

(*a*) Radiation from the heating surface of the specimen to the room.

(*b*) Conduction and convection from the paper rings at both ends of the specimen.

(*c*) Conduction through the wooden nosepiece.

(*d*) Conduction through the downstream end of the heating-coil tube.

(*e*) Conduction and convection through the air space at the downstream end of the specimen.

Loss (*a*) was calculated by Kirchhoff's and Stefan-Boltzmann's laws. Loss (*b*) was found, considering the paper rings as straight sheets protruding from a copper base at known temperature and exposed to the same air flow and at the same coefficient of heat transfer as the heating surface of the specimen. The calculation of the heat loss (*c*) was reduced to the problem of radial heat conduction in a hollow hemisphere with the inner surface area equal to the cross-sectional areas of the wooden prongs holding the nosepiece in the heating-coil tube. The inner temperature was measured for several representative runs by means of the thermocouples indicated in Fig. 6.

The heat loss (*d*) down the heating-coil tube was calculated from the temperature gradient, measured by the three thermocouples, shown in Fig. 7, the cross-sectional area of that tube and the thermal conductivity of the stainless steel. From the decrease of the temperature gradient the loss (*e*) was found.

The four losses, (*a*), (*b*), (*c*), and (*e*) together were less than 1.5 per cent of the total heat input. They were calculated for several representative runs throughout the entire velocity range of the experiments, and an average correction of 1.4 per cent was applied to each run.

The heat loss (*d*) was the only one of some weight. It amounted from 1.4 to 5.3 per cent of the heat input and had to be determined individually for each run.

Denoting the area of the heating surface by A, the rate of heat input by q_i, and the sum of the heat losses by q_j, the average surface temperature by t_s, and the temperature of the bulk of the air stream by t_a, the coefficient of heat transfer by convection is found from the equation

$$h = \frac{q_i - q_j}{A(t_s - t_a)} \qquad [2]$$

EXPERIMENTAL RESULTS

The experimental results are represented in Figs. 9 to 13, inclusive. They comprise 92 experiments under seven different starting conditions. Six of these were obtained by using the different starting pieces described in Table 1, and the seventh occurred when no particular care was taken to insure a continuous surface in gluing the paper ring in place. Sixteen runs were taken with this somewhat rough junction and twelve when the junction had been carefully smoothed with wax.

The range of the experiments is shown in Table 2.

TABLE 2 RANGE OF EXPERIMENTS

Item	Symbol	Units	Minimum	Maximum
Lengths ratio	L_{st}/L_{tot}		0.101	0.606
Air velocity	v_a	ft/sec	9.8	148.0
Air temperature	t_a	°F	43.0	83.5
Reynolds number	N_{Re}		45300	1450000
Heat input	q_i	B/hr	42.9	362.0
Heat losses	q_j	B/hr	2.0	9.0
Heat transferred by convection	q_c	B/hr	39.5	353.5
Surface temperature	t_s	°F	110.8	146.9
Temperature difference	$t_s - t_a$	F	55.8	86.6
Coefficient of heat transfer by convection	h	$Bhr^{-1}ft^{-2}F^{-1}$	2.55	26.2
Nusselt number	N_{Nu}		126	2660
Nusselt number for $L_{st}/L_{tot} = 0$	$(N_{Nu})_0$		146	2420

For each run the Reynolds number, N_{Re}, and Nusselt number, N_{Nu}, were calculated from the following equations of definition

$$N_{Re} = \frac{v_a L_{tot}}{\nu} \qquad [3]$$

and

$$N_{Nu} = \frac{h L_{tot}}{k} \qquad [4]$$

where ν is the kinematic viscosity and k the thermal conductivity of the air.

Since the characteristics of the boundary layer at any point depend on the total length from the start of hydrodynamic action to the point under consideration, the two dimensionless groups were formed with L_{tot} and not L_{th} as characteristic length. The former has been previously defined as $L_{tot} = L_{st} + L_{th}$. The definition of the starting length L_{st} is based on the fiction that every surface element of the starting piece was placed on a cylindrical surface having the radius of the heating cylinder. This is correct for the cylindrical sections of the starting pieces, but somewhat arbitrary, though reasonable for the nose portions. It can be assumed that L_{st} is a fair equivalent of the starting length of a plane surface.

Also the choice of temperatures at which ν in Equation [3] and k in Equation [4] should be taken is rather arbitrary. However, it is of secondary importance only because the temperature differences used were not too high (see Table 2). Since the Reynolds number is influenced by no other temperature but t_a in the starting section and partly by the same in the heating section, the kinematic viscosity ν was taken at this temperature. The thermal conductivity k, on the other hand, enters the process only in the heating section and depends a good deal on the film temperature $t_f = (t_a + t_s)/2$. Therefore it was taken at this temperature.

Figs. 9 to 13, inclusive, show plots of N_{Nu} versus N_{Re} for the various cases of a constant ratio, L_{st}/L_{tot}. The influence of the Prandtl number does not appear since all runs were made with air at virtually the same Prandtl number.

According to these figures the transition to turbulence was generally finished at $N_{Re} = 300{,}000$, with the rough junction, however, already at $N_{Re} = 100{,}000$ (see Fig. 12). It is striking that the relatively small roughness of the joint was sufficient to increase N_{Nu} by almost 10 per cent.

Fig. 13 shows the thermal behavior of the specimen in the laminar range and the starting of the transition in the runs where the ellipsoidal and the long conical nosepieces were used.

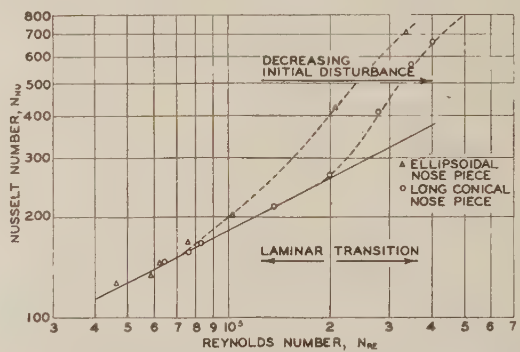

FIG. 13 EXPERIMENTAL DATA FOR L_{st}/L_{tot} = 0.122 AND 0.220 WITH ELLIPSOIDAL AND CONICAL NOSEPIECES

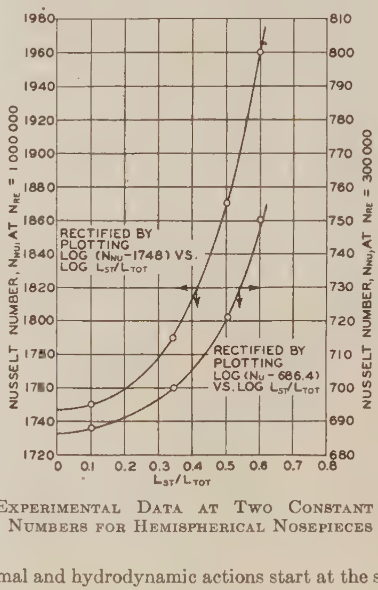

FIG. 14 EXPERIMENTAL DATA AT TWO CONSTANT REYNOLDS NUMBERS FOR HEMISPHERICAL NOSEPIECES

CORRELATION AND ANALYSIS OF THE RESULTS

Mean Heat Transfer. In Fig. 14 the Nusselt number is plotted versus L_{st}/L_{tot} for two constant values of N_{Re} in the turbulent range. These curves can be represented by an equation of the type

$$N_{Nu} = C_0(N_{Re})^m[1 + C_1(L_{st}/L_{tot})^n] = C(N_{Re})^m \quad [5]$$

or for N_{Re} = const

$$N_{Nu} = C_2 + C_3(L_{st}/L_{tot})^n \quad [6]$$

Determining the constants from the experimental data, the following equation for the turbulent region of the boundary layer was obtained

$$N_{Nu} = 0.0280(N_{Re})^{0.80}[1 + 0.40(L_{st}/L_{tot})^{2.75}] \quad [7]$$

If the thermal and hydrodynamic actions start at the same point, Equation [7] reduces to

$$N_{Nu} = 0.0280(N_{Re})^{0.80} \quad [8]$$

Fig. 15 shows a correlation of the experimental data based on these equations.

Whereas Equations [5] to [8], inclusive, hold only for fully established turbulence, there will also be an influence of the hydrodynamic starting length on the heat transfer for a laminar boundary layer. However, the present experimental arrangement allowed going back to Reynolds numbers in the streamline range only when $L_{st}/L_{tot} \gtreqless 0.220$. In this range the influence upon the turbulent layer would be only 0.6 per cent as a maximum, according to Equation [7]; no influence could be

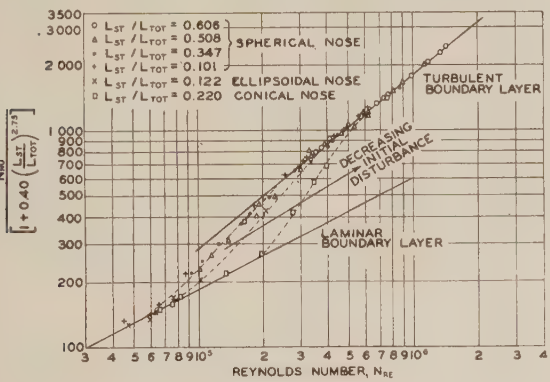

FIG. 15 FINAL CORRELATIONS OF EXPERIMENTAL DATA

observed in the mentioned range of laminar layers. The results of these tests were represented by the equation

$$N_{Nu} = 0.590(N_{Re})^{0.5} \quad \text{[9]}$$

Fig. 15 shows clearly the effect of the laminar and turbulent layers on the heat transfer. As could be predicted from the theory of boundary layers, there is no sharp critical Reynolds number but a transition, depending on the initial disturbances and the shape of the nosepieces. Increasing N_{Re}, the transition starts and ends earlier with spherical than with ellipsoidal nose and last with the long conical nosepiece. The cylindrical part of the starting length had no appreciable influence on the transition when the nosepiece was the same (spherical). In the fully developed turbulent range the points for all starting pieces fall into one line.

Local Heat Transfer. Information about the influence of hydrodynamic starting sections on the local coefficients of heat transfer is of considerable interest[11] and can be obtained from Equations [5] and [7]. However, since differentiation of an empirical equation is a delicate matter, the accuracy of the result should not be overestimated.

Considering a surface of arbitrary total length, L_{tot}, and constant starting length, L_{st}, and referring to the denotations in Fig. 16, Equation [5] can be written as

$$(N_{Nu})_{x,m} = C_0\,(N_{Re})_x{}^m\left[1 + C_1\left(\frac{x_1}{x}\right)^n\right] \quad \text{[10]}$$

where x is an arbitrary distance from the leading edge in the range from $x = x_1 = L_{st}$ to $x = L_{tot}$, the subscript x stands for this distance, the subscript x, m for the mean between $x = x_1$ and $x = x$.

Hence Equation [10] can be written as

$$\frac{h_{x,m}\,x}{k} = C_0\left(\frac{v_a x}{\nu}\right)^m\left[1 + C_1\left(\frac{x_1}{x}\right)^n\right] \quad \text{[11]}$$

[11] Capt. M. Tribus, Air Technical Service Command, Wright Field, Dayton, Ohio, directed our attention to this fact.

Let q' be the rate of heat transferred over the length $x - x_1$, from a surface of unit width, by virtue of the temperature difference $\theta_s = t_s - t_a$; then

$$q'/\theta_s = h_{x,m}\,(x - x_1) \quad \text{[12]}$$

Substituting $h_{x,m}$ from Equation [11] and differentiating with respect to x

$$h_x = \frac{dq'}{\theta_s dx} = kC_0\left(\frac{v_a}{\nu}\right)^m x^{m-1}\left[m + (1-m)\frac{x_1}{x} - (n-m)C_1\left(\frac{x_1}{x}\right)^n + (1+n-m)C_1\left(\frac{x_1}{x}\right)^{n+1}\right] \quad \text{[13]}$$

q' is a function of x and $h_{x,m}$; but $h_{x,m}$, for given x_1, is a function of x only. Hence q' is a function of x and dq' is a perfect differential.

Substituting the numerical values of C_1, m, and n from Equation [7]

$$(N_{Nu})_x = \frac{h_x \cdot x}{k} = C_0(N_{Re})_x{}^{0.8}\left[0.8 + 0.2\,\frac{x_1}{x} - 0.78\left(\frac{x_1}{x}\right)^{2.75} + 1.18\left(\frac{x_1}{x}\right)^{3.75}\right] \quad \text{[14]}$$

The local Nusselt number at the start of the heating section is obtained by taking $x = x_1 = L_{st}$. Substituting this in Equation [14]

$$(N_{Nu})_{x=L_{st}} = 1.4\,C_0(N_{Re})_{x=L_{st}}{}^{0.8} \equiv (N_{Nu})_{L_{st}/L_{tot} = 1} = 0.0392\,(N_{Re})_{x=L_{st}}{}^{0.8}$$

as could be expected, considering the form and figures of Equation [7]

For $L_{st} = 0$ or $L_{tot} = \infty$, that is, $x_1/x = 0$

$$(N_{Nu})_{x=\infty} = 0.8\,C_0(N_{Re})_{x=\infty}{}^{0.8} \equiv 0.8\,(N_{Nu})_{L_{st}/L_{tot} = 0} = 0.0224(N_{Re})_{x=\infty}{}^{0.8}$$

These are the limits in which $(N_{Nu})_x$ may vary owing to the influence of starting length.

The local Nusselt number at the end of the heating length is obtained by taking $x = L_{tot}$. In the present experiments L_{st}/L_{tot} was varied from 0.101 to 0.606. For these two cases Equation [14] yields the local Nusselt numbers

$$(N_{Nu})_{x=L_{tot}} = 0.819\;C_0(N_{Re})^{0.8} \text{ and } 0.905\;C_0(N_{Re})^{0.8}$$

respectively, to be compared with the mean Nusselt numbers $N_{Nu} = 1.0007\;C_0(N_{Re})^{0.8}$ and $1.1005\;C_0(N_{Re})^{0.8}$, respectively.

The latter value is still considerably below the highest possible maximum $1.4\;C_0(N_{Re})^{0.8}$, whereas the lower limit $C_0(N_{Re})^{0.8}$ has virtually been reached in the present experiments.

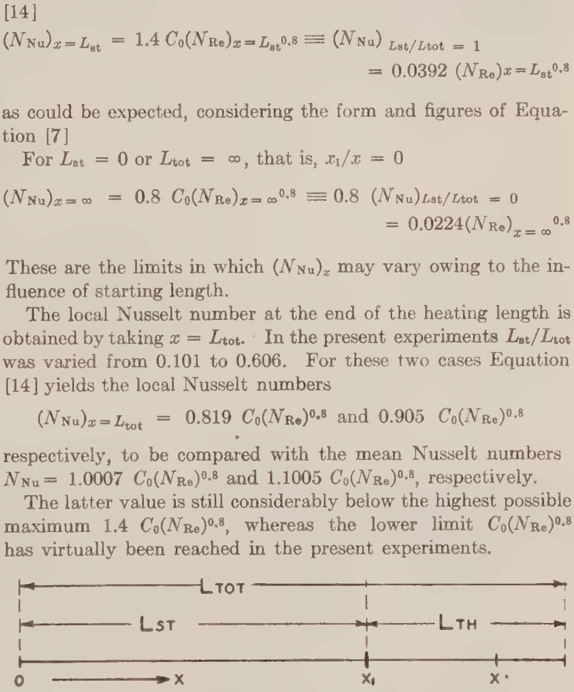

FIG. 16 DENOTATIONS OF LENGTH SECTIONS

Influence of Surface Curvature in General. It will have to be proved by further experiments how far the present results can be applied to surfaces of other curvatures and especially to plane plates. However, an estimate of the influence of curvature on the heat transfer can be obtained in the following way:

It is known that the temperature field and velocity field in a fluid flowing along a surface are almost similar. This had been assumed already by Osborne Reynolds and has been proved ex-

perimentally for the flow in a tube by Pannell (9) and on a plane surface by Éliás (10). Let y be the co-ordinate in the direction perpendicular to the surface, with $y = 0$ at the surface and $y = b$ at the imagined interface between boundary layer and bulk of the flow. The velocities and temperatures at those limits may be $v = 0$ and $v = v_b$, $t = t_s$ and $t = t_a$, respectively. Then because of the existing analogy

$$\frac{\theta}{\theta_s} = \frac{t - t_a}{t_s - t_a} = \frac{v_a - v}{v_a}$$

The rate of heat given up from a plane surface of width W to air in parallel flow between the limits $x = L_{st}$ and $x = x$ is

$$q_p = \int_0^b W\rho c_p v(t - t_a)dy = \int_0^b W\rho c_p \theta_s(v - v^2/v_a)dy \quad [15]$$

The corresponding rate of heat given up by a cylindrical surface of circumference $W = 2\pi r$ to air in parallel flow is

$$q_c = \int_0^b \rho c_p 2\pi(r + y)v(t - t_a)dy = \int_0^b W\rho c_p\theta_s(1 + y/r)(v - v^2/v_a)dy \quad [16]$$

Using the same symbols for v and b in both equations involves the assumption that these quantities are not different for flow parallel to a cylinder or to a plane plate. This assumption seems to give a fair approximation, even for relatively thick boundary layers, according to an observation of Eckert and Weise which will be discussed later on.

Then, according to Equations [15] and [16], the coefficient of heat transfer on a cylinder can be found by multiplying the coefficient for a plane surface by the factor

$$F = 1 + \frac{N - M}{M} = \frac{N}{M} \quad [17]$$

where

$$M = \int_0^b (v - v^2/v_a)dy \text{ and } N = \int^b (1 + y/r)(v - v^2/v_a)dy$$

Influence of Surface Curvature in the Laminar Range. For the laminar section of the boundary layer, the velocity distribution is exactly known from the calculations of Blasius. According to Pohlhausen (11) a close approximation is obtained by the equations

$$v = \left(\frac{2y}{b} - \frac{2y^3}{b^3} + \frac{y^4}{b^4}\right) v_a \quad [18]$$

and

$$b = 5.83\, x(N_{Re})_x^{-0.5} \quad [19]$$

Equation [19] represents the true thickness of the boundary layer and not the so-called displacement thickness for which, according to Pohlhausen, the factor 1.75 instead of 5.83 would have to be entered.

Substituting from Equation [18] in [17] and integrating yields

$$M = \frac{142}{315} bv_a$$

$$N - M = \frac{5}{126}\frac{b^2}{r} v_a$$

and

$$F = 1 + \frac{25}{284}\frac{b}{r} \quad [20]$$

where r is the radius of the surface, 0.054 ft in our case.

According to Equations [19] and [20], the correction factor F increases linearly with x and inverse linearly with $\sqrt{(N_{Re})_x}$. The extreme case in our experiments occurred with $L_{tot} = 0.759$ ft (ellipsoidal nosepiece) at $N_{Re} = 46{,}200$ (see Fig. 13). By susbstitution in Equations [19] and [20] $b = 0.0207$ ft and $F = 1.0338$ were found. Hence in our most extreme case a 3.4 per cent higher value had to be expected for the cylinder than for the plane plate.

From Fig. 13 it is seen that this is just the order of magnitude of scattering of our data. So, the differences of the coefficients of heat transfer for cylindrical and plane surfaces, if any, are in the limits of our accuracy. Should, however, really no difference exist in our range, then this would have the following consequence:

A layer of the bulk flow of unit thickness adjacent to the surface of the boundary layer at $y = b$ has a greater volume on the cylinder than on the plane surface of equal area. Hence its wiping capacity will also be greater and the thickness b may be reduced. Therefore, b in Equation [16] would be smaller than in Equation [15]. However, if Equation [18] were still holding for the velocity distribution, $(dv/dy)_{y=0}$ and, consequently, also $-(dt/dy)_{y=0}$ would become steeper which would mean a greater heat transfer. Hence in this case Equation [18] would have to be replaced by an equation giving a less steep velocity slope at $y = 0$.

Influence of Surface Curvature in the Turbulent Range. Referring to the turbulent section of the boundary layer, again Equations [15], [16], and [17] can be used. Equation [18] may be replaced by

$$v = (y/b)^{1/7}v_a \quad [21]$$

This is von Kármán's well-known equation which, notwithstanding its approximative character, may be used here, for the following reason: According to experiments about the flow in cylindrical tubes by Nikuradse (12), the exponent in Equation [21] decreases from $^1/_6$ to less than $^1/_{10}$ with increasing Reynolds number (13). However, it is not known how the Reynolds numbers for unbounded flow on surfaces are correlated to those for the flow in tubes. The range of turbulent flow covered in the present experiments ($N_{Re} \approx 300{,}000$ to 1,500,000) may correspond to the range between the so-called upper critical number in tubes, $N_{Re} \approx 10{,}000$ or 20,000 (see (14)[12] and (15)[13]) to $N_{Re} \approx 75{,}000$, in which range the exponent of Equation [21] equals about $^1/_7$.

Applying an equation of von Kármán (16), the thickness of the boundary layer can be expressed by

$$b = 0.366\, x'(N_{Re}')_{x'}^{-0.2} \quad [22]$$

where

$$x' = x - x_0$$

$$(N_{Re}')_{x'} = \frac{v_a x'}{\nu}$$

and $x = x_0$ is defined as that distance from the leading edge at which fully established turbulence should start in order to bring the boundary layer to the same thickness b at $x = x_{cr}$ which it actually attains in the laminar range (see Fig. 1). In other words, extending the turbulence curve in Fig. 1 to the left, would lead to $b = 0$ at a fictitious distance $x = x_0$.

Hence for $x = x_{cr}$ Equations [19] and [22] would yield the same b so that

$$5.83\, x_{cr}\left(\frac{v_a x_{cr}}{\nu}\right)^{-0.5} = 0.366\,(x_{cr} - x_0)\left[\frac{v_a(x_{cr} - x_0)}{\nu}\right]^{-0.2}$$

Solving for x_0 yields

[12] Loc. cit., p. 34.
[13] Loc. cit., p. 172.

$$x_0 = x_{cr}\left[1 - 31.82\left(\frac{v_a x_{cr}}{\nu}\right)^{-3/8}\right] \qquad [23]$$

From Equations [22] and [23] by some transformation

$$b = 0.366\, x \left\{1 - \frac{x_{cr}}{x}\left[1 - 31.82\left(\frac{v_a x_{cr}}{\nu}\right)^{-3/8}\right]\right\}^{0.8}\left(\frac{v_a x}{\nu}\right)^{-0.2}$$

or

$$b = 0.366\, x \left\{1 - \frac{(N_{Re})_{cr}}{(N_{Re})_x}\left[1 - 31.82\,(N_{Re})_{cr}^{-3/8}\right]\right\}^{0.8}(N_{Re})_x^{-0.2} \qquad [24]$$

The thickness b increases with increasing x and with decreasing $(N_{Re})_{cr}$ up to a maximum which would occur at $(N_{Re})_{cr} = 2908$.

One extreme case in our experiments occurred with a cylindrical starting piece having a hemispherical nose ($L_{tot} = 1.69$ ft) and with $(N_{Re})_{cr} \approx 50{,}000$ and $N_{Re} \approx 1{,}500{,}000$ (see Fig. 15). Using these values in Equation [24], $b = 0.0353$ ft was found.[14]

Substituting now from Equation [21] in [17] and integrating

$$M = \frac{7}{72}\, b v_a$$

$$N - M = \frac{7}{240}\,\frac{b^2}{r}\, v_a$$

and

$$F = 1 + \frac{3}{10}\,\frac{b}{r} \qquad [25]$$

With $b = 0.0353$ and $r = 0.054$, $F = 1.196$ was obtained.

The other extreme occurred with the spherical nose without cylindrical starting piece ($L_{tot} = 0.74$ ft) and with $N_{Re} = (N_{Re})_{cr} = 50{,}000$. Here $b = 0.01347$ ft and $F = 1.075$ were found.

This means that for the used cylindrical surface, heat-transfer coefficients, 7.5 to 19.6 per cent higher than for a plane surface may be expected. Should actually no differences exist, then the same consequences would have to be considered as drawn when dealing with the corresponding differences for a laminar boundary layer.

Comparison With Previous Work

The present results will be compared with theoretical and experimental results of previous investigators. Most of them can be reduced to starting length zero and represented by the form

$$N_{Nu} = C_0 (N_{Re})^m \qquad [26]$$

Values of C_0 and m, according to different workers, are shown in Tables 3 and 4, each in chronological sequence. For comparison it may first be noted that the present experiments led to $C_0 = 0.590$ and $m = 0.50$ for laminar boundary layer, and to $C_0 = 0.0280$ and $m = 0.80$ for turbulent layer.

Strangely enough, the first notable investigations on this subject date less than 25 years back and are purely theoretical.

For the laminar range Pohlhausen (17) in 1921 derived the following equation

$$N_{Nu} = 0.664 (N_{Re})^{1/2} (N_{Pr})^{1/3} \qquad [27]$$

Substituting $N_{Pr} = 0.71$ which holds for the average temperature of the present experiments, Equation [27] takes the form of Equation [26] with $C_0 = 0.592$ and $m = 0.50$ in excellent agreement with the result of the present experiments. Incidentally, Pohlhausen's derivation is one of the few existing direct solutions of Stokes's equations of viscous flow in combination with the equation of thermal conduction in moving fluids. The attempts made by Boussinesq, King, and Aichi before Pohlhausen, and by Lévêque afterward, failed because of oversimplified assumption. Lévêque, for instance, assumed a linear velocity distribution, instead of Equation [18]. These mathematical attacks of the problem have been thoroughly described by Drew (18).

For turbulent flow, Latzko (19), also in 1921, derived the following equation for the rate of heat flow:

$$q_{Lst/Ltot=0} = 0.0356\, L_{th} W \rho c_p v \theta_s (N_{Re})^{-0.2}$$

which can readily be converted to

$$N_{Nu} = 0.0356\,(N_{Re})^{0.80} N_{Pr} \qquad [28]$$

This equation has the same exponent as was found in our experiments. Since Latzko's derivation is restricted to $N_{Pr} = 1$, it holds only approximately when $N_{Pr} \neq 1$. However, substituting $N_{Pr} = 0.71$, $C_0 = 0.0253$ was obtained, our experimental value of C_0 being about 11 per cent higher, in satisfactory agreement with the presented theoretical analysis concerning the influence of surface curvature to the results.

Latzko's derivation is based on von Kármán's form of Equation [24], that is, $(N_{Re})_{cr}/(N_{Re})_x$ is neglected compared to 1. Instead of this, the fictitious point $x = x_0$ (see Fig. 1) may be taken as zero point of a system, denoted by prime signs; then

$$N_{Nu} = \frac{hL_{tot}}{k} = \frac{h(L_{tot} - x_0)}{k}\,\frac{L_{tot}}{L_{tot} - x_0} = N_{Nu}'\,\frac{L_{tot}}{L_{tot} - x_0}$$

and from Equation [28], using $N_{Pr} = 0.71$

$$N_{Nu}' = 0.0253\,(N_{Re}')^{0.8}$$

After some transformations

$$N_{Nu} = 0.0253 \left\{1 - \frac{(N_{Re})_{cr}}{N_{Re}}\left[1 - 31.82 (N_{Re})_{cr}^{-3/8}\right]\right\}^{-0.2} N_{Re}^{0.8} = C_0 N_{Re}^{0.8} \qquad [29]$$

The expression in curved brackets increases with N_{Re} and with decreasing $(N_{Re})_{cr}$ up to the previously mentioned maximum. Hence again the extreme occurred with $N_{Re} = 1{,}500{,}000$ and $(N_{Re})_{cr} = 50{,}000$. The calculation yields $C_0 = 0.0254$, compared to Latzko's value 0.0253. Hence $C_0 = 0.0280$, observed with our cylindrical surface, is about 10 per cent higher than the theoretical value for a plane surface, in satisfactory agreement with the average (13.5 per cent) of the theoretical values, calculated at the end of the preceding section.

[a] Results reduced to $m = 0.80$.

[14] This procedure involves the assumption that Equation [22] can be used through and past the transition region (see Fig. 1); the same assumption will be made in deriving Equation [29]. Within the transition region, however, it yields only approximation results.

Only one year after these two papers the first publication of Juerges' experiments appeared (20), followed in 1924 by a detailed report (21). He measured the heat transfer from a vertical plane copper plate, 1.64 ft × 1.64 ft, to air flowing parallel to the surface at velocities up to 100 ft/sec, surface temperatures from 115 to 140 deg F, and air temperature of 68 deg F. The hydrodynamic starting length in these experiments was 1.02 ft. For a polished plate Juerges found

$$h = 0.4497\, v^{0.775} \qquad [30]$$

which can be generalized into our standard form, Equation [26], by using the term in square brackets of Equation [7]. In this way $C_0 = 0.0452$ and $m = 0.775$ were obtained. In order to simplify the comparison with our values, Juerges' results were also represented with $m = 0.80$. This led to $C_0 = 0.0322$ and to values of N_{Nu} which differ less than ±2 per cent from the values obtained by Equation [30] between $N_{\mathrm{Re}} = 300{,}000$ and $1{,}500{,}000$, but are 15 per cent higher than our values based on $C_0 = 0.0280$.

Much of this difference is probably due to a blunt leading edge of the starting surface.[15] As mentioned in the first section of this paper, turbulence will start immediately past such an edge with the effect that considerably more heat is transferred in the thermal section. Therefore, Juerges' results cannot be directly compared with the present ones in which a laminar boundary layer preceded the turbulent layer. Reference is made to Fig. 12 which shows that even a small roughness in the starting section can have an effect on the Nusselt number of similar order of magnitude as was observed between Juerges' and the authors' experiments.

In the experiments of Éliás (10) which covered almost the same range of v_a and θ_s as those of Juerges, a starting piece 3.94 in. long, with sharpened leading edge and heating lengths of 3.94 to 15.76 in. were used.

Éliás represented his experimental results by curves of the velocity and temperature distribution in the boundary layer and used these curves to determine the heat carried past in the air stream by graphical integration, according to the first part of Equation [15].

From Éliás' reported values we calculated the heat-transfer coefficients and the Reynolds and Nusselt numbers with L_{tot} as characteristic length. Again the starting length was considered by means of Equation [7].

Éliás' and Juerges' data, reduced to $L_{st} = 0$, are compared with the present results in Fig. 17. It is seen that most of Éliás' points fall in between Juerges' and our line. They show an unusual steep increase with Reynolds number ($m > 0.9$). Seibert (22) considers this as evidence of not yet finished transitions and in fact, the points of Fig. 17 fit rather well with our observations in the state of transition shown in Fig. 15. The instability due to transition and the indirect determination of heat convection from flow and temperature measurements in the boundary layer may account for the considerable scattering of the points.[16]

In contrast to the steep increase of Éliás' values, Taylor and Rehbock (23) arrived at an improbably small exponent ($m = 0.725$), using Juerges' data and their own experiments, per-

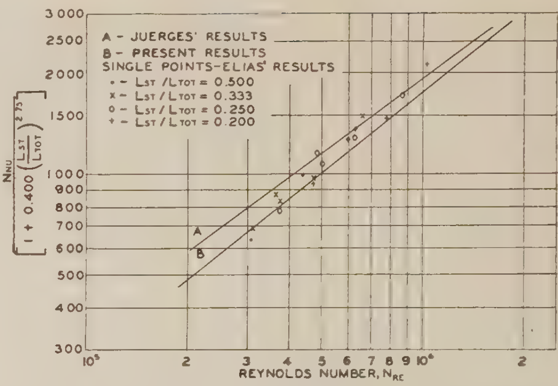

Fig. 17 Comparison of Present Results for a Turbulent Boundary Layer With Previous Experiments With Flat Plates

formed on a 6-in-sq copper plate at 75 to 235 ft/sec air velocity. Unfortunately, they did not indicate the value of the hydrodynamic starting length in their experiments. For this reason a comparison with present results is not possible.

Fage and Falkner (24) determined the heat transfer to air from platinum foils, 0.00127 cm thick, 1.27 cm wide, and from 0.333 to 1.27 cm long, in the laminar-boundary range. The air velocity was varied from 20 to 70 ft/sec, the air temperature was 72° F, the foil temperature was about 340°F. For the exponent m the usual value of 0.5 was found, for the constant C_0, however, the high value 0.750. This may be ascribed to the fact that with such short heating surfaces, the starting-section conditions prevail. Latzko (19)[17] analyzing an analogous case in the turbulent range found that in the starting section the constant C_0 should be higher than in established turbulence, whereas the exponent would remain unchanged. The same may hold for the laminar range.

Colburn (25) accepted Pohlhausen's equation and made a correlation according to which Fage and Falkner's results would be in agreement with this equation. Because we had found their values to be 27 per cent too high, we asked Dr. Colburn for an explanation of this discrepancy, and he found that due to a slide-rule error, all points representing Fage and Falkner's values in his Fig. 20 should be raised by 21 per cent. This explains the greatest part of the mentioned difference.

Colburn further correlated the experimental results of Juerges and Éliás in the turbulent region and expressed them by the following equation

$$\frac{h\, L_{\mathrm{th}}}{k} = 0.0321 \left(\frac{v_a L_{\mathrm{th}}}{\nu}\right)^{0.80}$$

Using[18] Juerges' $L_{st}/L_{\mathrm{tot}} = 0.383$ and converting from ν_f at film temperature (about 98°F) as used by Colburn, to ν at bulk temperature (about 68°F), correcting also for the influence of the starting length, according to Equation [7], Colburn's equation is reduced to our standard form with $m = 0.80$ and

$$C_0 = 0.0321 (L_{\mathrm{tot}}/L_{\mathrm{th}})^{0.2} [1 + 0.40 (L_{st}/L_{\mathrm{tot}})^{2.75}]^{-1} (\nu/\nu_f)^{0.8} = 0.0320$$

Seibert (22) also adopted Pohlhausen's theory in the laminar range. For turbulence he used the modification by which Prandtl had extended his original theory to the case of $N_{\mathrm{Pr}} \neq 1$ and in particular, ten Bosch's (3) extensions of this theory. Employing

[15] In Fig. 2 of Juerges' paper no sharpening or smoothing of the edge is indicated. Since many minor details are dealt with in the paper, the author would certainly have mentioned any sort of treatment of the leading edge.

[16] The accuracy of the experiments is unfavorably influenced by the difficulty to co-ordinate a considerable number of measured local velocities and temperatures to the exact values of y in a total range of boundary thickness of about 1/2 in. only. Moreover, the surface temperature was measured by thermocouples placed on the back side of the heating box. It is very questionable whether sufficient symmetry existed on both sides; the surface thermocouples themselves may have disturbed such symmetry.

[17] Loc. cit., p. 283, Fig. 7A.

[18] Éliás' range of ratios was $L_{st}/L_{\mathrm{tot}} = 0.2$ to 0.5.

Seibert's exponent $m = 0.786$, but correcting[19] for the difference in N_{Pr}, the value $C_0 = 0.0423$ was obtained. His results can be covered also by using $m = 0.80$ and $C_0 = 0.0349$. Comparison then shows that Seibert's theoretical values of N_{Nu} for plane plates are 25 per cent higher than those measured on a cylinder in the present work. This is at variance with Latzko's theoretical results which cannot be expected to be seriously in error at a Prandtl number so close to unity. However, Seibert's relation is based on different assumptions which would need to be checked, as he states himself.

Seibert also indicated the following formula for the transition state

$$N_{Nu} = 0.00178\ (N_{Re})^{0.986} \qquad [31]$$

It yields too low values compared to the transition lines in Fig. 15.

Also his method of inserting Éliás' results between a maximum and minimum of Nusselt numbers is questionable. The heating section gives up more heat (q_{max}) in actual measurements if an unheated starting length exists, than would be the case if the same total length were held at the same temperature excess θ_s as the heating section was in the actual experiments (q_{min}). Seibert, however, uses a sort of mixing rule for Nusselt numbers in his Equation [20], which is not correct.

Using Equation [7], the following is obtained

$$\frac{q_{min}}{q_{max}} = \frac{[1 - (L_{st}/L_{tot})^{0.8}](1 - L_{st}/L_{tot})}{1 + 0.4(L_{st}/L_{tot})^{2.75}} \qquad [32]$$

For the extreme ratios, employed by Éliás, $L_{st}/L_{tot} = 0.2$ and 0.5, Equation [32] yields $q_{min}/q_{max} = 0.901$ and 0.804, respectively, compared to the ratios $(N_{Nu})_{min}/(N_{Nu})_{max} = 0.945$ and 0.713, respectively, calculated according to Seibert, assuming the same exponent, $m = 0.8$. In general, much insight in the mechanism is not obtained by Seibert's method of asking what the heat transfer in a heated section would have been if the starting length had also been heated, whereas Equation [7], rough and improvable as it may be, considers the influence of the starting length in a straightforward way.

Finally, some theoretical and experimental papers may be mentioned which deal with the laminar part of the boundary layer at very high fluid velocity. The authors are Crocco (26), Hilton (27), Eckert and Weise (28), and Eckert and Drewitz (29). The result of these investigations is that Pohlhausen's equation can be applied up to as high speeds as twice the velocity of sound, provided that the temperature of the gas t_a is replaced by the temperature t_i which the unheated and perfectly insulated surface would assume in the gas stream. This temperature may be called "impressed temperature." For $N_{Pr} = 1$, it is found by adding to the ordinary surface temperature the temperature increment due to adiabatic stopping of the gas stream, $\theta_{ad} = v_a^2/(64.4\ Jc_p)$, where J is the mechanical equivalent of heat.[20] For $N_{Pr} \neq 1$, $\theta_i = \theta_{ad}$. $\varphi(N_{Pr})$ is to be added to t_s; values of the function φ are given in Table 5. They are calculated by means of Pohlhausen's theory; the first nine values have been taken from his original paper (17), the last two from Eckert and Weise's paper (28).

Also the heat transfer in the range of turbulent layer can be calculated with the formulas developed for small velocities if t_i is employed instead of t_a.

Hence it may be assumed that the results of the present paper also can be approximately used for high velocities and for other fluids than air if t_a is replaced by t_i.

[19] Seibert's Equation [17] has been used for this slight correction.

[20] For convenience J and c_p are expressed in the dimensions given in the "nomenclature;" the number 64.4, then, is not dimensionless.

TABLE 5 VALUES OF THE FUNCTION (φN_{Pr})

N_{Pr}	0.6	0.7	0.8	0.9	1.0	1.1	Gases
$\varphi(N_{Pr})$	0.77	0.835	0.895	0.95	1.00	1.05	
N_{Pr}	7.0	10.0	15.0	100	1000		Liquids
$\varphi(N_{Pr})$	2.515	2.965	3.535	6.7	12.9		

Concerning the influence of curvature of the surface in a plane perpendicular to the main flow direction, Eckert and Weise made some tests on wires with 0.2 to 2 mm diam in the range of $v_a = 400$ to 1000 ft per sec air velocity, corresponding to $N_{Re} =$ 50,000 to 500,000. Denoting the temperature excess of the unheated wire by θ_i, it was found that the ratio θ_i/θ_{ad} depended only slightly on the ratio b/r which was varied from 0.1 to 1. In the same range, Hilton measured θ_i/θ_{ad} for a plane plate and found only about 3 per cent higher values than Eckert and Weise on the thin wires. This is in good agreement with the deviation of 3.4 per cent calculated by the present authors for $b/r = 0.384$ in the fourth part of the previous section of this paper.

Summary and Conclusions

1 Systematic measurements of the heat transfer by convection from a cylinder to a fluid flowing parallel to its axis allow a simpler technique than measurements with plane surfaces. They should yield results which can be applied to plane surfaces up to rather high Reynolds numbers when cylinders with reasonably large diameters are used.

2 The present experiments were performed with air flowing parallel to an electrically heated smooth cylinder, 8 in. long, 1.3 in. diam. Wooden nosepieces of different shapes and cylindrical pieces of different lengths served as unheated starting sections. The heated lengths were varied from 40 to 90 per cent of the total length, air velocities from 10 to 150 ft per sec, corresponding to Reynolds numbers from 45,000 to 1,500,000, based on the total length as a characteristic dimension.

3 The results of the measurements could be expressed by the equations

$$N_{Nu} = 0.590\ (N_{Re})^{0.50} \qquad [9]$$

and

$$N_{Nu} = 0.0280\ (N_{Re})^{0.80}[1 + 0.40\ (L_{st}/L_{tot})^{2.75}] \qquad [7]$$

for laminar and turbulent boundary layers, respectively, where N_{Nu} and N_{Re} are Nusselt and Reynolds numbers with the total length L_{tot} as characteristic length, and L_{st} as the starting length. Transition to turbulence started between $N_{Re} =$ 50,000 and 200,000 and was virtually finished between 250,000 and 600,000 (see Fig. 15). The start and end of transition depended mainly on the shape of the nose. Even a slight roughness in the starting section caused a considerable increase of the heat transfer.

4 An equation for the local Nusselt number was derived from Equation [7] by differentiation.

5 The influence of the cylinder curvature has been studied theoretically, considering similarity between velocity and temperature distribution and assuming that the velocity distribution in curved boundary layers is the same as for plane layers. Under these assumptions 8.8 b/r and 30 b/r would be the percentages by which the Nusselt numbers for cylinders would exceed those for plane plates in the ranges of laminar and turbulent layers, respectively, where r is the cylinder radius and the thickness of the boundary layer b is taken from Equations [19] and [24], respectively. It was further shown what changes in the theory might be advisable if such differences should not actually occur.

6 Using these differences in the laminar range of the present experiments, the heat transfer should be higher by 0 to 3 per cent than for a plane boundary layer. This seems to be in agreement with some recent experiments which Hilton and Eckert and Weise performed at much higher air velocities and smaller lengths. Fage and Falkner, however, obtained 25 per cent higher

values in tests on short platinum foils. No difference was found between the present experimental data on cylindrical layers and those from Pohlhausen's generally recognized theory for plane boundary layers.

7 Applying the theory to the turbulent range of the present experiments, a 7 to 20 per cent larger heat transfer would be expected than for plane plates. Actually the present experimental data are about 10 per cent higher than those obtained from Latzko's theory for a plane surface. On the other hand, they are 20 per cent lower than those according to a theory of Seibert which is based on different and not yet proved assumptions. Experiments in the range of turbulent boundary layers on plane surfaces have been performed by Juerges and Éliás. A blunt leading edge seems to have caused relatively high heat-transfer values in Juerges' experiments 15 per cent above the present data. Éliás' results are between Juerges' and the present data.

8 A recent paper of Eckert and Drewitz shows that Pohlhausen's theory holds up to twice the velocity of sound if the fluid temperature is replaced by a temperature impressed on the surface because of adiabatic stopping and friction of the stream. The same is claimed for the turbulent boundary layer.

It may be concluded also that the results of the present investigation can be approximately employed up to much higher than the experimental velocities and applied to other fluids when the equilibrium fluid temperature is replaced by the "impressed temperature" of the surface. However, it is planned to extend the experiments to velocities higher than those used in the present experiments.

9 According to the authors' theoretical reasoning, the heat transfer on plane surfaces should be somewhat smaller than given by Equation [7]. This would be in agreement with Latzko's theory. Seibert's theory for plane surfaces, however, leads to higher values of heat transfer than observed on the cylinder. It is intended to decide this controversial question by experiments with cylinders of different diameters, varying also the starting and heating lengths. For the time being it seems to be safe to use Equation [7] tentatively for any convex smooth surface with arbitrary starting section when the radius of curvature in a plane perpendicular to the main flow direction is more than $^1/_2$ in. The influence of the starting length, in particular, should be nearly the same for cylinders and plane surfaces.

Temperature-Time Distribution in Rectangular Bars

By W. M. ROHSENOW,[1] M. J. ARONSTEIN,[2] AND A. C. FRANK[2]

Charts for determining temperature-time distribution in flat plates, infinite cylinders, and spheres have been published previously. The purpose of this paper is to amplify the lower end of the curves thus presented, and to give the results in graphical and in tabular form. In addition, the rapid convergence of the series solution is shown, and combined curve sheets for rectangular bars are presented.

Nomenclature

The following nomenclature is used in the paper:

t = temperature
t_s = initial temperature of bar
t_a = temperature of surrounding atmosphere
θ = time
k = coefficient of thermal conductivity
ρ = density
c_p = specific heat at constant pressure
w = half-width of bar in x-direction
u = half-width of bar in y-direction
$a = k/(\rho c_p)$ — thermal diffusivity
h = film coefficient of heat transfer
$b = h/k$
$T = (t - t_a)/(t_s - t_a)$

$$T_x = \sum_{n=1}^{\infty} X_n$$

X_n = defined in Equation [6]

Note: Any consistent set of dimensions may be used.

Introduction

When a homogeneous solid body at a uniform temperature is suddenly exposed to an atmosphere which is held at some constant temperature different from that of the body itself, heat is exchanged between the body and the atmosphere through a film on the surface of the body. The outer parts of the body approach the temperature of the atmosphere more rapidly than do the inner parts. Heat is transferred between the inner and outer parts of the body by conduction. After an infinite amount of time the solid body is uniformly at the temperature of the surrounding atmosphere.

In engineering applications the useful information concerning this transient-state heat-transfer process is of two forms. In one case it may be desirable to know the temperature distribution existing in a solid body at any instant of time; in the other case it may be desirable to know the temperature-time curve for any point in the body. An example of these cases is the hardening of a solid steel body. The solid body is heated to a uniform high temperature; then it is suddenly quenched in oil or water. The inner parts cool more slowly than the outer parts; hence there results a body of varying degrees of hardness throughout its volume. In order to determine the stresses produced in the bar by this unequal cooling, it is necessary to know the temperature distribution at any instant of time; and, in order to determine the degree of hardness at any point in the bar, it is necessary to know the temperature-time curve at that point.

Charts for determining temperature-time distribution in infinite flat plates, infinite cylinders, and spheres have been published by Gurney and Lurie (1, 2),[3] Hottel (3) and Newman (4). The purpose of this paper is to enlarge the lower end of these curves presenting the results in graphical and in tabular form; to show the rapid convergence of the series solution; and to present combined curve sheets for rectangular bars.

Since the number of variables is large and the calculations are laborious when applying the equations resulting from the mathematical solution of the problem to any given case, the series of charts constructed permits a convenient solution under any set of given conditions. From these charts the temperature-time-position relationship for two specific cases, namely, the square bar and the 2 × 1 rectangular bar, was found as a method of illustrating the procedure. It is hoped that these specific solutions along with the solution for the infinite flat plate will give a general idea of the range of values to be encountered.

Infinite Flat Plate

Consider an infinite flat plate (infinite in the Y- and Z-directions) of thickness $2w$, as shown in Fig. 1. The plate is initially at a uniform temperature t_s and is suddenly exposed to an atmos-

[3] Numbers in parentheses refer to the Bibliography at the end of the paper.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until March 11, 1946. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society, or the U. S. Navy, or Naval Service at large.

phere of temperature t_a, which may be colder or hotter than t_s. The heat-conduction equation for this case is

$$\frac{\partial t}{\partial \theta} = a \frac{\partial^2 t}{\partial x^2} \qquad [1]$$

where

$$a = k/(\rho c_p) \qquad [2]$$

The term a is called the thermal "diffusivity" of the material and is considered to be constant for any given solid material.

The solution of Equation [1] may be found in applied mathematics and in heat-conduction texts such as Carslaw (5). The solution is

$$\frac{t - t_a}{t_s - t_a} = \sum_{n=1}^{\infty} 2e^{-(a\theta/w^2)\delta_n^2} \cdot \frac{\cos \delta_n(x/w)}{\delta_n \csc \delta_n + \cos \delta_n} \qquad [3]$$

where δ_n, called "eigenwerte," are roots of the equation

$$bw \cot \delta_n = \delta_n \qquad [4]$$

The first five roots of Equation [4] are shown as a function of bw in Fig. 2. Note that since all are shown on the same ordinate scale, π must be added to the scaled value of δ_2, 2π to δ_3, etc. This arises from the fact that δ_1 varies from 0 to $\pi/2$, δ_2 from $\pi/2$ to $3\pi/2$, etc. Tabular values of these roots may be found in Gröber and Erk (6) and in Jahnke and Emde (7).

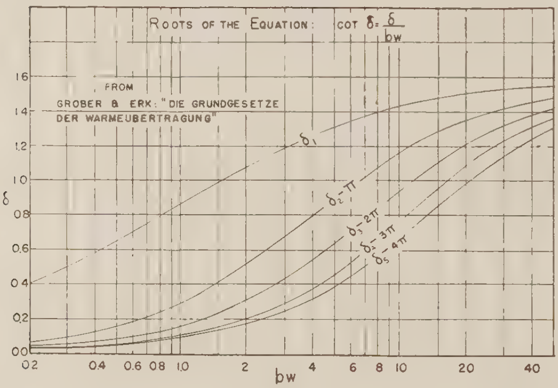

Fig. 2 Values of Eigenwerte, δ

In order to simplify the series notation of Equation [3], let it be written in the form

$$T_x = \sum_{n=1}^{\infty} X_n \qquad [5]$$

where

$$X_n = 2e^{-(a\theta/w^2)\delta_n^2} \cdot \frac{\cos \delta_n(x/w)}{\delta_n \csc \delta_n + \cos \delta_n} \qquad [6]$$

The first three terms of the series, X_1, X_2, and X_3 are shown in Fig. 3. The term X_3 is insignificant for values of $a\theta/w^2$ greater than 0.05, and term X_2 is insignificant for values of $a\theta/w^2$ greater than 0.20. The sum of the first three terms of the series Equation [5], T_x, is plotted in Figs. 4 through 8, for values of x/w = 0, 0.25, 0.50, 0.75, and 1, respectively.

These charts represent the solution of Equation [3] to determine the temperature-time distribution at 5 planes in one half of the infinite flat plate. The computed values obtained by adding

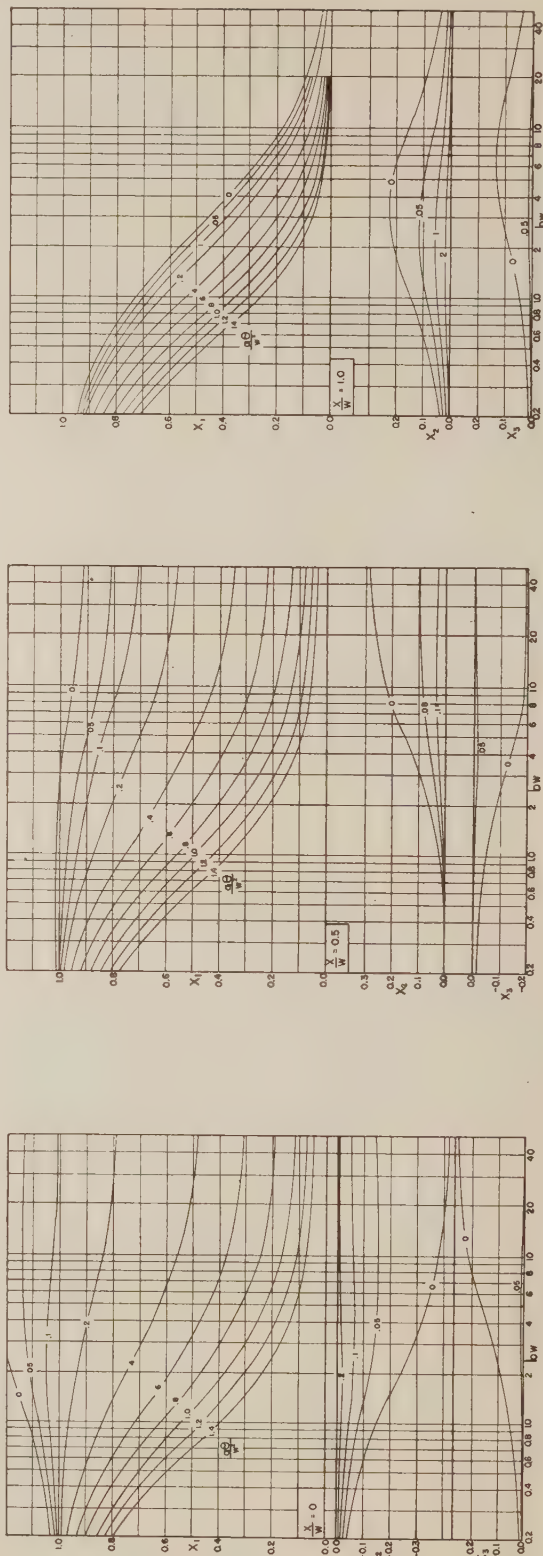

Fig. 3 First Three Terms of Series Solution, T_x

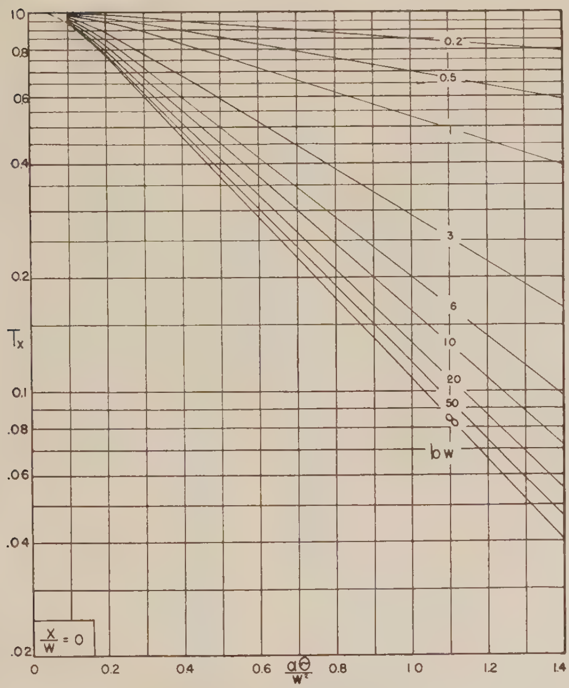

Fig. 4 T_x Versus $a\theta/w^2$ for $x = 0$

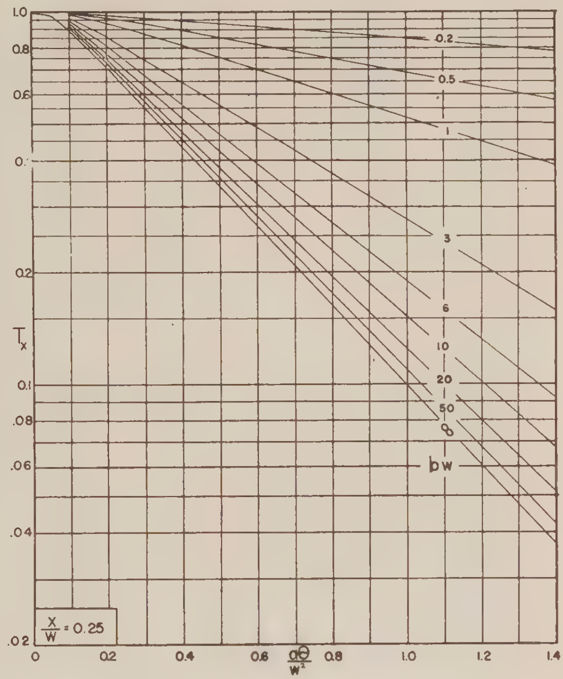

Fig. 5 T_x Versus $a\theta/w^2$ for $x = 0.25$

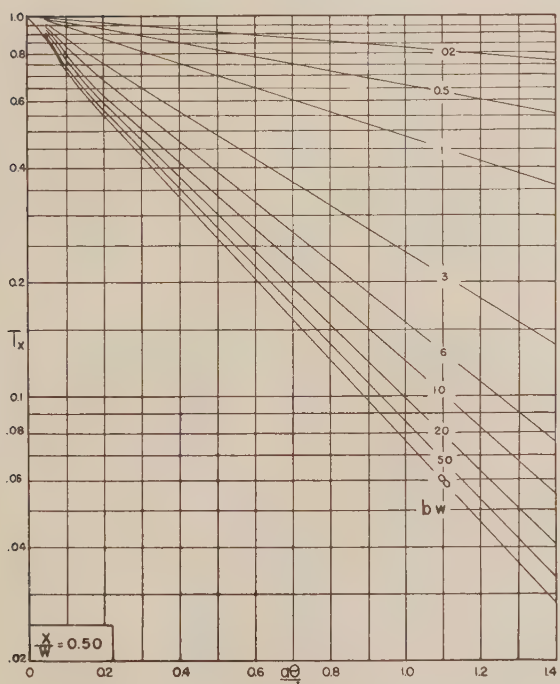

Fig. 6 T_x Versus $a\theta/w^2$ for $x = 0.50$

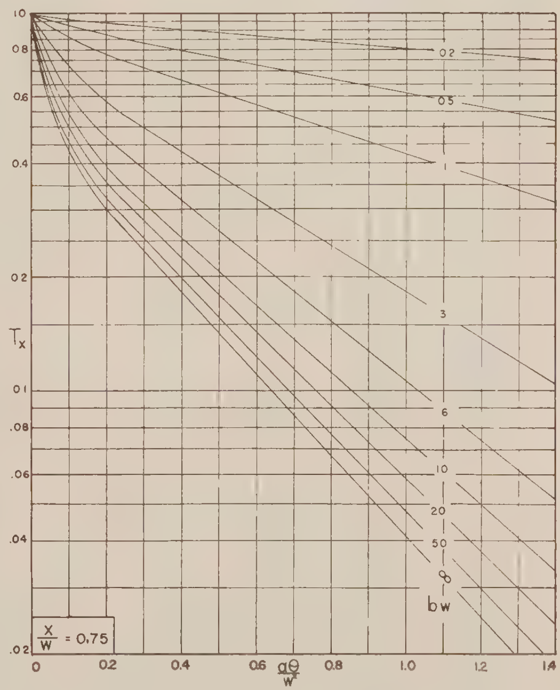

Fig. 7 T_x Versus $a\theta/w^2$ for $x = 0.75$

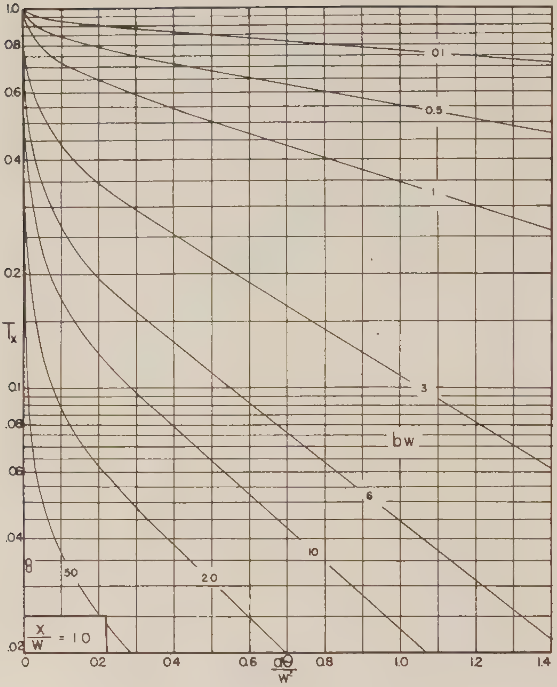

FIG. 8 T_x VERSUS $a\theta/w^2$ FOR $x = 1.0$

the first three terms of the series in Equation [5] are tabulated in Tables 1 to 5, inclusive.

INFINITE RECTANGULAR BAR AND RECTANGULAR BLOCK

The heat-conduction equation for the infinite rectangular bar represented in Fig. 9 is

$$\frac{\partial t}{\partial \theta} = a\left(\frac{\partial^2 t}{\partial x^2} + \frac{\partial^2 t}{\partial y^2}\right)\dots\dots\dots\dots\dots\dots [7]$$

By substituting in the partial differential equation, Equation [7], it may be shown that

$$T = T_x \cdot T_y \dots\dots\dots\dots\dots\dots [8]$$

is its solution, where T_x is the solution of

$$\partial t/\partial\theta = a(\partial^2 t/\partial x^2)$$

and T_y is the solution of

$$\partial t/\partial\theta = a(\partial^2 t/\partial y^2)$$

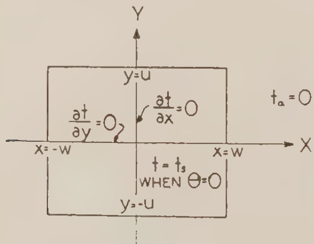

FIG. 9 QUARTER-CROSS SECTION OF INFINITE RECTANGULAR BAR

This is known as Newman's rule (4). Similarly, for a cube the differential equation is

$$\partial t/\partial\theta = a\left(\frac{\partial^2 t}{\partial x^2} + \frac{\partial^2 t}{\partial y^2} + \frac{\partial^2 t}{\partial Z^2}\right)\dots\dots\dots\dots [9]$$

the solution of which is

$$T = T_x \cdot T_y \cdot T_z \dots\dots\dots\dots\dots\dots [10]$$

where the T functions are defined as in Equation [8].

The functions T_x, T_y, T_z are given by Equations [3] and [5], and are plotted in Figs. 4 to 8, inclusive. In order to determine the solution T for any point in a bar or a block, evaluate T_x from Equation [5] (or from Figs. 4 to 8, inclusive) for each of the coordinate directions, thus obtaining T_x, T_y, T_z. The product of these three is the solution as indicated in Equation [10]. For an infinite rectangular bar, only T_x and T_y need be obtained.

A set of curves has been constructed in Figs. 11 and 12 for the solution of Equation [8] at the inner points of the infinite rectangular bar shown in Fig. 10. Fig. 11 is for a square bar, and Fig. 12, for a rectangular bar of side dimensions in the ratio of 2 to 1. In the case of a square bar, only 6 of the 9 positions indicated in Fig. 10 need be considered since there are three identical pairs of points because of symmetry.

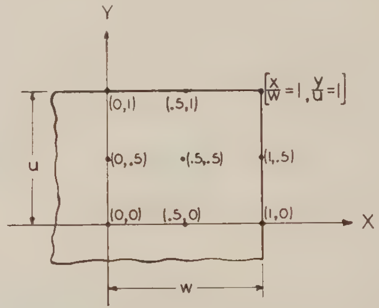

FIG. 10 QUARTER CROSS SECTION OF INFINITE RECTANGULAR BAR SHOWING POINTS FOR WHICH COMBINED SOLUTION IS PRESENTED

It will be noticed that for positions along the x-axis, the curves for the rectangular bar, Fig. 12, lie approximately midway between the curves for the square bar, Fig. 11, and the curves for the infinite flat plate, Figs. 4 to 8, inclusive. These curves are intended to indicate the range of possible values in rectangular-bar problems and to indicate a graphical method of procedure.

ILLUSTRATIVE EXAMPLE

Consider an infinite rectangular steel bar of dimensions w = 0.125 ft and u = 0.250 ft. Determine the value of temperature ratio t/t_s at the point x/w = 0.5, y/u = 0.5 at the time θ = 0.0271 hr. For a steel bar, k = 25 Btu/(hr)(sq ft) (deg F/ft), ρ = 493 lb/cu ft, and c_p = 0.11 Btu/(lb) (deg F); hence the thermal diffusivity is

$$a = 25/(0.11 \times 493) = 0.461 \text{ sq ft/hr}$$

If the film coefficient of heat transfer is

$$h = 200 \text{ Btu/(hr) (sq ft) (deg F)}$$

then

$$b = h/k = 200/25 = 8.0 \text{ ft}^{-1}$$

and

$$bw = 1.0,\ bu = 2.0,\ a\theta/w^2 = 0.8,\ a\theta/u^2 = 0.2$$

From Fig. 6 or Table 3 for

$$a\theta/w^2 = 0.8 \text{ and } bw = 1.0,\ T_x = 0.564$$

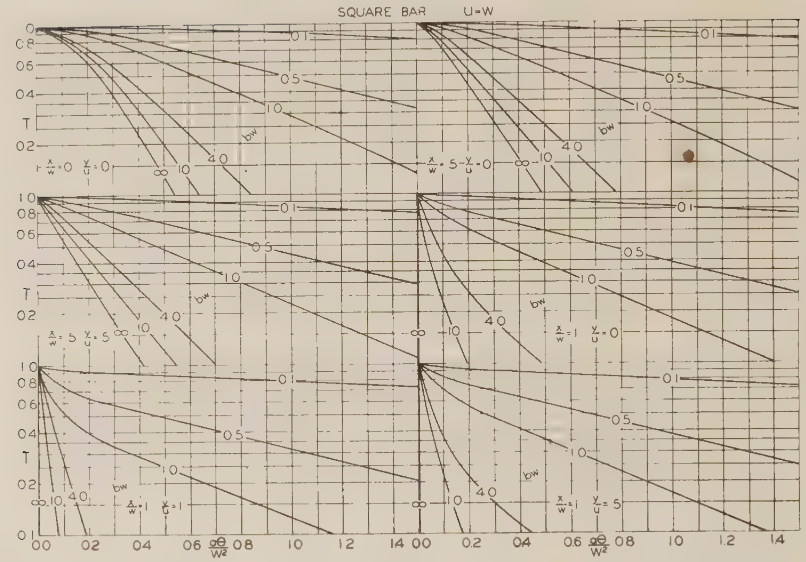

FIG. 11 COMBINED SOLUTION T, FOR POINTS IN INTERIOR OF AN INFINITE SQUARE BAR; ($u = w$)

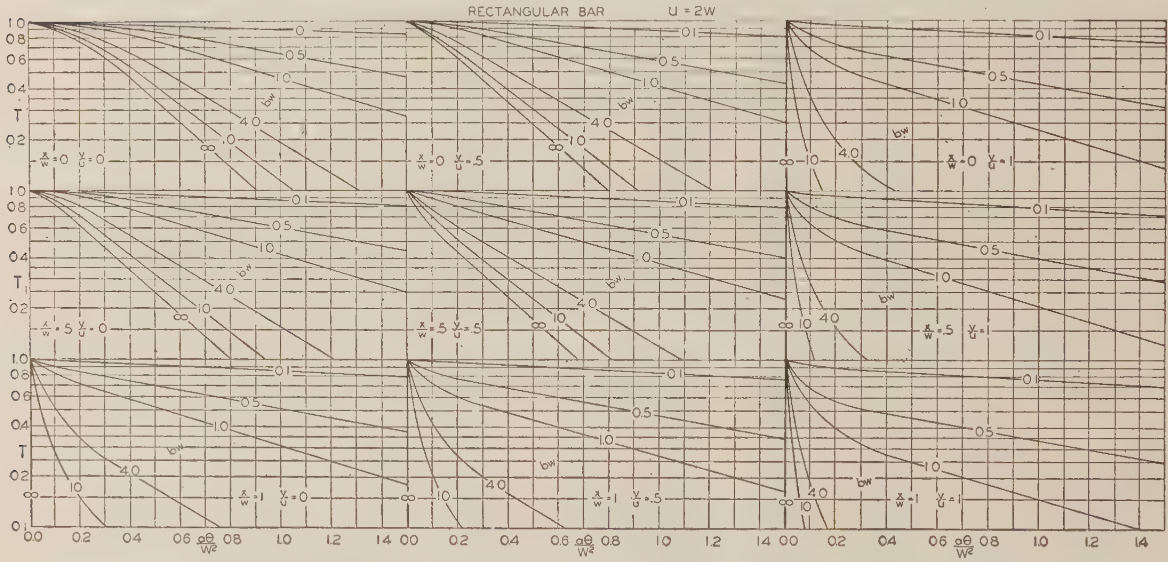

FIG. 12 COMBINED SOLUTION T, FOR POINTS IN INTERIOR OF AN INFINITE RECTANGULAR BAR; ($u = 2w$)

and for

$a\theta/u^2 = 0.2$ and $bu = 2.0$, $T_y = 0.80$ (estimated by interpolation).

Then

$$T = T_x \cdot T_y = 0.564 \times 0.80 = 0.451$$

This same result is obtained directly from curves for $x/w = 0.5$ and $y/u = 0.5$ in Fig. 12. For $a\theta/w^2 = 0.8$ and $bw = 1.0$, the value of T is seen to be 0.45, which is a close check.

CONCLUSIONS

Solutions to two-place accuracy may be obtained by interpolating in the curve sheets Figs. 4 to 8, inclusive, and Figs. 11 and 12, which were constructed from the values of T_x in Tables 1 to 5, inclusive.

More accurate solutions are obtained by solving Equation [3] directly. The first term of the series in Equation [3] is sufficient for three-place accuracy when $a\theta/w^2$ is greater than 0.3. The first two terms should be used for three-place accuracy when $0.1 < a\theta/w^2 < 0.3$.

ACKNOWLEDGMENT

The authors are gratefully indebted to Prof. T. B. Drew and Prof. W. J. Wohlenberg for many helpful suggestions in this work.

Logographs

By R. S. Tour[1]

A different type of chart[2] is presented for graphical solution of equations of the form $T^pU^qV^rW^s = K$. The charts are called "logographs" as distinct from nomographs and depend basically on the addition of logarithms. Logograph charts develop from the fact that a straight line drawn on semilog paper represents a function of the form: $\log y = a + bx$, or $x = c + n \log y$. The construction of logographs is explained and exemplified in the development of a chart for the calculation of heat-transfer coefficients in turbulent flow. As examples of more elaborate logographs, charts are also offered for the turbulent flow of fluids in pipes and for the flow of fluids through sharp-edged orifices. The equations underlying the last two charts represent new forms of the standard expressions and are briefly discussed and their limitations indicated.

To those who have constructed or used alignment charts involving four or more variables, the attendant difficulties are evident. The reference or blank scales that become part of such nomographs, the length of the scales for wide ranges in the values of the variables, the obliqueness of the intersecting lines that must sometimes be used with resultant inaccuracy, serve to multiply the difficulties. The construction of such alignment charts is also no simple matter since each of the lines requires a special scale laboriously laid out by hand.

These difficulties are particularly evident in nomographs for evaluating heat-transfer expressions wherein the variables may number seven, eight, or more, covering ranges for some of perhaps 10^6. In addition to special scales for each variable there will also be "dummy" scales (or their equivalent) numbering three less than the number of variables. The progressive series of alignments that must be made between the scales, taken in proper order, may make the use of the nomograph so tedious and confusing as to neutralize its value for rapid computations. Especially is this the case if a solution is desired for one of the variables other than that for which the nomograph was originally designed.

A fundamentally different type of chart eliminating most of the objectionable features of nomographs is described in this paper. It is applicable in general to functions expressible in the form

$$T^pU^qV^rW^s = K \qquad [1a]$$

$$p \log T + q \log U + r \log V + s \log W = \log K \qquad [1b]$$

The T, U, V, W terms represent variables, with p, q, r, s as constant exponents which may be either positive or negative, integers or fractions. The K is a constant, dependent on the function and on the dimensions ascribed to the individual variables. Expressions such as Equation [1a] arise frequently in engineering design and practice, especially in the fields of heat transfer and fluid flow. They lend themselves neatly to a graphical solution based on the addition of logarithms.

The principle involved in the computation charts offered here is based on the fact that the equation of any straight line drawn on semilog co-ordinate paper is of the form

$$\log y = a + bx$$

or

$$x = c + n \log y$$

The location of the line determines the constants c (or a) and the slope of the line defines n (or b). If each of the variables in Equation [1b] be plotted as a straight line on semilog paper with the c and n properly chosen, the linear (x) co-ordinates for any true set of values of the variables may be numerically added to accord with Equation [1b]. It is to be noted that a numerical addition is here substituted for the progressive series of graphical alignments used in nomographs. The process of addition is the quicker for such functions and is not subject to the manipulative errors of a series of alignments. But the chart used in this way is obviously not an alignment chart (i.e., nomograph); it is here descriptively titled a "logograph."

Logograph for Heat Transfer in Turbulent Flow

Recently a nomograph was published (1)[3] for the Dittus-Boelter equation for determining heat-transfer film coefficients with turbulent flow in smooth pipes. The equation used to determine these coefficients is of the Nusselt type and is generally given in any consistent units as

$$h = 0.0243 \frac{k}{D}\left(\frac{Du\rho}{Z}\right)^{0.8}\left(\frac{ZC}{k}\right)^{0.4} \qquad [2a]$$

This may be rewritten in an alternative form to eliminate fractional exponents

$$\frac{C^2k^3\rho^4u^4}{DZ^2h^5} = 1.18 \times 10^8 \qquad [2b]$$

In the usual mixed engineering units (specified) this becomes

$$\frac{C^2k^3\rho^4u^4}{DZ^2h^5} = 3.43 \times 10^{-3} \qquad [2c]$$

C = specific heat, Btu/(lb)(deg F)
k = thermal conductivity, Btu/(sq ft)(hr)(deg F/ft)
ρ = density, pcf
u = linear fluid velocity, fps
D = pipe diameter, in.
Z = viscosity, poises
h = heat-transfer coefficient, Btu/(sq ft)(hr)(deg F)

This equation with its seven variables, six independent, is an example of an expression for which a nomograph is not entirely satisfactory.

[1] Department of Chemical Engineering, University of Cincinnati.

[2] The charts (Figs. 1, 2, 3, 4) offered in this paper are simplified tracings from originals made on standard 11-in. × 17-in. three-cycle semilog paper. For convenience in size reduction and in printing, the tracings for this publication carry a minimum of co-ordinate lines. They are thus not satisfactory for computation purposes, but serve here merely to show the construction methods and use of logograph charts. If desired, the reader may transfer the lines shown to standard semi-log paper for more accurate computations. Full-size (11-in. × 17-in.) lithoprinted copies of the original charts are in use at the University of Cincinnati, and a limited number of these lithoprints will be available for distribution on request.

Contributed by the Heat Transfer Division and presented at the Cincinnati Section Meeting, Cincinnati, Ohio, Oct. 2–3, 1945, and at the Annual Meeting, New York, N. Y., Nov. 26–29, 1945, of The American Society of Mechanical Engineers.

[3] Numbers in parentheses refer to the Bibliography at the end of the paper.

A logograph for making computations from Equation [2c] is shown in Fig. 1. The illustrative example given on the chart shows the general method of using logographs. It is the same example used by Ryant (1) for his alignment chart, wherein it is desired to find the heat-transfer coefficient (h) for hot water flowing at a velocity (u) of 8 fps through 1-in-diameter (D) tubes, the specific heat (C), conductivity (k), density (ρ), and viscosity (Z) of the water being specified. Each of the known variables is in turn located on the logarithmic scale (ordinates) and from the appropriate line for that variable, a reading R (abscissa) is determined. The six R's are numerically added and the sum subtracted from the chart constant A. The result is the R (abscissa) for the remaining variable, in this case the heat-transfer coefficient (h), which is then determined from its line on the chart. Six R's are read, an addition and subtraction made, and the unknown variable (which can be any one of the seven) is determined.

Construction of Logographs

To construct a logograph for some specified function, it is first necessary to rewrite the function in the form of Equation [1a]. Having done this, the following procedure is suggested:

1 Choose semilog paper with N logarithmic cycles to cover some selected range in the magnitude of the variables. This choice is flexible since the range for any variable can be increased from 10^N to 10^{2N} to 10^{3N} by the addition of successive constants to the reading for that variable (see Fig. 1). In general, three-cycle semilog paper is quite satisfactory.

2 Select dimensions of suitable magnitude for each of the variables in Equation [1] so that the same logarithmic scale may serve for all variables. This avoids confusion in the use of the scales. Then modify the value of the constant K in original Equation [1a] to agree with the dimensions which are selected.

3 Transform the modified Equation [1a] into the logarithmic form of Equation [1b]

$$(p \log T) + (q \log U) + (r \log V) + (s \log W) = \log K \quad [3]$$

Although as written here the signs are positive, it should be remembered that some of the exponents (p, q, r, s) may be inherently negative. In the general case, a negative sign can be applied throughout in Equation [3]. The use of the + or — is a matter of convenience; a negative sign throughout leads to a logograph which is a mirror image of that with a positive sign.

4 A scale factor or modulus M for the linear co-ordinates (abcissas) is selected so that the linear divisions will cover some desirable range in the value of the logarithms of the variables. The factor M is used as a multiplier in Equation [3].

$$(Mp \log T) + (Mq \log U) + (Mr \log V) + (Ms \log W) = M \log K \quad [4]$$

The modulus M may be positive or negative and its magnitude is a matter of judgment. Its value controls the slope of all the lines and the relative accuracy of the readings of ordinates versus abscissas. The size of M is limited by the ranges to be covered by the various lines on the chart.

5 Added convenience in using the chart is obtained if all the linear co-ordinates (abscissas) are positive. Accordingly, add some specific positive constant of sufficient magnitude (e, f, g, h) to each of the variable terms of Equation [4]

$$(e + Mp \log T) + (f + Mq \log U) + (g + Mr \log V) + (h + Ms \log W) = e + f + g + h + (M \log K) = A \quad [5]$$

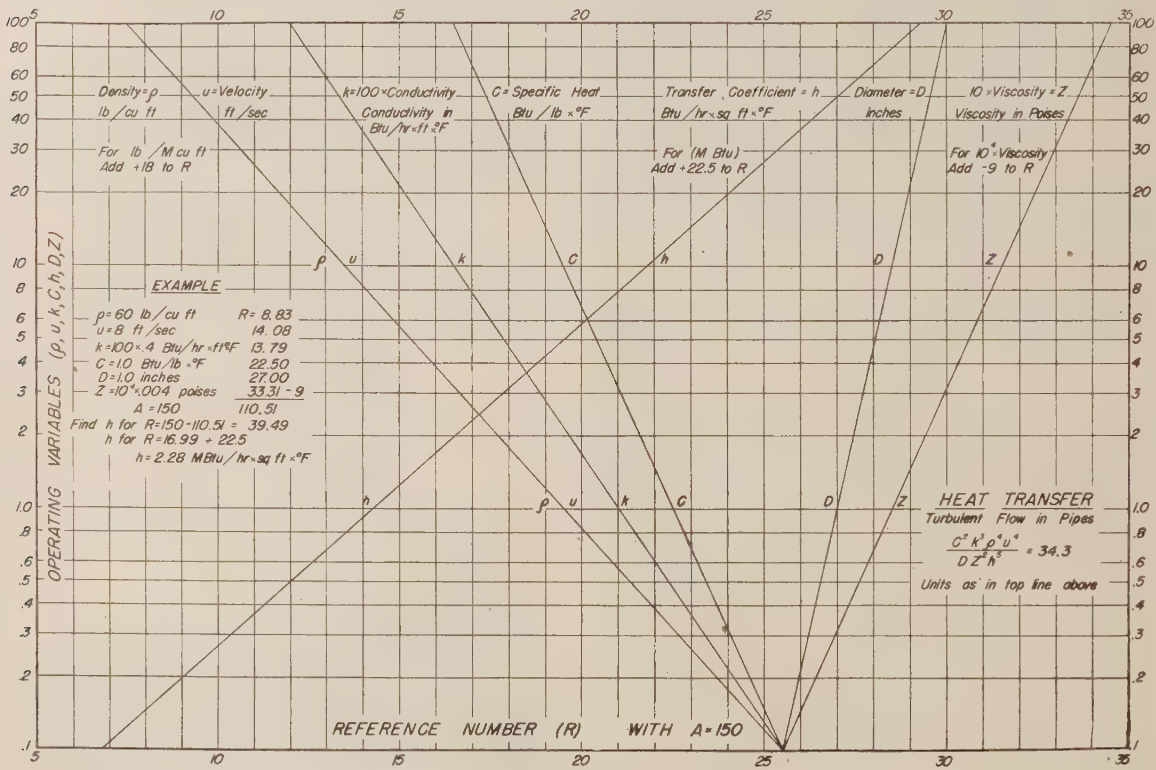

Fig. 1 Logograph for Heat Transfer

A wide choice exists for these addition constants. Their values control the relative locations of the lines on the chart. The constants should be selected so that the lines cross each other as seldom as possible and then not at too small an angle. The sum total A of the constants in Equation [5] should be some round number easily kept in mind, e.g., 150 (as in Fig. 1), and the value of A must be specified on the chart.

6 Each of the separated terms in parentheses in Equation [5] may now be plotted against the linear scale R, each plot resulting in a straight line on the semilog paper, all represented by the generalized expression

$$R_y = C + Mn \log Y$$

Here R_y refers to the abscissa readings for any one of the variables (T, U, V, or W) represented by Y, with n indicating its power (p, q, r, or s), and C the corresponding addition constant (e, f, g, or h). The lines for R_y may be located on the chart as follows: If the logarithmic scale ranges from 10^b at the bottom to 10^t at the top, then the intercepts at the bottom and top of the logograph for each of the variables Y are, respectively

$$R_y = C + (Mn)b \text{ (at bottom)}$$
$$= C + (Mn)t \text{ (at top)}$$

A line joining the bottom and top intercepts for each variable completes the chart.

7 If it is desired to increase the size of the units (or dimensions) of any one of the variables by a factor k, it is only necessary to add to reading R for that variable a quantity $+Mn \log k$. For example, a quantity expressed in inches on the chart may be read as feet by adding $+Mn \log 12 = +1.079Mn$ to the R_y obtained. Conversely, feet may be read as inches if the addition is $+Mn \log (1/12) = —1.079\, Mn$. The signs of M and n must not be neglected. A similar device may be used to change the range for any of the variables, which is equivalent to changing the size of the units for that variable by some power of 10.

8 Some expressions for which a logograph is desired may have one or more variables stated as a function of some more specific variable, e.g., $Y = F(y)$. In such cases the logograph is first designed for Y as described, but the straight line is replaced by a curve, the points for which are calculated so that a reading of y on the logarithmic scale calls for an R_y as determined by $Y = F(y)$, i.e., $R_y = M \log F(y)$.

Construction of Fig. 1. The foregoing directions, as applied specifically to the construction of the logograph in Fig. 1, may serve to clarify the procedure. The function for which the chart is to be designed has been given and the units specified under Equation [2c] as follows

$$\frac{C^2k^3\rho^4u^4}{DZ^2h^5} = 3.43 \times 10^{-3} \ldots\ldots\ldots\ldots\ldots [6]$$

The working range desired for each of the variables is

C: 10^{-1} to 10^1 = (10^{-1} to 10^1)
k: 10^{-3} to 10^0 = (10^{-1} to 10^2) $\times$ (10^{-2})
ρ: 10^{-4} to 10^2 = (10^{-1} to 10^2) $\times$ (10^{-3}) and (10^{-1} to 10^2)
u: 10^{-1} to 10^2 = (10^{-1} to 10^2)
D: 10^{-1} to 10^2 = (10^{-1} to 10^2)
Z: 10^{-5} to 10^1 = (10^{-1} to 10^2) $\times$ (10^{-4}) and (10^{-1} to 10^2) $\times$ (10^{-1})
h: 10^{-1} to 10^5 = (10^{-1} to 10^2) and (10^{-1} to 10^2) $\times$ (10^3)

Three-cycle ($N = 3$) semilog paper is suitable for these ranges, with double ranges required for ρ, Z, and h. For the log scale it seems best to take $b = —1$, $t = 2$, $N = t — b = 3$. To use the same ordinate readings (log scale) for all the variables it is necessary to express k as 100 times the conductivity (standard units) and Z as 10 times the viscosity (in poises), i.e., viscosity in decipoises. Further modifying Equation [6] to allow for this change in the units of k and Z

$$\frac{C^2k^3\rho^4u^4}{DZ^2h^5} = 34.3 \ldots\ldots\ldots\ldots\ldots\ldots [7]$$

Expressing Equation [7] in logarithmic form and applying a modulus $M = —1.5$

$$—3 \log C — 4.5 \log k — 6 \log \rho — 6 \log u$$
$$+1.5 \log D + 3 \log Z + 7.5 \log h = —2.30$$

To hold the number of intersections of the lines of the logograph to a minimum (see Fig. 1), the following addition constants have been chosen

Variable	Term	Bottom intercept	Top intercept
C	$22.5 — 3 \log C$	$22.5 + 3.0 = 25.5$	$22.5 — 6.0 = 16.5$
k	$21.0 — 4.5 \log k$	$21.0 + 4.5 = 25.5$	$21.0 — 9.0 = 12.0$
ρ	$19.5 — 6 \log \rho$	$19.5 + 6.0 = 25.5$	$19.5 — 12.0 = 7.5$
u	$19.5 — 6 \log u$	$19.5 + 6.0 = 25.5$	$19.5 — 12.0 = 7.5$
D	$27.0 + 1.5 \log D$	$27.0 — 1.5 = 25.5$	$27.0 + 3.0 = 30.0$
Z	$28.5 + 3 \log Z$	$28.5 — 3.0 = 25.5$	$28.5 + 6.0 = 34.5$
h	$14.3 + 7.5 \log h$	$14.3 — 7.5 = 6.8$	$14.3 + 15.0 = 29.3$
Add	152.3	Chart constant, A, = 152.3 — 2.3 = 150	

It remains only to construct the logograph and indicate the units applicable to each line (see Fig. 1). The reason for choosing the apparently haphazard constants, such as 22.5, 21.0, etc., is that crossing of lines has been largely avoided with six of the lines having a common bottom intercept at 25.5. The sum, A, of the constants is 150; hence to evaluate any one variable in Equation [7] in terms of the other six

$$R_1 = 150 — (R_2 + R_3 + R_4 + R_5 + R_6 + R_7)$$

The extended (doubled) scales with the range increased by 10^3 in each case for ρ, Z, and h are calculated by adding $+Mn \log 10^3 = —1.5 \times 3n = —4.5n$ for enlarging the unit 10^3 times and adding $+4.5n$ for reducing the unit 10^3 times. Applying the appropriate values of n

For ρ: add $+4.5 \times (+4) = +18$ (smaller unit, factor = 10^{-3})
For Z: add $+4.4 \times (—2) = —9$ (smaller unit, factor = (10^{-3})
For h: add $—4.5 \times (—5) = +22.5$ (larger unit, factor = 10^3)

An example illustrating how the lines on a logograph may be moved relative to each other by changing the addition constants is shown in Fig. 2, a logograph for the same Equation [2c]. Here, $b = —1$ and $t = 2$ both as before, $M = —2$, and the sum of the constants, A, totals 100. The distribution of the constants is such as to give a chart entirely different in appearance and probably less desirable than that in Fig. 1.

Application of Logographs

Graphical solutions become desirable for application in engineering design in so far as they simultaneously offer the qualities of simplicity, speed, and accuracy. Charts should be versatile in the matter of range of the variables included and if possible in the units in which those variables are measured, and they should visually reveal the comparative effects of changes in magnitude of the individual variables. They should require a minimum of instruments or special facilities for their use. Some of these criteria of good charts may be incompatible and must therefore be foregone in special applications. Thus there are conditions under which the standard nomograph is most desirable, others for which the logograph is definitely called for, and still others where specialized diagrams are particularly suited.

The simplicity of the logograph chart for functions of the form

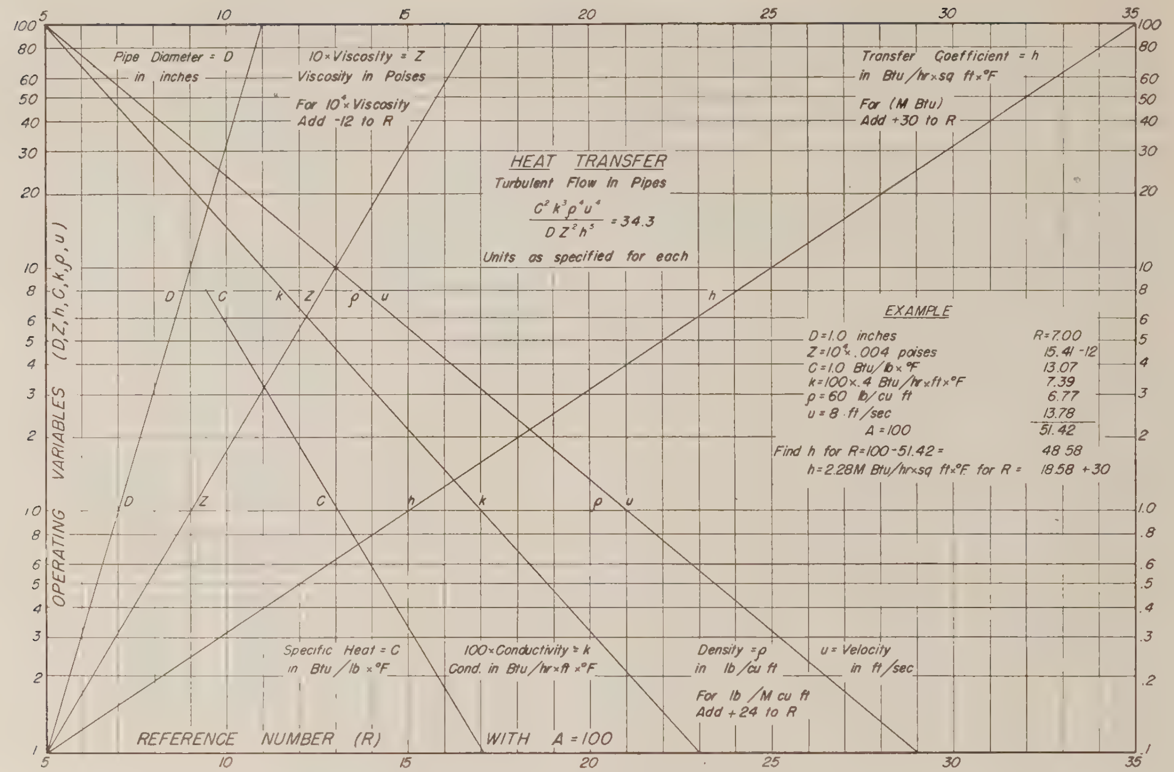

Fig. 2 Modified Logograph for Heat Transfer

of Equation [1*a*] is evident. Practically unlimited ranges (10^6 in Fig. 1) are possible for any of the variables, a change in the units for any one of the quantities may be obtained simply by the addition of a constant, and uniform accuracy is available for all the variables in any combination of ranges. The order in which the readings for the variables are taken from the chart is of no importance, and any one of the variables may be the unknown. In constructing the ordinary logograph, the plot for each variable is a straight line and no special scales need be drawn on or applied to any of the lines.

Various departures from the construction and use of logograph charts as here described may be found desirable or necessary in special applications. For example, instead of using logarithmic scaled paper, the lines of the chart may have their scales plotted directly on them. The location of the lines may become unimportant if they are considered merely as logarithmic vectors, with lengths taken off each of the lines from some point of reference, the various lengths then being added vectorially. Such a procedure may be accomplished wholly graphically by using a pair of triangles to lay off vectors parallel to those specified on the chart, and transposing the proper lengths with a pair of dividers. This method of addition is practical only when not too many vectors are to be so added and when the ranges for the individual vectors are comparatively small. It may be used to accomplish results not possible by numerical addition, e.g., in the Eiffel diagrams for airplane-propeller design (2). Eiffel charts have their scaled vectors so sloped that the addition of abscissa components develops one function of the variables while the ordinate addition determines another, the interrelation of the two functions being defined by some charted line intersected by the graphical vectorial addition.

Special purpose diagrams notwithstanding, numerical addition logographs plotted on semilog paper, as here described, will best serve for repetitive computations of functions of the form of $T^p U^q V^r W^s = K$, which so often arise in engineering design. Logographs cannot, however, replace nomographs where the equation to be solved involves an addition operation as well as a multiplication.

Two more logograph charts are offered in this paper not only as examples of somewhat more complicated logograph construction with appropriate explanation, but also for their intrinsic value in the calculation of industrial problems. For each of the two subsequent logographs, "turbulent flow of fluids in pipes," Fig. 3, and "fluid flow through orifices," Fig. 4, the basic equations are given and their source or development explained.

Turbulent Flow in Pipes

Although Equation [2] involves seven variables, it represents in form a simple type of logograph. One involving a curve develops from Fanning's equation for turbulent flow of fluids in pipes. Before presenting the logograph, a brief explanation is given of the underlying equation since it has not appeared in the literature in the form used here.

The variables involved in turbulent flow in pipes with units modified where necessary to suit the range of a three-cycle logograph are as follows:

Q = mass flow rate, M lb per min

P_1, P_2 = initial and final pressures, psia

ρ = density of the fluid, pcf

D = diameter of pipe, in.

f = friction coefficient $\approx 0.00759(DZ/Q)^{0.2}$

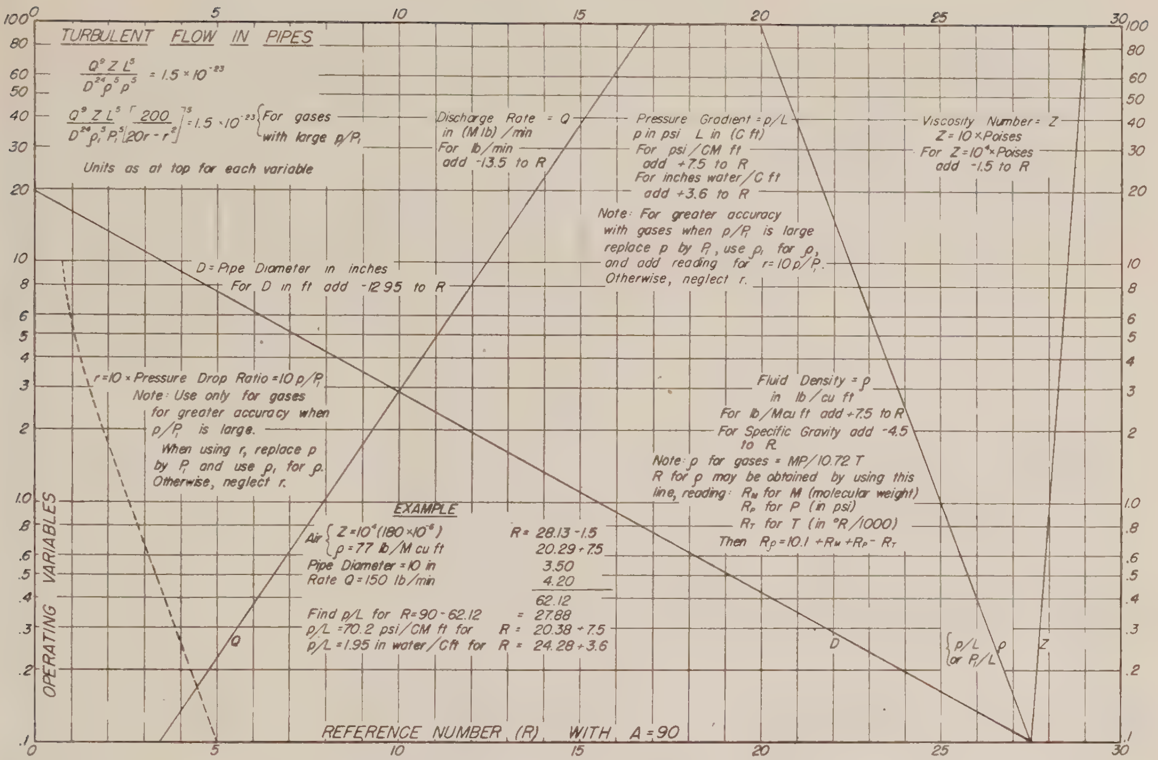

FIG. 3 LOGOGRAPH FOR TURBULENT FLOW IN PIPES

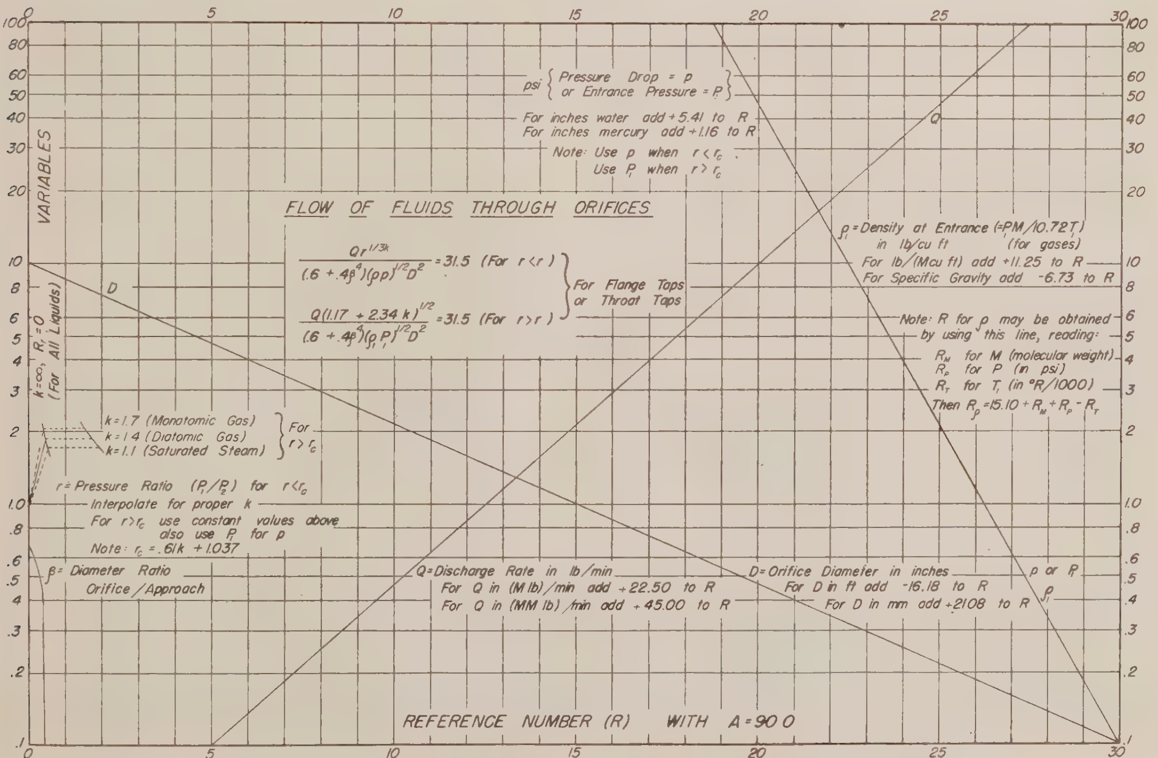

FIG. 4 LOGOGRAPH FOR FLOW OF FLUIDS THROUGH ORIFICES

L = length of pipe, ft in units of 100
p = pressure drop, psi
p/L = pressure gradient in the pipe line, psi/Cft
r = pressure drop ratio = $10p/P_1$
Z = viscosity of the fluid, decipoises
N = Reynolds number = 37,900 Q/DZ

In the foregoing units, assuming isothermal expansion and neglecting a logarithmic term which arises, Fanning's equation for turbulent flow leads to

$$Q = 3.215 \times 10^{-4} \sqrt{\frac{(P_1^2 - P_2^2)\rho_1 D^5}{fLP_1}}$$

This may be expressed by

$$\frac{fQ^2}{\rho D^5}\left(\frac{L}{p}\right) = 2.067 \times 10^{-7} \left\{\begin{matrix}\text{For all liquid flow or for} \\ \text{gases with small } p/L\end{matrix}\right\}$$

$$\frac{fQ^2}{\rho_1 D^5}\left(\frac{L}{P_1}\right)\left(\frac{200}{20r - r^2}\right) = 2.067 \times 10^{-7} \left\{\begin{matrix}\text{for gas flow} \\ \text{with large } p/L\end{matrix}\right\}$$

The coefficient of friction f is now expressed according to $1/f = 16(N)^{0.2} = 131.8\,(Q/DZ)^{0.2}$. The use of a constant exponent on N in any expression for f is not acceptable for smooth pipe or for pipe with specified roughness, but is nevertheless supported experimentally for industrial piping with its relative roughness decreasing (though its absolute roughness increases) for the larger pipe diameters. Inserting this expression for $1/f$ leads to

$$\frac{Q^9 Z}{\rho^5 D^{24}}\left(\frac{L}{p}\right)^5 = 1.5 \times 10^{-23} \left\{\begin{matrix}\text{for all liquid flow or for} \\ \text{gases with small } p/L\end{matrix}\right\} \quad \text{[8a]}$$

$$\frac{Q^9 Z}{\rho_1^5 D^{24}}\left(\frac{L}{P_1}\right)^5\left(\frac{200}{20r - r^2}\right)^5 = 1.5 \times 10^{-23} \left\{\begin{matrix}\text{gas flow with} \\ \text{large } p/L\end{matrix}\right\} \quad \text{[8b]}$$

Equations [8] are quite satisfactory for industrial piping up to Reynolds numbers of several million and offer an accuracy within a few per cent for Q. Greater precision is not required in ordinary practice since corrections for variations in original roughness of the pipe, for the effect of scaling or corrosion, and for the equivalent length of installed fittings are at best but approximate.

It must be remembered that Fanning's equation is in itself inaccurate in that it assumes isothermal gas expansion and also omits a logarithmic term. The equation may show considerable error for gas flow with large proportionate pressure drops and small frictional resistance. The inaccuracy increases nearly directly with pD/fLP_m where P_m is the logarithmic mean of P_1 and P_2; it becomes objectionable (depending on the accuracy desired) when the pressure gradient p/L exceeds some 100 times fP_m/D for gases, the error in Q then being 2 per cent (with units for p, L, P, D as previously specified). Fortunately this situation seldom arises in industrial practice.

A logograph for Equations [8] (a or b) is given in Fig. 3. The [8a] portion of the equation is a simple logograph covering five variables. The [8b] portion, used when greater accuracy is desired for gases and vapors that expand appreciably during the flow, substitutes P_1 for p in p/L with ρ taken as ρ_1 (compare Equation [8a] with [8b]) and adds a curve for the function of $r(=10p/P_1)$. This chart illustrates the use of a curved line.

An innovation, included in Fig. 3, further indicates the versatility of the logograph: R for ρ of the gas can be determined graphically from its molecular weight, pressure, and temperature if the gas is considered to be ideal. This auxiliary use of any straight line of a logograph is a direct consequence of the fact that for each variable, the line on the chart reads a value of $R_y = C + Mn \log Y$. The line can thus be used as a slide rule for calculation by logarithms.

Some sample computations from Fig. 3 may not be amiss. Air, for which the viscosity is 180×10^{-6} poises, is to be transmitted through a 10-in-diam flue at nearly atmospheric conditions (60 F, 30 in. Hg) with ρ = 77 lb per 1000 cu ft. For a flow of 150 lb per min (1950 cfm), the pressure gradient is desired. The solution for this problem is outlined in Fig. 3 and need not be repeated here. The p/L in this case is small and no consideration need be given to the expansion ($r = 10p/P_1$) during the flow.

Another example will show the use of r. Here high-pressure air (60 F, P_1 = 100 psia) is being delivered through a 2-in. pipe at a rate of 150 lb per min. The pressure gradient is desired. The solution is shown both neglecting r and including r. If desired, the $\rho_1(=0.524$ pcf) can be obtained from the chart with $R\rho = 10.07 + 21.34 + 20.0 - 25.71 = 25.70$.

	Neglecting r	*Including r*
Air { $Z = 10^4(180 \times 10^{-6})$ R =	28.13 — 1.5	28.13 — 1.5
Air { $\rho_1 = 0.524$ pcf	25.70	25.70
Pipe diameter = 2 in.	11.89	11.89
Rate = 0.15 M lb per min	4.20	4.20
P_1/L = 100 (for 100 ft pipe)		20.0
	68.42	88.42
Find p/L		
for R = 90 — 68.42 =	21.58	
p/L without r correction =	23.3 psi/Cft	
Find $r = 10p/P_1$		
for R = 90 — 88.42 =		1.58
r = 2.70 or p/L corrected =		27.0 psi/Cft

Fluid Flow Through Orifices

An example of a more elaborate logograph is shown in Fig. 4. Again the equation applying is first discussed since it has not been given previously. The basic equation for the flow of fluids through a standard sharp-edged thin-plate orifice is given in hydraulic form by

$$Q = 31.5D^2KY\sqrt{\rho_1 p} \quad \text{[9]}$$

where

Q = mass discharge rate, lb per min
D = diameter of orifice, in.
K = orifice coefficient (approach factor included)
Y = expansion factor for the gas
ρ_1 = entrance density, pcf
p = pressure drop, psi
P_1, P_2 = initial and final pressures, psia
β = diameter ratio; orifice/approach
r = pressure ratio: $P_1/P_2 > 1.0$
k = specific-heat ratio

A series of experiments conducted by the U. S. Bureau of Standards (3) has determined KY in the hydraulic form of flow, Equation [9], for β up to 0.6, and for expansion ratios r from 1.0 to critical r_c (r_c corresponds to sonic velocities in the fluid stream). The experimental data are very well correlated (to 1 per cent) by $KY = (0.6 + 0.4\beta^4)r^{-1/3k}$ for flange-tap or throat-tap pressure readings. This expression is sufficiently accurate for the purposes of this paper and will serve for liquids by taking $k = \infty$.

More recent and elaborate experimentation (4) has indicated that the coefficient is also a function of the actual pipe diameter and of Reynolds number, but this refinement is unnecessary here.

The simple expression for KY is substituted in Equation [9] for flows at pressure drops below critical r_c. For flows with drop greater than indicated by r_c, the effective r equals r_c, the KY for the orifice becomes constant, and the effective pressure drop p is $P_1(r_c - 1)/r_c$. Thus

$$\frac{Qr^{1/3k}}{(0.6 + 0.4\beta^4)D^2(\rho_1 p)^{1/2}} = 31.5 \text{ (for gases with } r < r_c) \ldots\ldots \quad [10a]$$

Take $k = \infty$ and $r_c = \infty$ in Equation [10a] $\left\{\begin{array}{l}\text{for liquids at}\\ \text{all values of } r\end{array}\right\}$

$$\frac{Qr_c^{1/3k}}{(0.6 + 0.4\beta^4)D^2(\rho_1 P_1)^{1/2}}\left(\frac{r_c}{r_c - 1}\right)^{1/2} = 31.5 \left\{\begin{array}{l}\text{for gases with}\\ r > r_c\end{array}\right\} \ldots\ldots\ldots \quad [10b]$$

The development of the logograph for Equation [10a] gives the usual straight lines for Q, D, ρ_1, and p. A curve is calculated for the term $(0.6 + 0.4\beta^4)$ up to $\beta = 2/3$; measurements are undependable beyond that value.

The principal limitation of the logograph arises in plotting the term $r^{1/3k}$. As in nomographs, functions with mixed variables cannot be represented except by a family of scales or lines. In Fig. 4 lines for r (up to r_c) are given, respectively, for $k = \infty$ (all liquids), and for $k = 1.7, 1.4, 1.1$, allowing for interpolation of k between these values. It is evident from the chart that the effect of the value of k for gases is small and a rough interpolation is satisfactory. No addition constant is included in the logarithm of the r function, hence for liquids with $k = \infty$, the R_r is zero, i.e., r and k are both neglected in using the chart for liquids.

The logograph for Equation [10b] is the same as for [10a] except that p is replaced by P_1 and the function of r_c becomes a constant depending only on k for the particular gas involved. It can be shown that

$$r_c = \left(\frac{k+1}{2}\right)^{\frac{k}{k-1}}$$

Although calculations for the logograph may be made directly from the foregoing expression for r_c, simpler empirical relations are suggested for extended calculations as follows

$$r_c \approx 0.61k + 1.037 \text{ (to 0.1 per cent)}$$

$$r_c^{1/3k}\left(\frac{r_c}{r_c - 1}\right)^{1/2} \approx \sqrt{1.17 + \frac{2.34}{k}} \text{ (to 0.1 per cent)}$$

In using Equation [10b] or the chart for gas flow with r far into the supercritical range, it must be remembered that the orifice calibration has not been experimentally determined in that region. The assumption that KY is constant for $r > r_c$ seems logical but may lead to some inaccuracy if carried too far. Orifices should not be used under conditions where r is much larger than r_c.

The logographs for Equation [10a] and [10b] may be combined into one if proper directions are given for its use. In this way Fig. 4 covers fluid flow through orifices for all cases and conditions: Liquids or gases for their complete range from $r = 1.0$ to $r = r_c$, and for $r > r_c$.

No example appears in Fig. 4, but two are given as follows: The simplest case is for liquid flow where $r (= P_1/P_2)$ is not involved. A sharp-edged orifice of 1 in. diam is being used in a 2-in. pipe line ($\beta = 0.5$) with water ($\rho = 62.4$ pcf). The pressure drop (p) is 10 in. Hg. Find rate of discharge (Q).

Orifice	$D = 1$ in.	$R = 15.00$
	$\beta = 0.5$	0.29
Water:	$\rho = 62.4$ pcf	19.41
Drop:	$p = 10$ in. Hg	22.50 + 1.16
		58.36
Find Q for $R = 90 - 58.36 =$		31.64
$Q = 360$ lb per min for $R =$		9.14 + 22.50

Using the same orifice as before for air ($k = 1.4$) with $P_1 = 100$ psia at 60 F ($\rho_1 = 0.524$ pcf) and $P_2 = 80$ psia in Case 1 (for $r < r_c$) or $P_2 < 53$ psia in Case 2 (for $r > r_c$), find the rate of discharge (Q).

		$r < r_c$	$r > r_c$
Orifice	$D = 1$ in.	$R = 15.00$	15.00
	$\beta = 0.5$	0.29	0.29
Air:	$\rho_1 = 0.524$ pcf	27.30	27.30
	$p = 20$ psi	21.37	
	$r = P_1/P_2 = 1.25$	0.17	
	$P_1 = 100$ psia		18.75
	$r > r_c$ for $k = 1.4$		1.70
		64.13	63.04
Find Q for $R = 90 - 64.13 =$		25.87	
	Q for P_2 at 80 psia =	60.6 lb per min	
Find Q for $R = 90 - 63.04 =$			26.96
	Q for $P_2 < 53$ psia =		84.7 lb per min

Acknowledgment

The author wishes to express his gratitude to Prof. H. J. Garber and Prof. W. Licht of the University of Cincinnati for their invaluable assistance in offering suggestions, drawing the logographs, and checking the manuscript for this paper.

Some Effects of Work Positioning When Face-Milling Steel

By FRED W. LUCHT,[1] DETROIT, MICH.

All of the work that has been done and all of the observations which have been made to date on the subject of face-milling steel with carbide cutters have indicated clearly that the longest cutter life is obtained when (1) the cutters have double negative rake angles, and (2) the full depth of cut is taken along some definite corner angle. Until recently, not much thought had been given to the positioning of the work in relation to the cutter, and only in limited cases has any consideration been given to the fact that the radial engagement angle between the face of the tooth and the edge of the work where the cutting edge enters it should be negative. Milling operations are frequently found where the diameter of the face mill is too small to permit the proper positioning of the work to a setting which gives longest cutter life. Under such a condition, there seems to be no definite means available which will assist in determining the diameter of a face mill capable of producing the maximum number of pieces per grind. This problem of determining optimum cutter diameter for a given face-milling job, and the proper positioning of the workpiece in relation to the cutter, led to a series of studies, the results of which are reported in this paper.

Introduction

All of the work that has been done and all of the observations which have been made to date on the subject of face-milling steel with carbide cutters have indicated clearly that the longest cutter life is obtained when (1) the cutters have double negative rake angles, and (2) the full depth of cut is taken along some definite corner angle.

There are certain operating conditions in every milling-machine setup which should at all times be maintained as nearly ideal as possible. These objectives are design, manufacture, and sharpening of the cutter; power capacity, feed and speed of the machine; and a flywheel to smooth out the roughness obtained from the necessarily coarser-tooth cutters removing stock at increased table travel. But even after all this has been done, the cutter performance and the number of pieces obtained per cutter grind still will show noticeable variations as the work position is shifted at right angles to the direction of feed of the work past the cutter.

Until recently, not much thought had been given to the positioning of the work in relation to the cutter, and only in limited cases has any consideration been given to the fact that the radial engagement angle D, Fig. 1, between the face of the tooth and the edge of the work where the cutting edge enters it, should be negative. It is interesting to note that when this angle has been negative, the number of pieces per grind has at least been more consistent than when no attention at all was paid to it, even though the cutter may not have produced its maximum number of workpieces per grind.

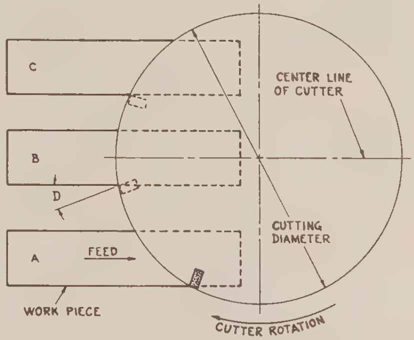

Fig. 1 Work Position Influences Face-Mill Life

It has also been found that a face-milling cutter usually gives a smooth cutting action together with the maximum number of pieces per grind when the workpiece is positioned about as shown at B. Position C generally rates second as to the number of pieces per grind, with quite consistent results. Position A rates third, with somewhat erratic results. This difference in results has been noticed for years while observing the face-milling of steel with high-speed steel cutters, but it has become more pronounced when milling steel with carbides.

Milling operations are frequently found where the diameter of the face mill is too small to permit the proper positioning of the work to a setting which gives longest cutter life. Under such a condition, there seems to be no definite means available which will assist in determining the diameter of a face mill capable of producing the maximum number of pieces per grind.

This problem of determining optimum cutter diameter for a given face-milling job, and the proper positioning of the workpiece in relation to the cutter, resulted in the investigation to be discussed.

Details of Test Procedure

Milling Machine. A No. 5-HM vertical milling machine in the engineering department of the author's company was used.

Power available:	
Main spindle, hp	20
Feed and rapid traverse, hp	5
Wattmeter:	
Main spindle, kw	30
Feed and rapid traverse, kw	12

Face-Milling Cutter. An 8-in-diam single-tooth face-milling cutter, enshrouded with an 18-in-diam × 4-in-thick steel flywheel, was used, Fig. 2. The tool-bit slot is parallel to the axis and the tool bits are clamped in place by setscrews. The combined weight of the cutter head flywheel tool unit was 255 lb.

Tool Bit. A total of twelve tool bits, as shown in Fig. 3, was used for this test. These tools were tipped with Carboloy Grade 78B, a general steel-milling grade.

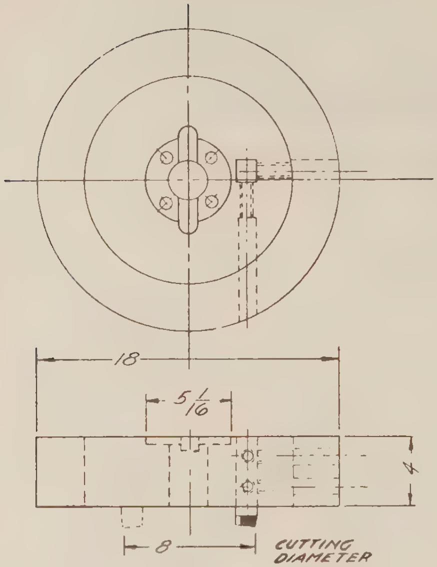

Fig. 2 To Eliminate Vibration, Cutter Was Enshrouded in a Flywheel

Both carbide and steel on all tools were rough-ground on a single-point tool grinder using a 60-grit silicon-carbide wheel. A 220-grit resinoid-bond diamond wheel was used for the final sharpening of the carbide only.

The cutting edges on all tools were inspected at 20 magnifications. Each edge along the corner angle and the chamfer was

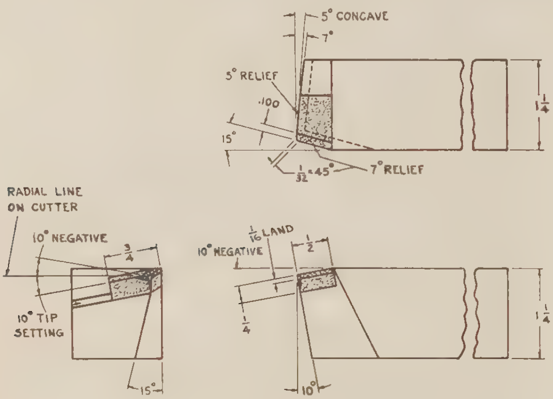

Fig. 3 All Tool Bits Used Were Ground to Same Cutting Angles

brushed lightly with a 320-grit silicon-carbide stone at an angle of about 45 deg to the face of the tool. This hand-honing removed any slight irregularities before the tool was assembled in the cutter head.

Positioning Tool in Cutter Head. Fig. 4 shows the method used to position the tool bit accurately in the tool-bit slot in the cutter head. Two sets of shims were required; one set, 0.100 to 0.200 in. thick, was used to maintain the 4-in. radius which gave the 8-in. cutting diameter; the second set, 0.180 to 0.310 in. thick, was used to maintain the 10-deg negative radial rake. This arrangement eliminated holding the corner location on the tool to close limits and facilitated correction for the stock which was

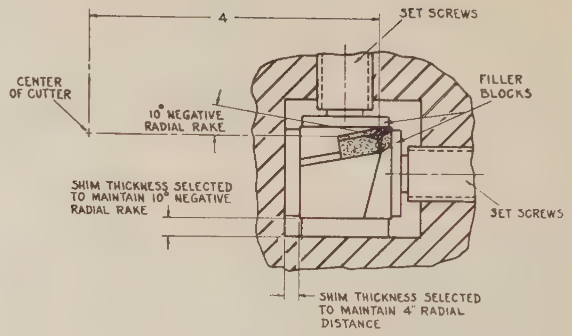

Fig. 4 All Tool Bits Were Accurately Positioned in Cutter Head by Aid of Shims

ground from the face of the tooth, the corner angle (side cutting-edge angle on the tool), and the face of the cutter (end cutting-edge angle on the tool) every time the tool bit was sharpened.

Work. For all face-milling runs, S.A.E.-1045 forged-steel billets were used. These billets were $1^1/_2 \times 3 \times 12$ in. in size. They were heat-treated and drawn to a Brinell hardness of 190 to 200.

Machine Setup. Fig. 5 shows the machine setup that was used while making all milling runs. In this setup the steel billet, or workpiece, was held rigidly in a plain vise in relation to the cutter, as shown.

Speed. The 8-in. face mill was operated at 238 rpm (498 sfpm) because previous runs had indicated that this speed gave the longest cutter life when milling S.A.E. 1045 steel having a Brinell hardness of 190 to 200.

Feed. The following feeds were used to permit exploration of a wide range of face-milling activity:

Table travel, ipm	Feed per tooth, in.
2	0.0084
$2^1/_2$	0.0105
3	0.0126
$3^1/_2$	0.0147

Depth of Cut. A depth of cut of 0.150 in. was taken on all runs. This is an average depth of cut which shows wear similar to that caused by deeper cuts, yet which does not involve the machining of excessive amounts of steel as would the deeper cuts.

Operating Detail and Observations. In order to determine the effect of work positioning in relation to the face mill while all other conditions were kept constant, as has been outlined, the following runs were made with the work:

1 Shifted horizontally.
2 Shifted in a direction perpendicular to the table travel.
3 Shifted to each one of the positions listed in Table 1.

The "angular position E" represents the position where the cutting edge on the 8-in-diam tool first contacts the work.

The dimension F gives the distance from the point at which the cutting edge on the 8-in-diam tool first contacts the work, to the 8 in. diam measured perpendicularly to the direction of feed. During the milling runs, the work was shifted through a series of positions as listed from one extreme position where E equaled 10 deg and F was 0.061, to the other extreme position where E equaled 127 deg 33 min and F was 6.437. At each of these two extreme positions, the outside diameter of the face mill overlapped the workpiece $^1/_{16}$ in.

Each tool was run until the cutting edge showed the first sign of breakout. This was detected either from the marking on the inner side of the chip which came from the cut; from the lines left on the work surface by the corner angle; or from the change

[a] Reported in deg-min.

in sound made by the milling operation. The distance traveled by the cutter, and the power readings, were recorded for analysis.

The cutting edge was inspected under a 20-power microscope and a record made in the form of an enlarged (to scale) freehand sketch showing the development of the cutting edge along the corner angle, the chamfer, and the face of the cutter. This sketch showed the width of the wear land behind the cutting edge along each of these three edges. It also showed the distance the cutting edge had worn back from the original corner-angle outline, and the width of the crater on the face of the tooth behind the cutting edge. All unusual signs of breakdown of the cutting edge were recorded on this sketch to serve as an aid in determining why the tool failed.

Using the twenty different work positions and the four different feed rates, a total of 190 runs was distributed as evenly as possible over the 12 tools. This gave 16 runs for each of 10 tools and 15 runs for each of the remaining two tools.

An average of the distances traveled up until the time of tool failure was plotted, Fig. 6, with its work position for each feed used. An average of all the runs made, irrespective of the feeds used for each work position, was also plotted.

The runs were made first at 2 ipm feed, i.e., 0.0084 in. feed per tooth. It was soon found that the various points arranged themselves in an irregular outline and also that the length of runs seemed to be somewhat erratic. Later, many additional runs were made at 0.0105, 0.0126, and 0.0147 in. feed per tooth, and it was found that not only did each set of runs follow the same general pattern but also that the lengths of runs were much more consistent than were those for the 0.0084-in. feed per tooth.

Analysis of How Tooth Contact Affects Cutter Life. To assist in determining why all the curves followed a definite general pattern, an enlarged wooden model, as shown in Fig. 7, was made of the cutter-work setup.

The model is shown in outline in Fig. 8 and is 10 times actual size. The base of the model is divided into angular spacing about a pivot point C. The block D, representing an exact 10-times enlargement of the cutting portion of the tool, is mounted on the end of the arm so that the intersection of the 15-deg corner angle and the 5-deg concavity angle is at a 40-in. radius.

Ten work blocks were made, as shown in Fig. 9, to the forms given in Table 2. This represents the exact contour cut by the cutter tooth when the entrance portion of the work is located at each one of the respective angular work positions.

To determine the type of contact for any given angular position of the cutter tooth, the work block for that angular position was placed against the guide block and slid past the 40-in. radius for a distance comparable to the feed per tooth, i.e., 0.105 in. for a 0.0105-in. feed per tooth. The cutter tooth was then swung in the direction shown until it contacted the workpiece. The type of tooth contact was observed. This procedure was repeated for each angular position. The results were compiled and the proper sequence of tooth contact for each position was recorded.

Figs. 10 to 18, inclusive, are close-up views of the various possible types of initial contacts between the cutter tooth and the

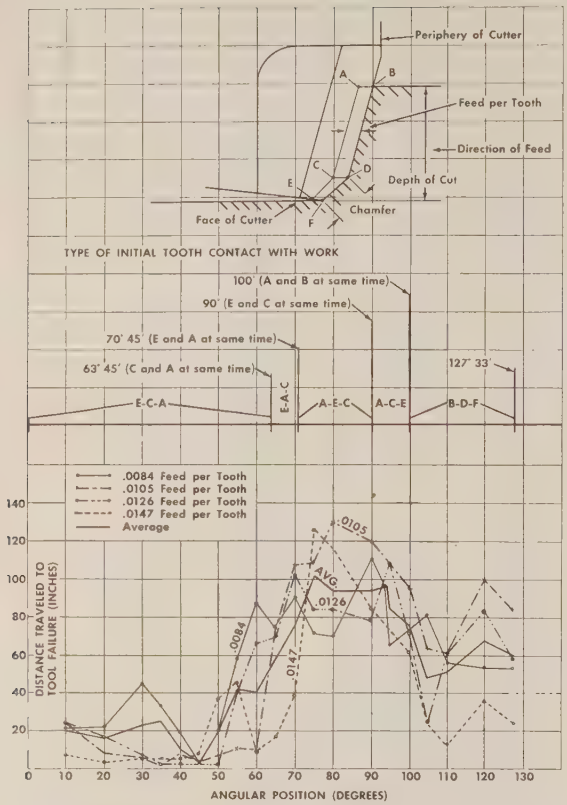

Fig. 6 Cutter-Life Curves for Various Work Positions and Feeds per Tooth

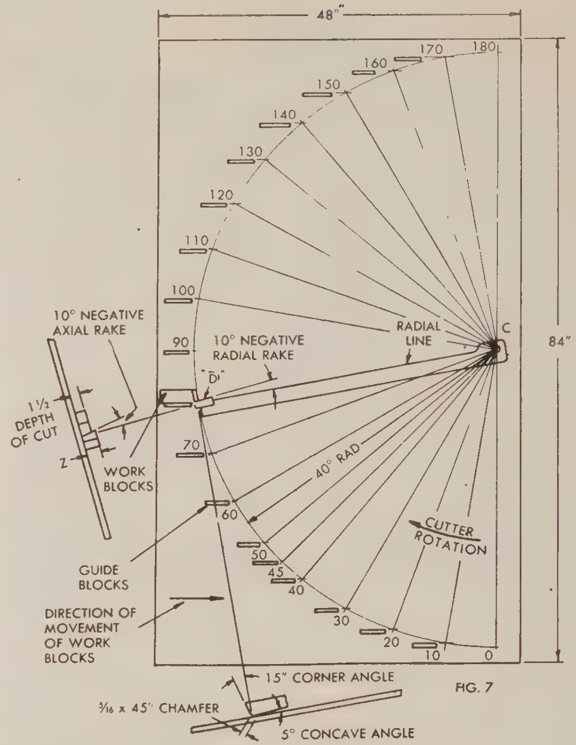

Fig. 8 Detail Dimensions of Wooden Model

Fig. 7 Enlarged Wooden Model Showing Tooth Approaching a Work Block

work. All of the original photographs were taken looking outward from the center of the cutter in a direction along the 10-deg negative radial rake angle on the face of the tooth.

Fig. 10 covers the conditions which exist when the point of initial tooth contact with the work is at E on the face of the tooth where it intersects the face of the cutter and is at a distance from the cutting edge on the chamfer equal to the feed per tooth. This is followed by point C, and finally by point A, contacting the work. This occurs when the tooth enters the cut anywhere from the zero position up to the 63-deg 45-min position.

At the 63-deg 45-min position, the initial contact point of the face of the tooth with the work still remains at E, as is shown in Fig. 11. However, as the cut progresses, the entire face of the tooth along the corner angle gives a line contact from A to C. This line contact is at a distance from the cutting edge equal to the feed per tooth.

In Fig. 12 we can see that between the 63-deg 45-min position and the 70-deg 45-min position, the face of the tooth makes contact with the work in the order of points E at the face of the cutter; A at the top of the cut; and C at the intersection of the corner angle and the chamfer.

Fig. 13 shows the set of conditions which obtain at the 70-deg 45-min position where both A and E on the face of the tooth contact the work at the same time. This is followed by point C, also on the face of the tooth, and making the final contact. The point A is located at a 0.150-in. distance, which is the depth of cut from E at the face of the cutter. This marks the beginning of the true double-negative cutting action, which extends up to the 100-deg position.

Between the 70-deg 45-min position and the 90-deg position, the initial point of contact is at A. This is followed by contact at E, and finally by contact at C. Fig. 14 clearly illustrates this set of conditions.

When the cutter tooth contacts the work at the 90-deg position, the initial contact is still at A. This is on the face of the tooth, as illustrated in Fig. 14. This is, however, followed by a line contact which is along the face of the tooth extending from C to E. This is parallel to the chamfer and is shown in Fig. 15.

Fig. 16 shows the initial tooth contact being made on the face

of the tooth at *A*, as illustrated in both Figs. 14 and 15. This is followed by contact at *C* and finally at *E*. This set of conditions prevails from the 90-deg position up to the 100-deg position.

At the 100-deg position, the initial contact between the face of the tooth and the work is a line connecting point *A* with *B*. The length of this line represents the feed per tooth. Fig. 17 shows this condition. At this position the engagement angle between the face of the tooth and the entering side of the work changes from negative to positive. In other words, at this position the initial contact point moves from a point *A* on the face of the tooth, which is at a distance equal to the feed per tooth away from the cutting edge, up to a point *B* on the edge itself.

Finally, Fig. 18 shows the condition which exists at all angular positions beyond the 100-deg position. The initial contact between the cutting tooth and the work is at a point *B*, which is located at the cutting edge itself. This is followed by cutting-edge contact at *D* and then at *F*.

Analysis of Results

The data, compiled in Fig. 6, quickly indicate that a face-milling cutter having a 10-deg negative axial rake; a 10-deg nega-

tive radial rake; a 15-deg corner angle, and a $^1/_{32}$-in. × 45-deg chamfer:

1 Gives the longest cutter life when the nose or corner on the cutter enters the cut anywhere between the 70-deg 45-min and 100-deg work positions. The reason for this is the point *A* on the face of the tooth which contacts the work first.

(*a*) A 0.0105-in. feed per tooth gives the longest as well as the most uniformly consistent cutter life between the 70-deg 45-min and 100-deg work positions.

(*b*) A 0.0084-in. feed per tooth gives the shortest cutter life but has a tendency to cover a wider range of work positioning between 63 deg 45 min and 100 deg. Evidently the reason for this is the second point of contact with the work, which happens to be at *A* even though its initial point of contact is at *E*.

(*c*) The longest cutter life for a 0.0147-in. feed per tooth is confined within the narrowest range of work positioning for the four feeds used.

(*d*) At about the 90-deg tooth-entry position, the cutting edge along the 45-deg chamfer contacts the entry edge of the work broadside. This actually tends to decrease the length of run by a slight amount. An analysis of all tools run at this position shows that the initial breakdown occurs along the chamfer.

2 The life of the cutter is short and erratic when the cutter nose enters the work first anywhere between zero position and the 63-deg 45-min angular work position. This is due to the fact that the point *E* on the face of the tooth, which is below the point where the chamfer intersects the face of the cutter, contacts the work first.

This is substantiated by an analysis of the wear record of all the tools run at these positions, which indicates that a chip out of the cutting edge at *E* is followed by a complete collapse of the chamfer.

(*a*) It will be noted that an 0.0084-in. feed per tooth shows the longest cutter life, and that the 0.0126, 0.0106, and 0.0147-in. feeds per tooth, in the order given, show the shortest cutter life between the zero-deg and 55-deg work positions.

(*b*) At the 45-deg angular position, all of the feeds per tooth gave practically a zero cutter life. Plenty of runs were made at this work position to verify the results. There is no indication that this is the result of a change in the type of tooth contact because the same type of contact exists all the way from the zero-deg to the 63-deg 45-min angular position.

An analysis of the wear record of all the tools which were run at the 45-deg position showed that the cutting edge in the vicinity of the intersection of the corner angle and the chamfer consistently failed by spalling off in the same manner. It was assumed that this was due to the direction of, and also the intensity of, the impact load at the time the tooth hit the work. To verify this, an analysis was made of the major cutting forces at the time of the initial tooth impact, using the assumption that the longitudinal force (in the direction of feed) is 30 per cent of the tangential force, as outlined in Fig. 19.

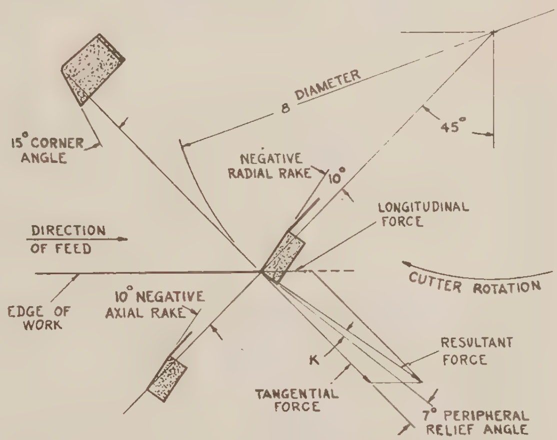

FIG. 19 GRAPHICAL ANALYSIS OF DIRECTION OF RESULTANT TOOTH-IMPACT FORCE, AT 45-DEG POSITION

This type of analysis was applied to each work position from the zero position to the 90-deg position. The angle *K*, which gives the relationship of the resultant force to the peripheral relief angle behind the cutting edge for each one of the various work positions, was determined graphically and then plotted as shown in Fig. 20.

It will be noticed that for the 45-deg position, which is shown in Fig. 19, the resultant-force line lies 3 deg 30 min within the peripheral-relief-angle line. It will also be noted that the angle *K* is zero for a work position of 32 deg. This means that the direction of the resultant force coincides with the peripheral relief angle behind the cutting edge. This also means that for all work-position angles which are less than 32 deg, the direction of

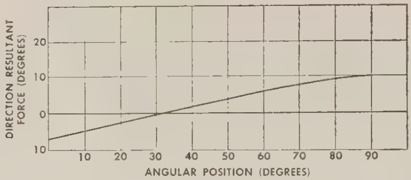

Fig. 20 Graph Showing How Direction K of Resultant Impact Force Varies With Work Position

the resultant force lies outside the peripheral relief angle, and shows why there is an inclination to spall off behind the cutting edge.

(*c*) There is a tendency for cutter life to decrease slightly at the 63-deg 45-min work position. This is apparently owing to the fact that at this position the entire cutting edge along the corner angle enters the work at the same time. This causes a momentary increased shock, which tends to break down the cutting edge.

(*d*) At the 70-deg 45-min work position, the face of the cutter tooth contacts the work at both A and E at exactly the same time. This momentarily increased contact also has a tendency to reduce cutter life by a slight amount.

Rating Work Position by Total Distance Cutter Is in Contact With Work

It is a known fact that when work is so positioned in relation to a face mill that the center line of the work and the center line of the cutter, measured in the direction of the feed, actually coincide, the arc of contact B between the cutter tooth and the work is at its minimum, Fig. 21. This arc of contact increases grad-

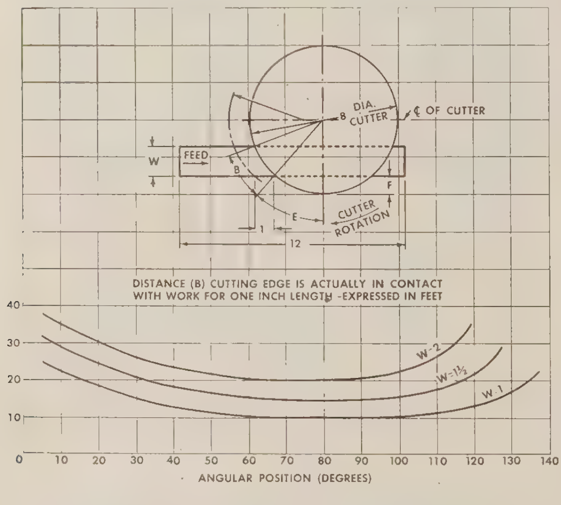

Fig. 21 Analysis of Length of Tooth Path Through Work When Considering Work Width and Work Position

ually as the work position is shifted to either side of this central position. It is at its maximum under the present set of conditions, either where E equals 10 deg and F equals 0.061, or where E equals 127 deg 33 min and F equals 6.437, as we saw listed in Table 1.

Table 3 shows the length of this arc of contact B, expressed in inches, for the various work positions for the $1^1/_2$-in. width of cut which was used in the test runs. This arc of contact (tooth path) has been called by the mathematical term "an arc of a looped trochoid." Since the width of cut is narrow, however, it will be treated here as an arc of the cutter circumference. This will give a close approximation to the theoretical curve already mentioned.

Table 3 also shows the total length of these arcs of contact expressed in feet for a 1-in. length of cut for the various work positions when using an 0.0084-in. feed per tooth. This is obtained by multiplying the length of the arc of contact for one tooth pass by the number of tooth engagements, with the work in a 1-in. length of cut for the given feed per tooth. (This is expressed in feet to reduce the number of digits in the figures.) The following example shows the method used to arrive at the total length of arc of tooth contact with the work for each inch of length of cut when using the 80-deg work position and the $1^1/_2$-in. width of cut

$$\frac{1.509\,(\text{Length of arc of contact}) \times 238\ (\text{rpm})}{2\,(\text{Inches per minute}) \times 12\ (\text{inches to feet})} = 14.96 \text{ ft}$$

The lengths, given in Table 3, were compiled for the several work positions, and the graph shown in Fig. 21 was plotted from them. This graph shows that there is a marked difference in the distance which a cutter tooth has to travel as the work position changes from either side of the central position where the center line of cutter and center line of work coincide.

This information is also expressed on a percentage basis, using the position where the arc of contact is shortest, as at 100 per cent.

In order to determine the effect of changing the width of the work on the length of arc of tooth contact with the work, similar data were compiled for both 1-in. and 2-in. cuts.

Using the data compiled for the $1^1/_2$-in-width cut in Table 3,

and shown in the graph in Fig. 21, a new set of tool curves as shown in Fig. 22 was developed to take the place of those shown in Fig. 6. This was done by multiplying "the distance traveled to tool failure," expressed in inches, by the "total length of arc of contact with the work for each inch length of cut," expressed in feet, and plotting the result against the various work positions.

This set of curves follows the same general pattern as those shown before in Fig. 6, and these curves:

1 Amplify the point that at both the low and the high angular work positions, the rapid failure of the cutting edge on the cutter tooth is accentuated by the increased distance that it is actually in contact with the cut.

2 Clearly show that there are critical work positions at 45 and 105 deg.

3 Also show the effect of the tooth engagement with the work at the 63-deg 45-min, 70-deg 45-min, 90-deg, and the 100-deg work positions in about the same manner as when rated on the actual distance traveled to point of tooth failure.

Effect of Changing Corner Angle on Work Positioning

It frequently happens that the outline of the workpiece, where the cutting edge first contacts it, is of such a shape that a corner angle other than 15 deg is required to keep the corner of the cutter from hitting the work first.

Fig. 23 (a) shows a condition where a cutter tooth having a 15-deg corner angle and a small chamfer contacts the work first next to the face of the cutter. This naturally results in short cutter life because the intersection M of the chamfer at the face of the cutter usually chips out first.

Fig. 23 (b) shows the same work outline. However, the cutter tooth has been reground to an increased corner angle of 45 deg, which takes the initial contact with the work at some point N at a distance from the intersection of the corner angle and the chamfer. This slight change of conditions prolongs the life of the cutter.

When all the data from the test runs made with a face mill having a 15-deg corner angle used on work with a square corner (90-deg included angle) had been compiled, it was learned that the best work-position angles were between 70 deg 45 min and 100 deg. The analysis of the $^1/_{32}$-in. × 45-deg chamfer angle showed that the best work-position angles for a 45-deg angle were between 90 and 100 deg.

The same analysis also showed that the high limit of this range of best work-position angles was always a constant for a given negative radial rake angle on a cutter, and was equal to 90 deg plus the negative radial rake angle on the cutter, irrespective of the corner angle.

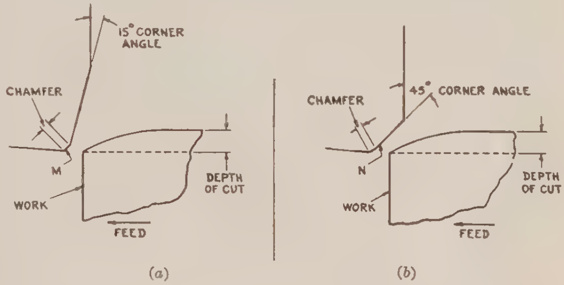

Fig. 23 Effect of Changing Corner Angle to Suit Work Contour

The analyses showed that the low limit of this range of the best angular work positions is at the work-position angle where the initial point of contact of the face of the cutter tooth and the work begins at M, in Fig. 23. A change in the corner angle on the cutter changes the angular work position where the initial contact at the point A, which was shown previously in Fig. 6, actually begins. For a 15-deg corner angle, the work position is 70 deg 45 min. For a 45-deg corner angle, the angular work position is 90 deg.

The curve X shown in Fig. 24 was developed as an aid in obtaining the best angular work positionings for other corner angles. This curve covers the work positions shown previously in Fig. 11, where points A and C contact the work at the same time. This curve shows that as the corner angle is increased with all other conditions identical, the range of operation of the best angular work position decreases, and vice versa.

Curve Y shows a similar line plotted to indicate where the face of the tooth makes initial contact at A and E at the same time, which is followed by contact at C. This set of conditions was shown in Fig. 13. The location is important because it tends to reduce cutter life. It also tends to decrease the width of range of longest cutter life as the corner angle increases.

All tests made while using the cutting angles of 15 deg corner angle, 10 deg negative radial rake, and 10 deg negative axial rake clearly indicated that the cutter life would tend to be at its lowest whenever the initial tooth contact with work would be at an angular position of 70 deg 45 min or less. This forces the work positions which gave the longest cutter life into the narrow operating band between 70-deg 45-min and 100-deg angular positions, as indicated by the curve marked 0.0105, which was previously shown in Fig. 6. This same curve also shows practically no cutter life for all angular positions of 60 deg or less.

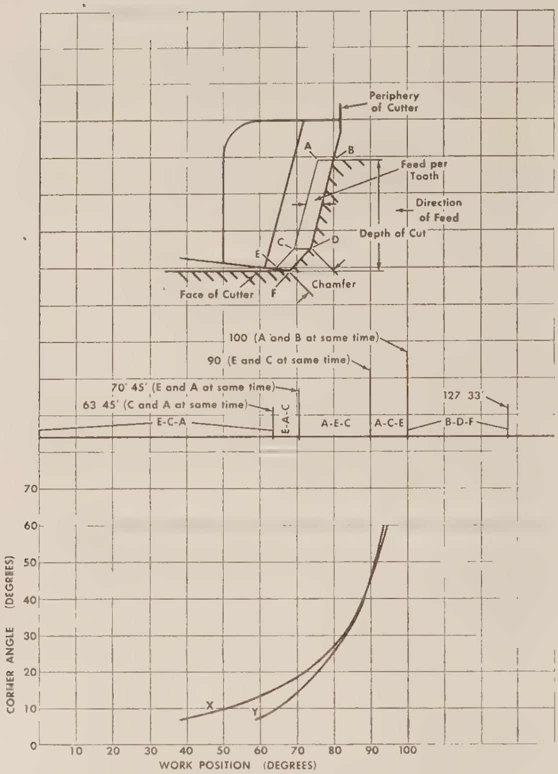

Fig. 24 Graphs Showing How Critical-Point Positions Vary With Corner Angle

The last-mentioned conditions offer a real challenge, and so a series of 60 runs was made with 40 tools while using increased corner angles to determine some means whereby the cutter life in general could be improved. The tools used were ground as follows: 14 tools to a 25-deg corner angle, 13 to a 35-deg, and 13 to a 45-deg corner angle. All other tool angles were kept the same as were ground on the tools which had the 15-deg corner angle, except for those tools with the 45-deg corner angle. In this case no chamfer was ground between the corner angle and the face of the cutter. Instead, it was broken lightly with a 320-grit silicon-carbide stone. A total of 20 runs were made for each set of tools which had the same corner angle, while using the work positions ranging between the 10 and 90 deg.

All the operating conditions were duplicated while using a table travel of $2^1/_2$ ipm (0.0105 in. feed per tooth). The distance traveled in inches per minute up to the time of tool failure was plotted for each one of the various work positions and corner angles, as shown in Fig. 25. The tool-life curve, previously shown as Fig. 6, for the same feed per tooth when using a 15-deg corner angle was also duplicated.

General Conclusions

A comparison of the four curves shows that for a face mill having a 10-deg negative radial rake and a 10-deg negative axial rake and operated under the conditions as already outlined:

1 Cutter life reaches maximum when a 15-deg corner angle is used. The only way this maximum cutter life can be obtained is by using special care to see that the initial point where the tooth enters the work lies between the 70-deg 45-min and the 100-deg work positions.

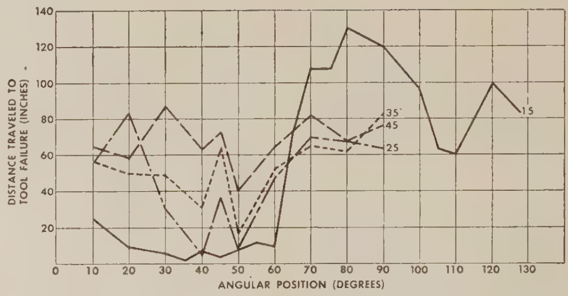

Fig. 25 Effect of Corner Angle on Cutter Life

2 The limited long-life working range between the 70-deg 45-min and the 100-deg positions, when using a 15-deg corner angle, makes it necessary for the face mill to overhang the entrance side of the work by an increased amount. This results in the use of face mills slightly larger in diameter than have been ordinarily used on most face-milling jobs.

3 Cutter life is at its minimum with a 15-deg corner angle when the initial point where the tooth enters the work lies between the zero-deg and the 70-deg 45-min work positions.

4 Cutter life can be improved by using corner angles greater than 15 deg when it becomes necessary to operate a face mill within the zero-deg to 70-deg 45-min work positions.

5 When a 25, 35, or 45-deg corner angle is used, the cutter life for the 70-deg 45-min to 100-deg work position is only from 50 per cent to 60 per cent of that obtained from a face mill which has a 15-deg corner angle.

6 Any face mill with a 45-deg corner angle will produce the maximum cutter life when practically no attention at all is given to work positioning. The 35-deg and then the 25-deg corner angles rate next in the order given.

7 Mediocre but somewhat consistent results can be obtained with a face mill having a diameter slightly larger than the work width, provided that it has a 45-deg corner angle.

8 The face mill can be adapted to various face-milling operations by grinding an appropriate corner angle on it and then properly positioning the cutter entry edge of the work to the cutter. This indicates the possibility of standardizing carbide-tipped face mills and adapting them to a large number of jobs.

9 Cutter life was shortest for the 45-deg work position when operating a face mill with a 15-deg corner angle at all feeds per tooth. When the corner angle was changed to either 25, or 35, or 45 deg, the cutter life was considerably longer for the same position. However, the one work position which gave the reduced cutter life was transferred to two positions, one at 40 deg and the other at 50 deg, on either side of the 45-deg position. This set of conditions is worth further analysis. It must be kept in mind that all conclusions were reached as a result of using a face mill on work having a $1^1/_2$-in-width cut.

While these tests were being run, it was observed that when runs were made at the critical 45-deg work-entry position the cutter life could be increased many times for some cuts wider than $1^1/_2$ in., even though the stock removal was much greater. This seems to indicate that the position where a cutter tooth leaves the work or a possible variation in cutter-flywheel-spindle momentum may affect cutter life. This is another phase of work positioning which will be given extensive study in the future.

(Owing to travel emergency conditions existing when this paper was presented, discussion will be accepted until March 11, 1946)

Circular Bulging of Aluminum-Alloy Sheet at Room and Elevated Temperatures[1]

By GEORGE SACHS,[2] GEORGE ESPEY,[3] and G. B. KASIK[3]

In this paper preliminary results are reported on the strength characteristics and forming limits of various aluminum-alloy sheet, when subjected to hydraulic pressure over a circular area at temperatures up to 500 F. The strain distributions were analyzed by means of a photogrid, after these bulges failed. The bulges exhibited a practically balanced biaxial strain state over most of the contour with the exception of a very narrow range of local deformation in the vicinity of the fractures. The maximum meridional strain outside the necked area observed at the pole of a bulge, in spite of its biaxial nature, generally exceeded the uniform elongation known from tensile tests. The forming limits for all annealed conditions increased considerably with increasing temperature if the temperature exceeded a certain critical value, between 250 and 400 F, depending upon the alloy. The heat-treated conditions of the alloys 24S and 61S were only slightly affected by the testing temperature, while the forming limits (uniform stretch) of 75S-T, R301W, and R301T were materially increased at elevated temperatures. The reduction of thickness, which is a measure of the ductility of an alloy, followed approximately the same trend as the forming limit.

THE use of a fluid as a pressure medium has been restricted in the past primarily to testing purposes and to such minor cold-forming operations as the bulging of recesses in tubular parts. However, various shapes can be formed by bulging or hydraulic application of uniform pressure to one side of a sheet over a confined area. This process has found a restricted commercial application for the forming of letters and other shapes on signs.

Temperatures in the vicinity of 400 F (200 C) are, to a small extent, being used in the bending, joggling, and dimpling of high-strength aluminum-alloy sheet. The application of temperatures in this range presumably does not impair the properties of high-strength alloys.

Hydraulic bulging at elevated temperatures has been used successfully for the fabrication of magnesium-alloy parts. On the contrary, this method has previously not been found useful for the hot-forming of aluminum alloys, as an excessive temperature was considered necessary, 850 F (450 C), approximately.

The test results obtained on this project, however, indicate that temperatures between 250 and 400 F (120 to 200 C) substantially improve some forming characteristics of a number of high-strength aluminum alloys.[4] This fact, if substantiated by further experimentation, may render forming by means of hydraulic pressure at elevated temperatures a valuable addition to the various commercial methods of aluminum-alloy-sheet forming.

Examples of specimens bulged for this investigation are shown in Fig. 1.

The metal at the crown or pole of a circular bulge is subjected to a practically uniform tensile stress, and tensile strain in all directions parallel to the metal surface. This applies throughout the test until the "forming limit" is reached when failure by local necking or fracturing occurs. Such a "balanced biaxiality" constitutes a fundamental stress-and-strain state, for it is a borderline case which many types of actual forming operations approach and which is present in aircraft and other structures in service. Therefore, rather than measure the depth of the cup or bulge at the moment of failure, the unit strains (in the vicinity of the break) which the metal exhibits after failure, were determined. These are considered as important metal characteristics.

No attempt will be made, at present, to evaluate the fundamental significance of the data discussed here. Further reports will cover various other phases of cold- and hot-forming aluminum alloys, and their fundamental analysis.

MATERIAL, EQUIPMENT, AND PROCEDURE

Materials Tested

Twenty-one different conditions of seven aluminum alloys (3S, 52S, 61S, 24S, 75S, R301, and R303) were tested. The alloys 3S, 52S, and 61S are supplied in bare (unclad) sheets, and only bare R303 was tested. 75S and R301 were available only as clad sheet, and alloy 24S was tested both bare and clad.

For the general tests on circular bulges, sheet of the same thickness for all alloys, 0.040 $^{+0.002}_{-0.0015}$ in., was selected. For any particular alloy condition, specimens were cut from a single sheet for which the thickness variations were within ±0.001 in.

The yield strength, tensile strength, and elongation (2 in. gage length) in both the transverse and longitudinal (rolling) directions are assembled in Table 1.

The various alloy conditions are assembled into two main groups and four subgroups as follows:

Group I Annealed Sheet	Group II Heat-Treated Sheet
(A) Nonaging alloys	(A) Room-temperature-aged alloys
(B) Heat treatable alloys	(B) Artificially aged alloys

[1] This paper is the first published report on the research program on hot-forming of aluminum alloys conducted at Case School of Applied Science under contract with the Office of Production Research and Development of the War Production Board. This research, which was supervised by the War Metallurgy Committee under the "restricted" Project NRC-547, is the basis of this paper which has been released for publication by the O.P.R.D.

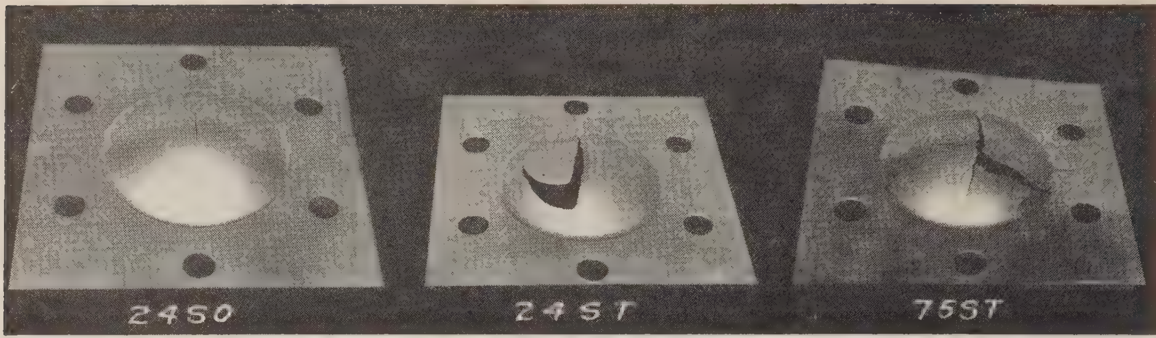
Contributed by the Metals Engineering Division of The American Society of Mechanical Engineers.

[4] A particularly valuable application of hot-forming, at these temperatures, has been found to be the roll-forming of sections in the rather brittle high-strength alloys, suggested recently by an unpublished report on another phase of this W.P.B. research investigation.



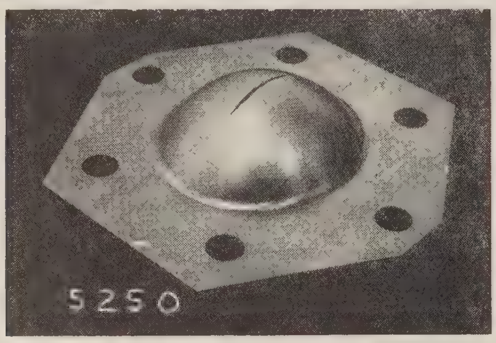


Fig. 1 Typical Hydraulic Circular Bulges

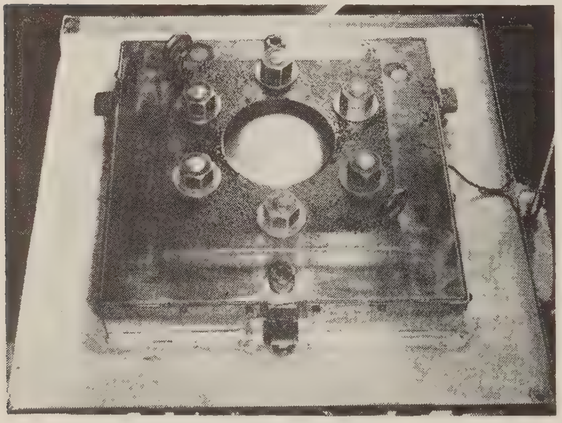

Fig. 2 Head for Hot Hydraulic Circular Bulging With Specimen in Place

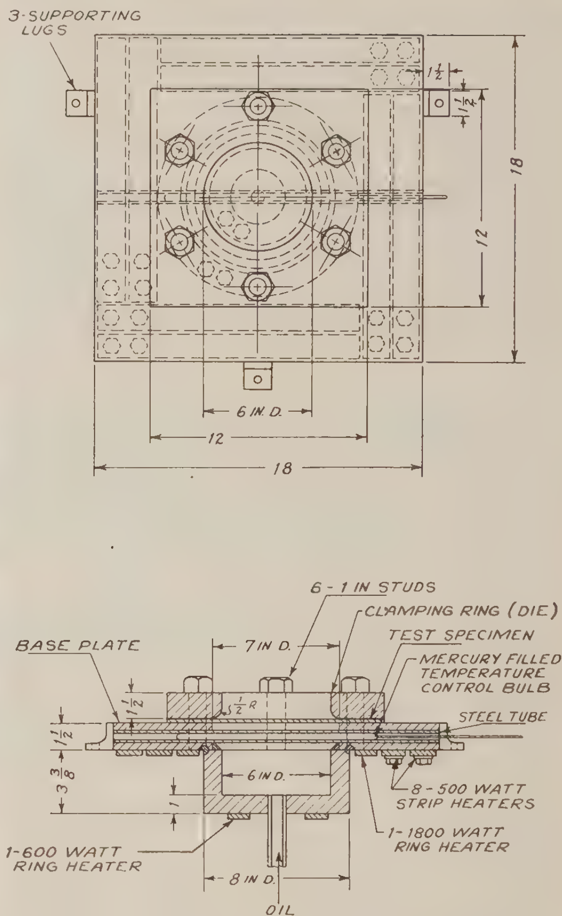

Fig. 3 Detail of Hot Hydraulic Bulging Head

The alloys investigated represent all conditions for the structural alloys of high strength available at present for production and a few additional alloys which are also used in aircraft fabrication, because of their superior forming properties.

Details of Equipment

The equipment[5] consisted of a bulging head and a hot-oil displacement cylinder capable of furnishing oil under pressure up to 3000 psi to the head on which the specimen was clamped, Figs. 2 and 3. The clamping ring (die) had a $^1/_2$ in. radius to prevent tearing of the specimen at the edge of the die contour. Originally, an as-machined surface of both the base plate and clamping-ring interfaces provided satisfactory gripping surfaces. As the die became nicked it was necessary to serrate the surface with four buttress teeth per inch ($^1/_8$ in. deep $\times$ $^1/_4$ in. long).

Oil pressure for the bulging was supplied from a displacement

[5] The equipment for these tests was developed by E. J. R. Hudec and C. L. Bennett, Instructors under the supervision of G. B. Carson, Associate Professor of Mechanical Engineering, Case School of Applied Science.

*Does not meet minimum specified by the Army Air Force Specification, No. 11354.

cylinder, the piston of which was actuated by the lead screw of a broaching machine that was driven from a variable-speed drive, Figs. 4 and 5. The total volume-displacement capacity of the cylinder was 95 cu in.

The bulging pressure was recorded by a helical-type 3000-psi recording pressure gage tapped into the oil line connecting the bulging head and displacement cylinder. A synchronous-motor drive for the recording chart permitted the recording of a pressure-time (stroke) curve for any desired test.

The elevated temperatures were obtained by heating the lower plate, the reservoir, and the oil-displacement cylinder by means of resistance heaters. A mercury-tube temperature-control switch, sensitive within ±5 deg F, inserted into the base plate, controlled the temperature of the bulging head and the oil in the head. Two manually adjusted thermoswitches (50–600 F) were used for controlling the temperature of the oil in the displacement cylinder. The actual temperature was indicated by a thermometer set in a well in the exhaust end of the cylinder, Fig. 5.

The temperature of the specimens and various parts of the bulging fixture was determined (within ±3 deg F) with a Cambridge surface pyrometer, mold type, 50–600 F range, having a minimum accuracy of 2 per cent of full scale.

To protect the operators from the danger of hot oil at high pressure, a safety-glass cover was constructed to fit over the bulging head, Fig. 4. The cover was built of $^{1}/_{4}$-in. heat-tempered plate glass set in a $^{1}/_{8} \times$ 1-in. angle-iron frame.

For the low-temperature (30–50 F) tests, a small 3-gpm rotary gear pump was employed by which refrigerated oil was pumped from a 5-gal sump, containing dry ice as a coolant, to the reservoir of the bulging fixture, and thence circulated through the displacement cylinder. Dry ice was placed around the bulging head to maintain it at testing temperature.

Testing Procedure

A 20-line-to-the-inch orthogonal grid was applied to one side of each test specimen by a modification of the photogrid process

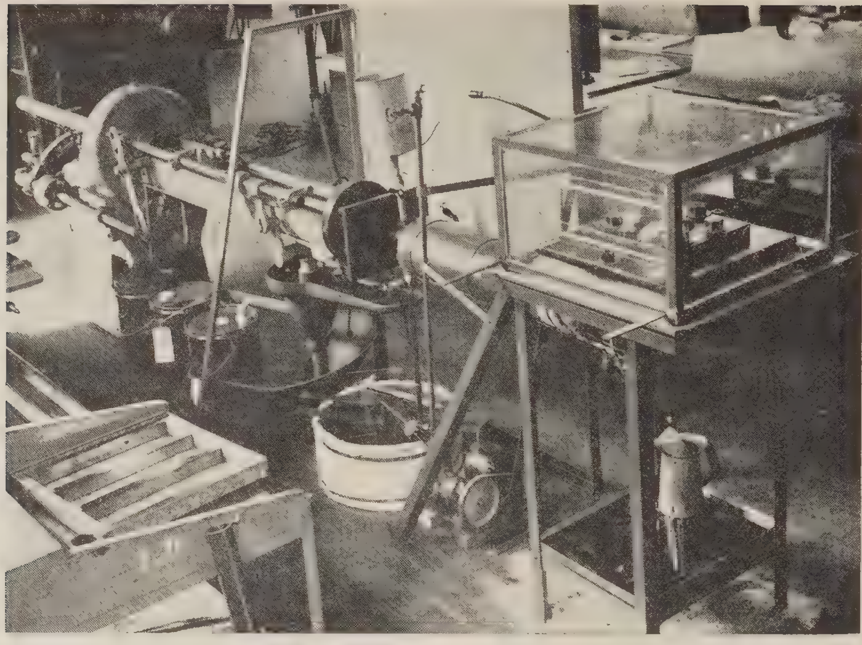

Fig. 4 Equipment for Experimental Hydraulic Bulging

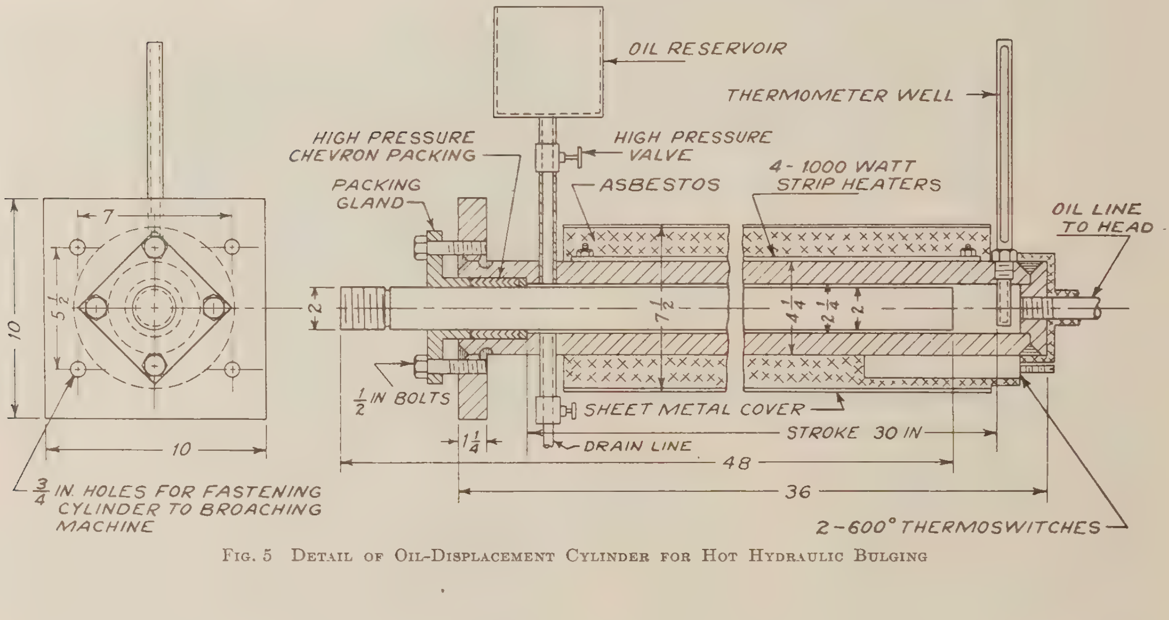

Fig. 5 Detail of Oil-Displacement Cylinder for Hot Hydraulic Bulging

(1, 2).[6] The grid lines were applied parallel to the transverse and longitudinal directions of the sheet. The maximum variation of the grid for $^1/_2$ in. gage lengths was 0.5 per cent.

The 12-in-sq test specimens were set in a jig and drilled with six $1^1/_{16}$-in-diam holes to accommodate the 1-in. studs in the base plate.

The bulging head, with the clamping ring in place, and the displacement cylinder were held at the predetermined testing temperature for at least 15 min prior to the start of a given run. To minimize the temperature gradient across the bulge and to insure the absence of air in the head, care was exercised to have the oil level in the reservoir flush with the surface of the base plate before placing a test specimen on this fixture.

The general testing procedure was to place the test specimen on the bulging head, set the preheated die loosely in place and allow 10 min time in which to take several temperature determinations around the bulge, and then tighten the clamping ring onto the specimen. It was found that the sheet reached a constant temperature within 2 min after being placed on the bulging head. The circular edge of the sheet next to the die was generally above the temperature of the center of the sheet by 5 to 10 deg F in the vicinity of 250 F and 10 to 20 deg F in the vicinity of 500 F.

The tightening of the die, which took a few minutes, was deferred until near the end of the 10-min period (after 7 min of preheating), for it was found that premature tightening favored heat-warping of the restrained sheet specimen. After the 10-min heating period the safety cover was placed over the head and the actual bulging was started and proceeded without interruption until failure. The forward speed of the piston was held constant throughout these tests at $5^3/_8$ ipm; this gave a displacement volume of 17.7 cu in. per min. Each test required approximately 2 min for the actual bulging operation. The time required to remove the clamping plate brought the total time for each test, during which the sheet specimens were exposed to the elevated temperature, to between 14 and 16 min.

For the purpose of comparing the properties of the various alloys at different testing temperatures, the maximum bulging pressure or "bursting pressure" has been used as a measure of the metal strength. In addition, the strain distributions along the "principal axes" after failure of the specimens were determined, and the ductility characteristics were obtained, as discussed in the following section.

Measurement of Strains

The over-all investigation, of which this paper is a part, entails the consideration of the effects of various degrees of stress biaxiality. For a better understanding of the forming limits, this necessitates the theoretical consideration of various geometrical shapes, which include the border cases of a flat sheet, a tube, and a sphere. It has been found necessary to deviate from general practice and adopt a different and comprehensive system of co-ordinates and directions which will permit an unambiguous description of any stress or strain in any given part.

A system of co-ordinates which will fit those cases having two perpendicular planes of symmetry for which the strains are measured along the "principal axes" has been selected as follows: The intersection of the two planes of symmetry and surface will be designated as the "pole." For any point on the surface, the "normal direction" N is readily recognized as the direction perpendicular to the surface at that point, Fig. 6. A "meridian line" is taken to be the intersection between the part surface and a plane passing through the pole and the line normal to the surface at the point under consideration. At the given point, the "meridian direction" M is determined by the line of tangency to

[6] Numbers in parentheses refer to the Bibliography at the end of the paper.

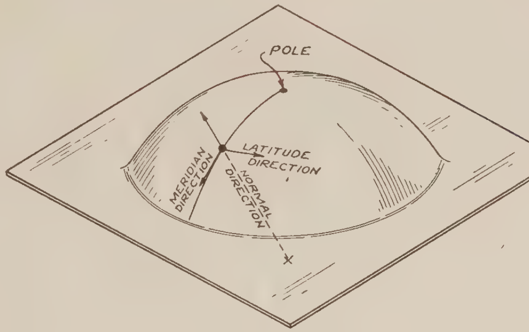

Fig. 6 Diagrammatic Representation of Co-Ordinate Designations

the meridian line. The "latitude direction" L is defined as the perpendicular to both the normal and meridian directions at the point under consideration. The relation of these terms to those used for a plane, a tube, and a sphere are readily recognized; they are assembled in Table 2.

TABLE 2 TERMS USED IN STUDIES

Adopted terms	Common terms: Plane	Tube	Sphere
Normal N	Normal	Normal or radial	Normal or radial
Meridian M	(In the surface, longitudinal or transverse)	Axial or longitudinal	Circumferential or tangential
Latitude L		Circumferential or tangential	Circumferential or tangential

In the case of an extended part, the "principal axes" will be defined by the intersections between the part surface and the two symmetry planes. The axis in the direction of the larger dimension will be designated by the letter a, and that of the smaller dimension by the letter b. Even in the case of a circular bulge such axes are also necessary to designate the grain direction.

For the circular bulge the a-axis has been chosen as parallel and the b-axis as perpendicular to the rolling direction of the sheet. The strains have been designated as "meridional" e_{aM} or e_{bM}, if measured along the axes a and b, respectively, and "latitudinal" e_{aL} or e_{bL} if measured perpendicular to the axes, where the subscripts a and b refer to points along the a- and b-axes, respectively. Strains not measured at points on one of the principal axes will be referred to a special set of co-ordinates for the particular case in question.

It was observed in the tests, as discussed later, that the strain distributions were usually characterized by a rather flat maximum at the pole of the bulge, disregarding a very narrow range containing the failure. These maxima in the principal meridional directions of the sheet were considered as the "forming limits" for the bulging processes, Figs. 9 to 12, inclusive, and represent the maximum amount of strain which the metal permits without failure by local necking or fracture. The strain at the forming limit for a bulged part could not be obtained in the same manner as for a regular tensile test specimen, i.e., by measuring a value of strain some distance away from the fracture. The measurements of the strain along the two major axes of the specimen, Fig. 7, with w, and cross-grain x, however, revealed that the strain values both parallel to the direction of each axis or "meridional," and perpendicular to the direction of each axis or "latitudinal," increased continuously from a zero value somewhere at the radius of the die to a maximum value at the crown of the bulge; a few representative plots are illustrated in Figs. 7 and 8.

For a rapid determination of the forming limits, the strains occurring in an area approximately 3 in. sq and in the proximity

of the pole of the bulge were measured along and in the direction of the principal axes by means of a strip of orthogonal co-ordinate paper to within $^1/_2$ per cent (stretch). A gage length of $^1/_2$ in. was generally used, although in some cases a gage length of $^1/_4$ in. was necessary for measurements near the break and in directions intersecting the failure on both sides (these values of $^1/_4$ in. gage length are distinguished by parentheses in the curves). No such measurements were made closer than $^1/_8$ in. to the fracture, nor across the fracture, i.e., including the fracture. A number of curves obtained in this manner are represented in Figs. 9 to 12, inclusive. That these measurements do not include the necked regions is shown by the thickness distribution perpendicular to the locus of failure, Fig. 13. From the figure it can be seen that for the very ductile alloy 52S-O, the necked region does not extend more than 0.01 in. on either side of the fracture.

The "reduction in thickness," at the point of failure constitutes another metal characteristic, corresponding to the contraction in area (reduction of area) of a regular tensile test presumably measuring the ductility of the metal. This value was determined by measuring the thickness of the sheet at the fracture by means of a measuring microscope at $\times 10$ magnification. Three readings approximately evenly spaced over a total distance of $^1/_2$ to 1 in. at the center of the primary fracture yielded values which could be readily reproduced.

In order to obtain the local (normal) strain distribution in the circular bulge in the vicinity of failure, thickness measurements were made with a measuring microscope at appropriate intervals on specimens sectioned in a plane perpendicular to the locus of failure. Reduction in thickness values thus obtained for two alloys yielded quite smooth strain-distribution curves, Fig. 13.

General Characteristics of Strain Distribution

The agreement between the meridional strains along the two principal axes was rather close. The maximum was flat and quite definite for all specimens yielding uniform stretch values of less than 25 per cent, Figs. 7 to 12, inclusive. The maximum was sharper for more ductile materials and differed slightly in position and value along the two axes, a difference of up to 3 per cent for temperatures below 375 F, and of up to 6 per cent for the tests at higher temperatures being observed. Less regular curves were occasionally obtained at the highest testing temperatures, probably because of slight variations in temperature. It appeared that if the temperature differences over the surface of the bulge exceeded 10 deg F during the test, such irregularities resulted.

The values of both the meridional and latitudinal strains measured along any one meridional axis, showed a variation up to $\pm 2^1/_2$ per cent (stretch) for a meridian distance within 2 in. from the crown or pole of the bulges; this change was greatest for the soft alloys and/or tests at high testing temperatures, Figs. 7 to 12, inclusive.

The depth of a bulge within an accuracy of ± 10 per cent was primarily a function of the forming limit. The depth corresponding to various values of uniform stretch was approximately as follows:

Stretch, per cent	10	20	30	40	50	60
Depth, In.	1	$1^1/_2$	2	$2^3/_8$	$2^5/_8$	$2^7/_8$

The measured values for reduction in thickness generally exceeded those calculated from the meridional strains. The meaning of these values which should measure the local ductility of the metal is rather obscure, as a radical change of stress state from balanced biaxiality to plane strain occurs as soon as local necking begins. No attempts have been made, as yet, to evaluate the significance of the reduction-in-thickness measurements.

Some thickness measurements in a plane perpendicular to the

locus of failure show that the strain gradually increases toward the locus of failure and that the larger fracture strain only affects a very narrow region,[7] Fig. 13. A very ductile alloy, 52S-O, yielded practically the same forming limits from such measurements extrapolated to the fracture, as from the grid measurements. The more brittle alloys, such as 24S-T, exhibited some irregularities in the immediate vicinity of the failure. However, disregarding this range of irregularity the curve of thickness change extrapolates to practically an identical value, as calculated from the average of two meridional-strain values at the pole, as shown in Fig. 13.

The more tedious thickness measurements, therefore, would yield practically the same average value of forming limit as the rather simple grid measurements of the strains.

RESULTS OF TESTS

Bursting Pressure

The bursting pressure can be considered as a semiquantitative measure of the ultimate strength of the metal, under conditions of biaxial tension. While the ratio of bursting pressure to strength is affected by the amount of strain, or rather the curvature of the sheet, at the point of failure, this effect is apparently considerably smaller than that of the testing temperature.

As a general rule, the bursting pressure decreased continuously with increasing temperature above room temperature. Such a behavior is normal for any metal or alloy in a stable condition.

Of the alloys investigated, Figs. 14 to 24, inclusive, those of Group II-A, or the room-temperature-aged conditions, might have been expected to deviate from the general rule if artificial aging had taken place to such an extent that this change exceeded the reverse temperature effect. Obviously, this aging effect was not very pronounced, but a slight hump in the curves of all room-temperature-aged alloys, Figs. 18 to 20, inclusive, can be taken as such an effect.

A comparison of the two investigated nonaging alloys of Group I-A, showed 3S-O to be somewhat more respondent to the effect of temperature on the bursting pressure up to 200 F, while the per cent loss in this property was the same for both alloys at 400 F.

Of the alloys of Group I-B, or the annealed conditions of the age-hardenable alloys, Figs. 15 to 17, inclusive, 24S-O, both bare and clad, was least affected (10 per cent approximately) of all alloys investigated by testing temperatures up to 300 F. On the contrary, the strength of R301-0, 75S-O, and 61S-O, decreased noticeably at rather low testing temperatures, and to a considerable extent, 25 to 30 per cent, at 300 F. Alloy 75S-O suffered the largest decrease of the bursting pressure at still higher temperatures.

In the Groups II-A and II-B, Figs. 18 to 24, inclusive, i.e., room-temperature-aged and artificially aged alloys, respectively, again all 24S conditions exhibited considerably less reduction in strength on increasing the testing temperature than the other alloys, R301, 61S, and R303. At the highest temperatures investigated, 400 F and higher, the reduction of the bursting strength was largest for the alloys 75S and R303.

The absolute values of bursting pressure, of course, varied within wide limits for the different alloys and conditions, ranging between 350 and 1400 psi at room temperature, and between approximately 200 and 800 psi at 400 F. Thus, at 400 F the strength and forming resistance of the high-strength alloys are reduced almost to the values of the softest alloy investigated, 3S-O, at room temperature.

Of the alloys in Group II-A, 24S-T clad and R301-W clad, possessed approximately the same bursting strength at room temperature, while the bursting strength of 61S-W at the same temperature was only 60 per cent of 24S-T clad; 24S-T bare, was the strongest alloy of this group. At 400 F, however, the alloy R301-W required only approximately 70 per cent of the bursting pressure for 24S-T clad and at 450 F was not appreciably stronger than 61SW bare.

Of the heat-treated alloys, 75S-T clad, and R303-T315 bare, were the strongest up to 250 F, and 24S-T81 clad, and 24S-T86 clad, were the weakest at temperatures up to 300 F, while 24S-T bare and clad, R301-W and R301-T, were intermediate, Figs. 20 to 24, inclusive. At temperatures between 300 and 450 F, however, 24S-T required considerably larger bursting pressures than either 75S-T or R301-W, R301-T, and R303-T315.

At the lowest temperature investigated, approximately 35 F, the bursting pressure was usually equal to or slightly higher than at room temperature. Exceptions were 24S-T86 bare and, less pronounced, 24S-T86 clad. The decrease of the bursting strength of these alloys with decreasing temperatures, in the range below room temperature, is explained by the corresponding loss in ductility, which is apparent in both the reduction in thickness and the uniform stretch. The alloys 24S-RT both bare and clad, also exhibited irregular and low strength, and low ductility properties in a temperature range close to room temperature, and up to 250 F. Alloy 24S-T bare and clad yielded rather uniform results on specimens taken from a single sheet.

Artificial aging had very little effect on the alloy R301, while both cold-rolling (RT) and, even more, artificial aging (81 and 86), considerably reduced the bursting strength of 24S, up to a temperature of 400 F. At still higher temperatures, the different aged alloys of either 24S clad, or 24S bare, appeared to possess practically the same bursting strength.

Forming Limits

Regarding the effect of testing temperature on the forming

[7] This region is extremely small as compared with the region of necking in tension tests on 0.50-in-wide specimens.

limits, the annealed alloys, Group I, may be considered together, whereas it is advantageous to discuss individually the room-temperature-aged conditions, Group II-A, the various conditions of 24S, and the artificially aged alloys Group II-B.

It appears that the forming limits of all the annealed alloys except 3S-O and 75S-O were slightly reduced by raising the temperature up to a certain limit which varied for the different alloys between 100 and 250 F (24S-O), Figs. 14 to 17, inclusive. With further increasing temperature, the forming limit of all these alloys increased continuously by as much as 35 to 40 per cent (stretch) at the testing temperature of 450 F. The magnitude of this effect probably depended considerably upon the rate of loading and was rather large for these tests because of the slow speed.

The forming limits (for the annealed conditions) at room temperature were highest for the alloys of Group I-A, 3S-O and 52S-O, and for two alloys of Group I-B, 61S-O and R3010, while 75S-O and 24S-O, both bare and clad, exhibited only approximately 70 per cent of the forming capacity of the other alloys. With increasing temperature the difference between 24S-O and the other alloys was retained, while 75S-O showed almost as high strain values as the more ductile alloys, and markedly higher strain values than 24S-O, at temperatures between 200 and 350 F. The alloys of Group II-A, Figs. 18 to 20, inclusive, aged at room temperature, were in general more responsive to the effect of temperature in the lower temperature range, but at the higher testing temperatures did not increase to definitely higher strain values than the respective artificially aged conditions.

The forming limits for the aged conditions were highest for the alloys R301-W, 61S-T, and surprisingly also R301-T, for practically the entire range of temperatures investigated.

The alloy 61S-W showed rather low strain values in comparison to the other alloys of this group, and were not appreciably higher than 24S-T.

Testing temperatures up to 250 F caused practically no change in the forming limits for all aged conditions of the alloy 24S, but slight improvement in formability was observed for all these alloys at still higher temperatures.

The lowest strain values occurred in 24S-T86 and 24S-RT, while 24S-T and 24S-T81 were intermediate.

Artificial aging of 24S-T and 24S-RT to 24S-T81 and 24S-T86, respectively, caused a surprisingly small reduction in the forming limits by not more than 1 to 2 per cent, when tested at room temperature, Figs. 18, 19, 21, and 22. However, the results at testing temperatures in excess of 200 to 300 F revealed that the artificially aged alloys have the higher forming limits after passing through a minimum at 200 F.

The cold-rolling of 24S-T clad, resulting in 24S-RT clad, Figs. 18 and 20, caused the expected reduction in strains by approximately 5 per cent, but this effect could not be recognized for 24S-RT bare, the strain values of which scattered within wide limits; with increasing temperatures this difference between the forming limits for 24S-T clad and 24S-RT clad, gradually decreased.

The alloys of Group II-B, the artificially aged conditions, Figs. 21 to 24, inclusive, were markedly affected by testing at higher temperatures, and between 300 and 400 F their forming limits exceeded those of the room-temperature-aged conditions.

The forming limit for R301-T, and to a smaller extent for R301-W, 61S-W, and 61S-T, materially increased with increasing temperature, particularly at slightly elevated temperatures. The alloys 75S-T and R303-T, possessed very low forming limits at room temperature; however, the strain values for these alloys at temperatures above 200 and 300 F, respectively, exceeded those of 24S-T. Alloy R301-T values were not appreciably different from R301-W, except that the latter showed a slight minimum in the forming-limit curve for the tests in the range 300 to 400 F. Both alloys had identical forming limits at 450 F.

Regarding the absolute strain values, some recent results show these values to be appreciably increased by increasing the sheet thickness using the same die diameter.

Reduction in Thickness at Failure

The rather large variations of the values of reduction in thickness do not permit a clear evaluation of this metal property, which measures the (local) ductility, Figs. 14 to 24, inclusive.

Of the two nonaging alloys of Group I-A, 3S-O was slightly superior and more affected by elevated temperature than was 52SO.

Of the annealed conditions of the age-hardenable alloys, Group I-B, 61S-O possessed by far the highest ductility at lower temperatures, even better than 52S-O. However, the other alloys approached such a high ductility with increasing temperatures: 75S-O above 250 F, R3010 above 400 F, and 24SO, both bare and clad, apparently above 450 to 500 F, Figs. 15 to 17, inclusive.

The forming temperature up to 450 F had only a comparatively slight effect on the ductility of the room-temperature-aged alloys, Group II-A, Figs. 18 to 20, inclusive. The reduction in thickness of the various conditions of 24ST increased continuously with increasing temperature, at a rate of 2 to 3 per cent (ductility) per 100 deg F, up to a value which was approximately $^1/_3$ higher at 450 F than at room temperature. The other two alloys investigated, 61S-W and R301W, showed a peculiar maximum in the range of 200 to 250 F, followed by a minimum at 350 F. Both of these alloys exhibited slightly higher values of reduction in thickness than 24S-T clad, over the whole range of temperatures tested, while 24S-T bare, 24S-RT clad, and 24S-RT bare, were inferior to 24S-T, by approximately 5 to 10 per cent (ductility).

Of the alloys of Group II-B, the artificially aged conditions of 24S-T were only slightly affected regarding their ductility at temperatures up to 250 F, while their ductility increased considerably between 250 and 350 F, and then approached or even exceeded that of the corresponding room-temperature-aged condition, Figs. 21 and 22. The ductility of R301-T improved markedly at temperatures slightly above room temperature, and then continued to increase at a slow rate with further increasing temperature. On the contrary, the ductility of 75S-T and R303-T appeared to increase at a steadily increasing rate, at temperatures exceeding 150 and 200 F, respectively. Both at room temperature and at approximately 400 F, the ductility of the alloys 24S-T81 clad, R301-T, 75S-T and R303-T, was approximately the same and considerably higher than that of 24S-T86 clad, 24S-T81 bare, and 24S-T86 bare. At temperatures between 200 and 300 F, however, the ductility of the alloys R301-T and 75S-T exceeded that of 24S-T81 clad, and also that of 24S-T clad.

Effects of Cladding

A comparison of the respective clad and bare aged conditions of the alloy 24S revealed a rather pronounced effect of the cladding on the forming limits and local ductility (reduction in thickness). These values were considerably more uniform for the clad than for the bare alloys. In particular, quite uniform strain values could be obtained for 24S-T clad, 24S-T81 clad, 24S-T86 clad, and 24S-RT clad, while extreme variations were encountered in 24S-RT bare, and 24S-T86 bare.

The reduction in thickness of the clad alloys was slightly larger than that of the bare conditions, on the average, by 5 per cent (0 to 10 per cent ductility).

On the contrary, the forming limits were frequently higher for the bare alloys, and very high values were occasionally encountered in both 24S-RT bare, and 24S-T86 bare. No explanation can be given for these peculiar findings. The higher stretching ability of bare alloys, however, cannot be utilized because of their larger variations, and the minimum values of the bare and clad conditions usually differed only slightly.

Alloys 24S-O clad, and 24S-O bare possessed almost identical forming limits, while the reduction in thickness was slightly higher for 24S-O clad.

As was to be expected, the bursting pressures were, on the average, approximately 10 per cent higher for the bare alloys than for the clad alloys, other factors being equal.

Types of Fracture and Defects

While most of the blanks tested failed by splitting close to the crown in the longitudinal direction, the final appearance of a bulge after the test appeared to be determined primarily by the ductility of the alloy, Fig. 1. The various types of failures observed are diagrammatically illustrated by plan views in Fig. 25. The ductile alloys generally formed several variations of single cracks, without branches, which were designated by "D-1" and "D-2." The brittle alloys ruptured in various manners, types "B-1" to "B-4" exhibiting a well-defined straight primary crack with several secondary branches which appeared to be caused by rather violent failure of the bulge.

Two variations of ductile failures were observed. The one consisted of a straight crack, running, without exception, in the longitudinal direction, type "D-1," Figs. 1 and 25. The other, type "D-2," apparently started as a short crack but continued circumferentially to one side of the crack, forming a more or less C-shaped flap rather than a straight split. While the straight split was found to occur always in the longitudinal direction, not more than $^1/_2$ in. away from the crown, the center of the flap-type crack ran longitudinally with some alloys, but with others (R301 and 75S) in various directions; however, it also approached

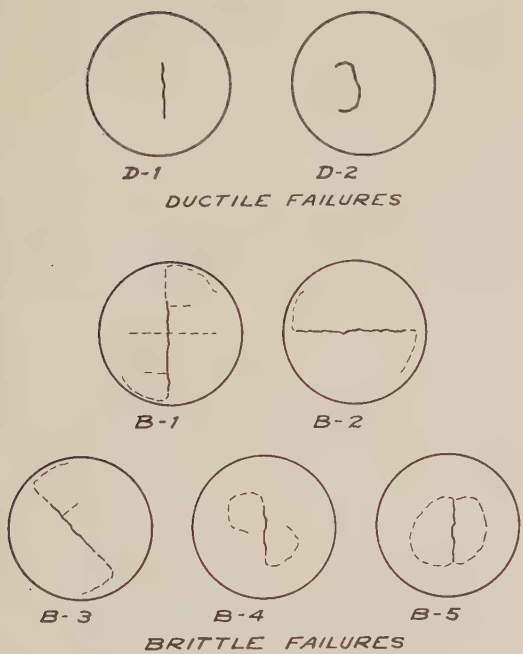

Fig. 25 Diagrammatic Sketch of Representative Types of Failures

the crown within a distance of less than $^1/_2$ in.[8] Only in three instances (24S-O bare, at 345 and 375 F, and 52S-O at 285 F), a branch in the fracture was observed for a ductile alloy.

The type of failure of the heat-treated alloys, Groups II-A and II-B, differed for the various specimens of each alloy. Most of the specimens exhibited a longitudinal primary crack, while a smaller number showed a pronounced transverse crack, and a still smaller number possessed a center crack at different angles to the rolling direction. Apparently, the more brittle the specimen, the more violent was the bursting and the more branched was the fracture.

With increasing temperature, the cracks usually became shorter and more regular, and in some instances, degenerated into a pinhole at the highest temperature used.

Rather pronounced orange peel was also encountered in the alloy 61S-W, and slight orange peel in the alloys R301-0, 75S-O, 24S-RT clad, 24S-T81 clad, 24S-T86 clad, 75S-T (at higher temperatures). The results of the investigation do not appear to be markedly affected by this condition.

The heat-treated alloys, with the exception of 61S-W and 61S-T, exhibited pronounced heat warping ("oil-canning") after the tests.

[8] Only at the highest temperatures some fractures occurred farther apart from the pole of the bulge associated with a rather irregular strain distribution. This is explained by temperature variations as previously mentioned.

Tests in which some draw-in occurred because of insufficient hold-down pressure were discarded, as were the results for a few specimens which yielded pinhole fractures because of slight irregularities in the sheet. The strain values of these specimens were generally lower than those of perfect specimens.

Little difficulty was caused by failure at the radius. A few specimens of the alloy, 24S-T86 bare broke at the radius at low pressures and exhibited a peculiar small fold extending toward the inside of the bulge into the oil. Also, one specimen of 24S-T clad failed at the radius when tested at a temperature of 525 F.

Conclusions

The pressure required to burst a sheet with a circular area exposed to gradually increasing hydraulic pressure on one side is, according to the theory of strength, a function of the tensile strength of the metal, and the thickness and curvature of the part at the moment of failure. However, as far as the effect of increasing temperature is concerned, the bursting pressure follows much the same trend as the tensile strength, according to previous investigation (3). On the contrary, the relation between different alloys is clearly different in the bursting test than in the tensile test. Of the artificially aged alloys of very high strength, only 75S-T exceeded 24S-T in bursting strength at room temperature, while 24S-RT, 24S-T81, 24S-T86, and R301-T exhibited a lower bursting strength than 24S-T. No explanation can be given for this phenomenon, at present.

The general significance of the two strain values, namely, the forming limit and reduction in thickness (area), used as metal characteristics and supplied by the tests on circular bulges, and their relation to the corresponding strain values supplied by the tensile test, is also obscure at present. In a tensile test the forming limit is the uniform strain or "infinite gage length elongation" and is entirely independent of the contraction in area at failure, or "zero gage length elongation." On the contrary, the bursting tests yielded forming limits, which always apparently paralleled the reduction in thickness (or area) at failure.

This also conforms to the fact that the forming limits of the bulges considerably exceeded the uniform tensile strain, and in most instances the conventional 2-in-gage-length elongation (3). No exception to this rule was observed in these tests. However, if the metal should possess an extremely low ductility, i.e., contraction in area, this should be exhausted in a bulge test earlier than in a tensile test, and a forming limit in bulging below that in tension could be expected.

Discussion

In 1945, when there was a ban on national meetings, some papers originally scheduled for these meetings were presented before local groups. In the case of these papers the Commitee on Publications suspended its rule, which requires simultaneous publication of paper and discussion, and accepted discussion based on the published paper.

Acceleration Damper: Development, Design, and Some Applications[1]

B. S. Cain.[2] This interesting paper develops the mathematical theory of the acceleration damper by analytical methods. The authors wish "to give a clear step-by-step picture of the mechanism of the acceleration damper and thereby facilitate handling of transient cases, effect of rebound, and extension of theory to modified cases." A graphical method, however, seems also to be effective in these cases. If we plot the two limits of motion of the mass particle against time, then, in any steady motion, it can easily be seen that the particle stays at one limit until this passes through a point of inflection, after which the particle moves freely until it again reaches a limit.

Taking the case of sinusoidal motion, the kinetic-energy loss per cycle is easily obtained for any conditions. It can also be seen at once that the maximum damping is obtained when the free path of the particle is π times the semiamplitude of the motion, as given in the paper. This simple graphical method lends itself to a clear picture of the operation, with easy calculation of the results. It is easy to introduce the effects of any wave-shape, of transients, of rebound, and of friction.

The graphical method is particularly adapted to practical design and analysis of behavior, because the whole picture can be seen at once, and it is not necessary to use Dirac functions or even the calculus to obtain practical results. The results of graphical analysis can be used for correlation with viscous damping without difficulty. In view of the advantages of the graphical method, it would be interesting to know if the authors have used it and what disadvantages they have found in comparison with the methods which they describe.

The experimental results and the application to flutter analysis show that a simple and easily understood theory of the acceleration damper is of real value, and the authors are to be congratulated on their contribution.

Harry Frissel.[3] The authors state that theoretical calculations show the acceleration damper to be effective in raising the flutter speed, but this had not been confirmed by experiment. In an earlier paper,[4] H. Voight mentions briefly the results of model experiments using this same device in an aileron.

In the latter case it was called a "disturbance damper." A plot of vibration amplitude versus dynamic pressure shows that for an aileron mass, balanced with a disturbance damper, the critical dynamic pressure is 4 times that for an aileron with damper inoperative. Also, if cork plates were used for the bottom of the container holding the balls, the critical dynamic pressure was approximately twice that of an aileron with damper inoperative. When the damper is inoperative, the vibration amplitude increases rapidly as the velocity approaches the critical value. With the damper acting, the vibrations at first commence in the same way. The balls then break away from their support when $1g$ acceleration is exceeded, and the amplitude is constant with increasing velocity. The function of the damper is to upset the phase relations necessary for flutter. When the impact energy of the damper can no longer upset the phase agreement sufficiently, the amplitude again rises sharply.

Authors' Closure

The authors appreciate that Mr. Cain has brought to their attention an interesting graphical method for determining the characteristics of the acceleration damper. It is believed that the graphical method proposed by Mr. Cain will prove especially useful when the effects of viscosity, friction, etc., on the motion of the particle are considered. It is noted that in spite of the involved mathematical treatment contained in the theory, the essential formulas used in the design of an acceleration damper for a specific application are simple algebraic equations and therefore the authors have not given consideration to graphical analysis.

The authors wish to bring to Mr. Frissel's attention that the type of acceleration damper considered in the theoretical investigation of its effect on the flutter characteristics of an airplane embodies a structural feature which is essential to its efficient operation and which is not contained in the disturbance damper described by H. Voight.[4] It is noted that the theory of the acceleration damper assumes that a gravitational or any other constant field does not act on the moving mass. Therefore this theory does not describe the behavior of a disturbance damper in which the motion of the particle perpendicular to the earth is acted upon by an acceleration of g. Since this paper has been submitted for publication, the authors have embodied in their acceleration damping device a structural means for realizing in practice a physical configuration treated by the theory. This feature ascertains the functioning of the damper and its effective operation for all accelerations however small, which is essential in order that the damper operate effectively in controlling flutter. The device described by Mr. Voight is not effective until accelerations of g or greater are attained. It is also noted that the disturbance damper cannot be designed to operate as effectively as the acceleration damper even when accelerations of g are exceeded, since the effect of the gravitational field changes the phase angle between the mass particle and the motion of the configuration which is being damped. As demonstrated by the theory, the selection of a suitable phase angle and its maintenance are especially important for the efficient operation of the acceleration damper. Herein lies one of the essential differences between the acceleration damper and the disturbance damper described.[4]

Another significant consideration embodied in the design of an acceleration damper is that the length of the free path of the mov-

ing mass is definite and is determined by Equation [13] of the paper. This dimension determines the phase angle such that the damper can operate at maximum efficiency. This design criterion is not included in the description of the disturbance damper given by Mr. Voight.

Figs. 4, 5, and 6, in which the effect of the gravitational field is not considered, were intended to describe the structure of the acceleration damper schematically.

The authors regret that this was not given more emphasis in the original paper.

Jet Propulsion and Rockets for Assisted Take-Off[1]

By M. J. ZUCROW,[2] AZUSA, CALIF.

This paper discusses the two kinds of jets which may be used for propelling bodies through the atmosphere: (a) Highly heated compressed atmospheric air admixed with products of combustion formed by burning a fuel in the air; the thermal energy of the fuel being employed to raise the air temperature. This type is known as a "thermal-jet engine." (b) A jet formed by generating large quantities of gases by chemical reaction. The equipment in which such a jet is produced is known as a "rocket motor." Operating principles and estimated performance characteristics of thermal-jet engines are treated, and certain unrestricted information on the use of rocket motors or "Jato" units for assisted take-off of aircraft is presented.

Nomenclature

The following nomenclature is used in the paper:

T = propulsion thrust, lb
G = weight flow, lb per sec
g = acceleration due to gravity, ft per sec per sec
w = relative exit velocity of jet, fps
V = flight speed, fps
c = absolute exit velocity of jet, fps
a = acoustic velocity, fps
$m = \frac{G}{g}$ = mass flow, slug per sec
P_T = thrust power (TV), ft-lb per sec
P_L = exit loss, ft-lb per sec
P = propulsion power, ft-lb per sec
c_p = specific heat, Btu per lb per deg F
D = diameter, ft
$\mathbf{M}$ = Mach number
T_1 = temperature of entering air, deg R
T_2 = temperature at entrance to compressor, deg R
T_3 = temperature at end of isentropic compression, deg R
T_4 = temperature at end of actual compression, deg R
T_5 = temperature of air entering turbine, deg R
T_6 = temperature at end of isentropic expansion from turbine inlet pressure to turbine back pressure, deg R
T_7 = temperature at end of actual expansion in turbine, deg R
T_9 = temperature at end of isentropic expansion from turbine back pressure to atmospheric pressure, deg R
$\phi = T_2/T_1 = 1 + 0.2\mathbf{M}^2$ for air
$\theta = (P_3/P_2)^{\frac{k-1}{k}} = T_3/T_2$
$\alpha = T_5/T_1$
$\nu = V/w$ = velocity ratio
ρ = density, slug per cu ft
η = over-all efficiency = $\eta_i\eta_P$
η_i = internal efficiency
η_P = propulsion efficiency
η_c = compressor efficiency
η_t = turbine efficiency

$$\Sigma = \left(1 - \phi\frac{\theta - 1}{\eta_r\eta_t\alpha} - \frac{1}{\phi\theta}\right)\left[\frac{1 - \phi\dfrac{\theta - 1}{\eta_c\alpha}}{1 - \phi\dfrac{\theta - 1}{\eta_r\eta_t\alpha}}\right]$$

Subscripts:

a = air
f = fuel

Introduction

In its broadest sense, the term jet propulsion refers to the art of propelling a body by the reaction or thrust of a fluid jet. There is no limitation, in general, upon the conceivable means which may be employed to produce the jet. Furthermore, the working fluid may be a liquid, vapor, heated air, the gaseous products of a chemical reaction, or combinations of these. However, when it comes to propelling bodies through the atmosphere by jet propulsion, the jet may be one of two kinds.

1 There is the jet consisting of highly heated, compressed, atmospheric air admixed with the products of the combustion formed by burning a fuel in the air; the thermal energy of the fuel being employed to raise the air temperature. A jet of this type will be termed a "thermal jet," and the equipment utilized for producing it will be termed a "thermal-jet engine."

2 There is also the jet formed by generating large quantities of gases by a chemical reaction. These gases are usually produced by reacting a fuel with a chemical oxidizer, but reducing reactions are not ruled out. The significant thing is that atmospheric oxygen does not enter into the chemical reaction, which is therefore independent of the atmospheric surroundings. A jet produced in this manner will be termed a "rocket jet," and the equipment wherein the chemical reaction takes place, including the discharge nozzle, will be called a "rocket motor."

This paper discusses certain basic features of jet propulsion as a mode of propelling bodies through the air. In this connection, the comments on thermal-jet engines will be restricted to operating principles and estimated performance characteristics. Another purpose of this paper is to present certain unrestricted information on the rocket motors used for the assisted take-off of aircraft, commonly referred to as "Jato" units.

Reaction and Momentum Principles

The fundamental operating principle of any jet-propulsion device is the "action-equals-reaction" principle known as Newton's third law of motion. This states: "To every action there is an equal and opposite reaction." This principle is exceedingly common in Nature, and is so well known to engineers that it merits little discussion here. It should be noted, however, that where motion of a body through a fluid medium is concerned, the

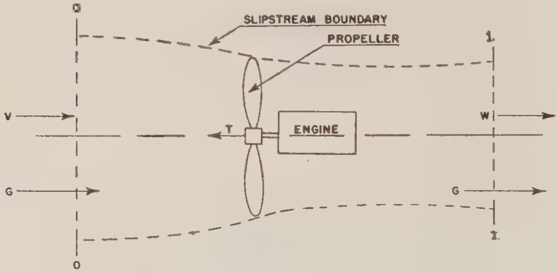
Contributed by the Aviation Division and presented at the Aviation War Conference, Los Angeles, Calif., June 11–14, 1945, of The American Society of Mechanical Engineers.

reaction principle predominates.[3] Thus the screw employed for propelling a ship, the propeller for moving an airplane, and jet propulsion all operate by virtue of this principle. In every one of these cases a fluid is accelerated in the direction opposite to that of the desired motion for the body, and the reaction due to the acceleration produces a propulsion force or thrust in the direction of motion. The magnitude of the propulsion force is determined by applying the momentum principle, "the rate of change of the momentum of a bounded mass system of discrete particles (body of fluid) is equal to the sum of the external forces acting on the system."[4]

Thrust Equations for Propulsion Systems

Fig. 1 illustrates the application of the foregoing principles to the engine-driven propeller. Since the air reactions on a body



(1) MOMENTUM ENTERING SECTION O–O

$$M_0 = \frac{G}{g} V = mV$$

(2) MOMENTUM LEAVING SECTION 1–1

$$M_1 = \frac{G}{g} w$$

(3) CHANGE IN MOMENTUM PER. SEC.

$$T = M_1 - M_0 = \frac{G}{g}(w - V) \text{ LB}$$

AND

$$\frac{T}{G} = \frac{w}{g}\left(1 - \frac{V}{w}\right) = \frac{w}{g}(1 - \nu)$$

(4) THRUST POWER

$$P_T = TV = \frac{G}{g} w^2 (1 - \nu)\nu$$

Fig. 1 Momentum Principle Applied to Propeller

depend only upon the relative velocity between it and the air, the body may be assumed to be stationary and the air to approach it with the actual speed of the body. In the ideal case the propeller creates a slip stream as indicated in the figure. The air enters the slip stream with the linear velocity V feet per second relative to the propeller and leaves it with the exit relative velocity w feet per second. If the air flow through the slip stream is G pounds per second, then the thrust developed is

$$T = \frac{G}{g}(w - V) \qquad [1]$$

It will be seen that the difference between the characteristics of propeller propulsion and jet propulsion is not as great as might be assumed. Thus if the propeller and engine are enclosed in a duct, so that the propeller acts as a blower or compressor, and the air of the slip stream is heated by burning a fuel in it, the resulting thermal-jet engine is that originally ascribed to S. Campini. This arrangement is illustrated in Fig. 2. The essential difference between this system and the propeller is that the relative

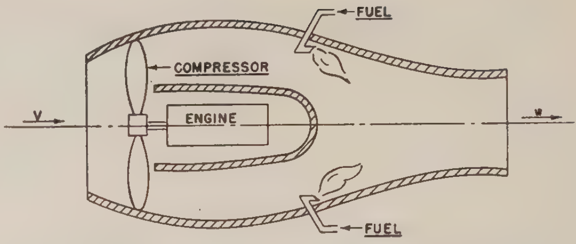


Fig. 2 Momentum Principle Applied to Campini System

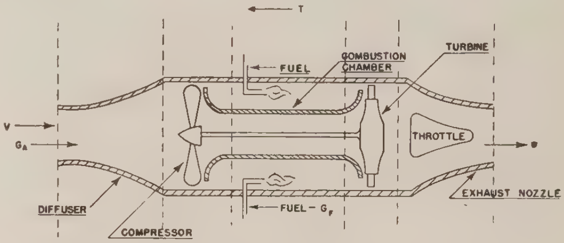


$$T = \text{THRUST} = \frac{G_A}{g}(w - V) + \frac{G_F}{g} w \approx \frac{G}{g}(w - V)$$

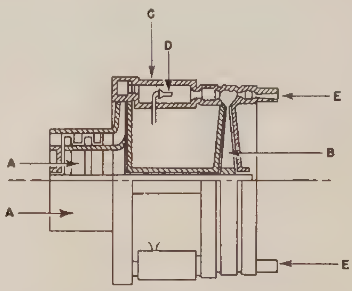
$$\frac{T}{G} = \text{THRUST/LB. OF AIRFLOW} = \frac{w}{g}\left(1 - \frac{V}{w}\right) = \frac{w}{g}(1 - \nu)$$

$$P_T = TV = \frac{G}{g} w^2 (1 - \nu)\nu$$

Fig. 3 Momentum Principle Applied to Thermal-Jet Engine

exit velocity of the gases (mainly air) has been increased by virtue of the addition of thermal energy. The thrust equation has the same form, but the thrust per unit mass of air flow is larger owing to the increased exit velocity. It should be noted, however, that the absolute exit velocity of the gases $c = (w - V)$ has also been increased so that the kinetic energy lost in the exit gases is also larger.

Fig. 3 illustrates the type of thermal-jet engine currently the most popular. The major difference between this and the Campini system is that the air compressor is driven by a gas turbine instead of an internal-combustion engine. The patent literature discloses many different arrangements for this type of thermal-jet engine. Their apparent differences, however, are not basic, but are confined to such features as the type of air compressor, the type of turbine, the combustion-chamber arrangement, and construction details. All of them have the same objective, i.e., to compress air, heat it, drive a turbine, and



A = AIR COMPRESSOR

[3] "Raketenflugtechnik," by E. Sänger, R. Oldenbourg, Munich, Germany, 1935.

[4] "Fundamentals of Hydro- and Aeromechanics," by L. Prandtl and O. G. Tietjens, McGraw-Hill Book Company, Inc., New York, N. Y., 1944, p. 233.

discharge heated gases through some form of nozzle. The most successful pioneer in this field has been Air Commodore Frank Whittle of the R.A.F. It is interesting to note that his British Patent Application, No. 347,206, filed January 16, 1930, illustrated in Fig. 4, embraced all of the necessary elements.[5] For a review of the patent literature, the reader is referred to a text by G. Geoffrey Smith.[6]

It is seen by reference to Fig. 3 that the equation for the thrust developed by this type of thermal-jet engine is given by

$$T = \frac{G_a}{g}(w - V) + \frac{G_f}{g}w \qquad [2]$$

Let $G = G_a + G_f$ which is approximately equal to G_a; since G_f can be neglected because it is ordinarily less than 3 per cent of G_a. The equation for the thermal-jet engine then becomes

$$T = \frac{G}{g}(w - V)$$

which is identical with Equation [1].

The thrust equations for the propeller and thermal-jet propulsion systems can be transformed to show the relation between the thrust and the velocity ratio ν; the latter being the ratio of the velocity of the moving body (V) to the exit relative velocity of the fluid (w). Thus for these two propulsion systems

$$T = \frac{G}{g}w(1 - \nu) \qquad [3]$$

or the thrust per pound of air flow per second is

$$\frac{T}{G} = \frac{w}{g}(1 - \nu) \qquad [4]$$

Equation [4] indicates how thrust developed, per pound of fluid flowing through the propulsion system per second, varies with the exit velocity (w) and the velocity ratio (ν).

It is seen that as the velocity ratio approaches unity, the thrust per pound of air flow per second approaches zero. Consequently, to develop thrust under conditions close to unity velocity ratio, the quantity of working fluid required becomes very large; hence a large exit area would be needed for passing the fluid. For a fixed velocity ratio the size of the required exit area increases as the speed of the airplane decreases; hence the propeller, with its ability to handle extremely large quantities of air at velocity ratios close to unity, is well adapted to the propulsion of bodies at moderate and low speeds. This is particularly true since, as will be seen later, operation close to unity velocity ratio gives high propulsion efficiency.

Fig. 5 is a plot of the thrust per pound of air flow per second as a function of the velocity ratio for different flight speeds. In the same figure is plotted the ideal propulsion efficiency as a function of the velocity ratio.

Fig. 6 illustrates the jet-propulsion action of the rocket system. The arrangement illustrated utilizes the chemical reaction between a liquid fuel and a liquid oxidizer; each liquid is termed a propellant. The propellants are removed from the supply tanks at the constant rate of G pounds per second. They may be, for example, gasoline and a sufficient quantity of liquid oxygen to burn it completely. At (1) the pressure of the liquids is increased by a suitable pressurizing means, and at (2) the propellants are injected into the combustion chamber. As the propellants flow through the combustion chamber they react at substantially constant pressure, producing large quantities of hot combustion gases. The combustion is completed by the time the gases reach the entrance to the exhaust nozzle through which they expand adiabatically and from which the gases are discharged with supersonic velocity.

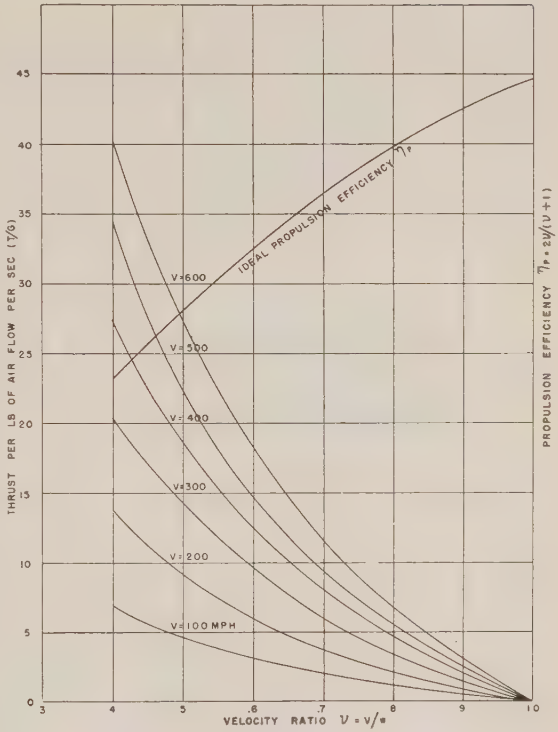

FIG. 5 THRUST PER POUND OF AIR FLOW PER SECOND AS A FUNCTION OF THE VELOCITY RATIO

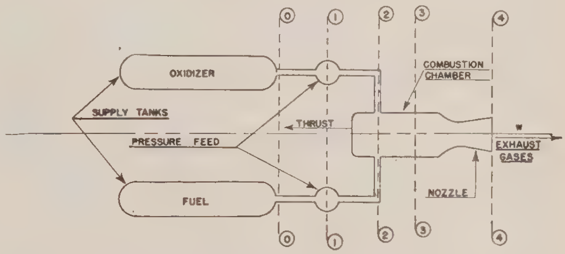

FIG. 6 JET-PROPULSION ACTION OF LIQUID ROCKET SYSTEM

If the area ratio for the nozzle is selected so that the gases are expanded to the pressure of the atmosphere surrounding the nozzle-exit section, then with a constant pressure in the combustion chamber, the thrust is given by

$$T = \frac{G}{g}w = mw \qquad [5]$$

where w is the velocity of the exhaust gases relative to the nozzle, and is called the "effective exhaust velocity."[7]

[5] Thirty-second Wilbur Wright Memorial Lecture, by Sir A. H. Roy Fedden, *Journal of The Royal Aeronautical Society*, London, Eng., May 26, 1944.

[6] "Gas Turbines and Jet Propulsion for Aircraft," by G. G. Smith, published in the United States by Aerosphere, Inc., 370 Lexington Ave., New York, N. Y., 1944.

[7] "Characteristics of the Rocket Motor Unit Based on the Theory of Perfect Gases," by F. J. Malina, *Journal of The Franklin Institute*, vol. 230, 1940, pp. 433–454.

It should be noted that whereas the thrust developed by the propeller and the thermal-jet engine depends upon the difference between the relative exit velocity of the gases and the speed of the propelled body, the thrust of the rocket motor is independent of the motion of the rocket system; it depends only upon the effective exhaust velocity of the rocket jet.

Fig. 7 illustrates a rocket motor utilizing a solid propellant, fuel plus oxidizer. This is the type of rocket motor used most extensively for Jato. To obtain the desired action the propellant characteristics must be such that the propellant burns at a

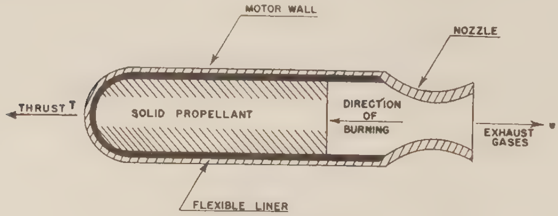

Fig. 7 Jet-Propulsion Action of Solid-Propellant Rocket Motor

uniform rate in layers perpendicular to the motor axis, that is, the burning is restricted to take place in one direction. One way of accomplishing this is by bonding the propellant stick and the steel walls of the motor with a special flexible sealing material, or liner, which allows the propellant stick the freedom of motion it requires for adapting its shape to the deformations produced by the gas pressure, thermal expansion, and internal stresses. The thrust equation for the solid-propellant rocket motor is, of course, identical with that for the liquid-propellant system.

Propulsion Power and Propulsion Efficiency

By propulsion power is meant the total power furnished the propulsion system. A portion of this power is converted into the thrust power required to maintain motion; the thrust power being the product of the thrust developed and the speed of the propelled body. The difference between the propulsion and thrust powers depends on the energy losses associated with the propulsion system. The ratio of the thrust power to the propulsion power is termed the propulsion efficiency and is denoted by η_p. Obviously, to obtain high values of propulsion efficiency the energy losses must be kept small.

The propulsion power P of the engine-driven propeller is the power supplied to it by the engine. In the thermal-jet engine the propulsion power is derived from the thermal energy of the fuel burned in the combustion chamber. For the rocket motor, the propulsion power comes from the heat of reaction of the fuel with the particular oxidizer employed. For all of these systems the energy loss, in the ideal case, is that associated with the kinetic energy of the fluid being ejected from the propulsion system. This is called the leaving or exit loss P_L and is given by

$$P_L = {}^1/_2 \frac{G}{g} c^2 = {}^1/_2 \frac{G}{g} (w - V)^2 \ldots\ldots\ldots [6]$$

Obviously, the prerequisite for a small exit loss is a low value for the absolute exit velocity of the propulsion fluid.

For all three propulsion systems, if it is assumed that the only energy loss is the exit loss, the propulsion power must be equal to the thrust power TV, plus the exit loss P_L. The ideal propulsion efficiency for each system is given by a general equation of the form

$$\eta_P = \frac{TV}{P} = \frac{TV}{TV + P_L} \ldots\ldots\ldots\ldots [7]$$

By substituting for the thrust and the exit loss from the preceding equations, the ideal propulsion-efficiency equations for each system are obtained; thus

(a) *Ideal Propeller:*[8]

$$\eta_P = \frac{TV}{P} = \frac{2V}{V + w} = \frac{2\nu}{\nu + 1} \ldots\ldots\ldots\ldots [8]$$

(b) *Ideal Thermal-Jet Engine:*

$$\eta_P = \frac{2V\,[(G_a + G_f)\,w - G_a V]}{(G_a + G_f)w^2 - (G_a - G_f)V^2}$$

If G_f is neglected so that $G = G_a \mp G_f$, then

$$\eta_P = \frac{2\nu}{\nu + 1}$$

(c) *Rocket Motor:*

$$\eta_P = \frac{TV}{TV + \frac{G}{2g}(w - V)^2} = \frac{2V}{w^2 + V^2} = \frac{2\nu}{1 + \nu^2} \ldots [9]$$

It is seen from the foregoing that the propeller and the thermal-jet engine have identical ideal propulsion-efficiency equations and that their efficiencies depend upon the velocity ratio. It should be noted, however, that for these propulsion devices operation at unity velocity ratio is impossible because the thrust then falls to zero. For these two propulsion systems the relation between the thrust power and the velocity ratio is

$$P_T = TV = \frac{G}{g} w^2 (1 - \nu)\nu \ldots\ldots\ldots [10]$$

This equation shows that for a constant rate of fluid flow G, the thrust power is a quadratic function of the velocity ratio. The maximum value for the thrust power is obtained under these conditions when the velocity ratio is $\nu = 0.5$. The corresponding value of the propulsion efficiency is then $\eta_P = 0.667$. It is seen therefore that the velocity ratio for maximum thrust power and maximum propulsion efficiency are different.

In the case of the rocket jet, the thrust depends directly on the exhaust-gas velocity w. Consequently, operation at unity velocity ratio or higher is a possibility. Thus assume that w = 6000 fps, then at unity velocity ratio the body propelled by the rocket-jet motor must be traveling at a speed of 4100 mph. Fig. 8 shows the effect of flight speed on the propulsion efficiency of a rocket jet, based on w = 6000 fps. Obviously, the rocket jet is an extremely inefficient propulsion device at travel speeds comparable to those attained by the fastest fighter aircraft.

Fig. 9 presents the estimated propulsion-efficiency curves for the propeller, thermal jet, and rocket jet at 20,000 ft altitude.[9] The propeller and thermal-jet curves intersecting at 550 mph indicate that the propeller is the more efficient at speeds below that value. These two efficiency curves intersect at lower speeds with increasing altitude. At 30,000 ft, for example, the intersection point is at 450 mph. The rocket jet has a very low propulsion efficiency except at extremely high speeds of travel.

The over-all efficiency η, of any of these propulsion systems is, of course, the product of the thermal efficiency of the power plant (or the internal efficiency η_i) and the propulsion efficiency

V = true air speed, fps
w = relative exit velocity of propulsion fluid, fps

PROPULSION POWER AND DISCHARGE AREA

Fig. 10 is a plot of the so-called propulsion parameter $V\sqrt[3]{D^2\rho/P}$, as a function of the ideal propulsion efficiency. This curve is applicable to the engine-driven propeller and the thermal-jet engine. When applied to the propeller, D is its diameter, ρ is the atmospheric density,[10] V is the airplane speed, and P is the power furnished by the engine. For the thermal-jet engine, D is the diameter of the discharge jet, ρ is the density of the jet gases, and the propulsion power P is calculated from the increase in the kinetic energy of the gases entering and leaving the system; thus

$$P = \frac{G}{2g}(w^2 - V^2)$$

[10] It has been assumed that the density of the air is increased 15 per cent in passing through the actuator disk.

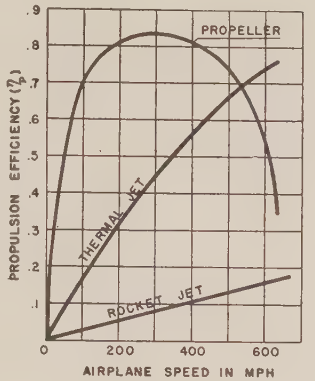

FIG. 9 COMPARISON OF PROPULSION EFFICIENCIES OF PROPELLER, THERMAL JET, AND ROCKET

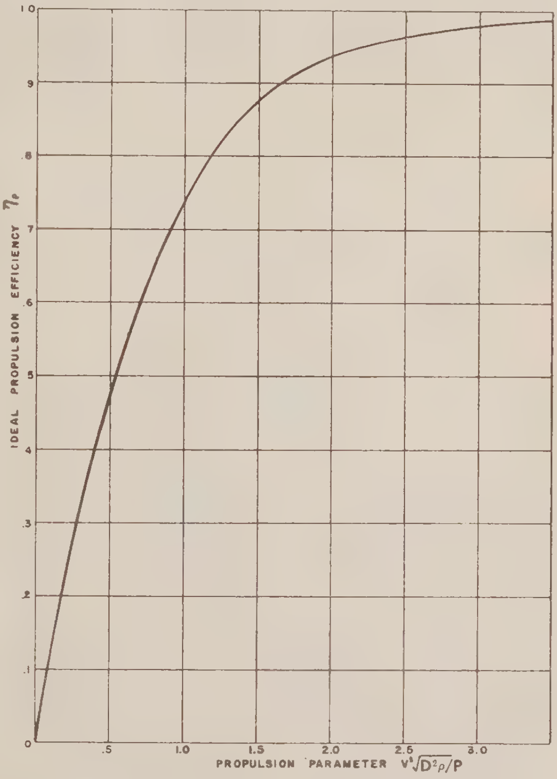

FIG. 10 PROPULSION EFFICIENCY VERSUS PROPULSION PARAMETER FOR PROPELLER AND THERMAL JET

The equations relating the propulsion parameter and the ideal propulsion efficiency are presented for reference as follows:

Propeller[11] *Thermal Jet*[12]

$$V\sqrt[3]{D^2\rho/P} = \frac{0.82\eta_P}{\sqrt[3]{1 - \eta_P}} \approx \frac{1.364\,\eta_P}{\sqrt[3]{8 - 12\eta_P + 4(\eta_P)^2}} \quad [11]$$

[11] Reference 8, p. 204.
[12] "The Modern Gas Turbine," by T. Sawyer, Prentice Hall, Inc., New York, N. Y., 1945, p. 178.

The curve gives the maximum attainable propulsion efficiency for either type of propulsion system. It is seen that to obtain high values of efficiency with low airplane speeds, D must be large, assuming the other factors constant. This operating condition is most readily met with propeller propulsion.

When flight speeds in excess of 500 mph are considered, there arise problems connected with the engine size, as well as those due to the effect of compressibility of the air upon the propeller efficiency, for the power requirements increase as the cube of the airplane speed. Thus if it takes 1200 hp to propel a given airplane at 360 mph at a given altitude, it would require an engine developing approximately 3200 hp to propel it at 500 mph, assuming all other factors remained unchanged. This calls for a heavy and complex power plant, even if this power can be furnished by a single engine. On the other hand, the thrust power for attaining this speed can be obtained from a thermal-jet engine of relatively light weight, with a jet diameter of 1 ft and an exhaust velocity of approximately 1500 fps.

Reciprocating internal-combustion engines for large power outputs require a multiplicity of accessories which result in an increase in their specific weights. Furthermore, they introduce complicated installation and maintenance problems. The probable trend in the specific weight of large internal-combustion engines, as estimated by Sir A. H. Roy Fedden, is presented in Fig. 11.

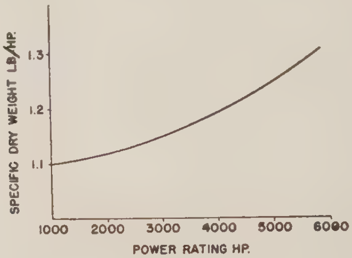

Fig. 11 Trend in Reciprocating-Engine Weights With Power Rating

The efficiency of an actual propeller will be approximately 0.85 of the ideal propulsion efficiency, or 0.833. This is due to various factors neglected by the momentum theory, such as whirl energy imparted to the slip stream, nonuniformity of the thrust distribution over the blades, blade-profile drag, and periodicity of the flow.

It was shown previously that to obtain the maximum propulsion power from a thermal-jet engine, the velocity ratio should be approximately 0.5. The propulsion efficiency for this condition is 0.667. Assuming the operating data used for the propeller previously discussed, and the discharge temperature for the jet at 1200 deg R, so that $\rho = 0.00102$ slug per cu ft, then the propulsion efficiency is about 68 per cent of that obtainable with an ideal propeller; the further assumption being made that the propeller is unaffected by compressibility. To obtain the same ideal propulsion efficiency as that for the propeller, the velocity ratio must be decreased, with the consequence that the required diameter of the jet becomes very large.

Thermodynamic Analysis of Thermal-Jet Engine

The analysis presented here is based on the following simplified assumptions:

(*a*) There is full recovery of the dynamic pressure of the entering air (100 per cent ram).

(*b*) There is no change in the mass rate of flow of fluid passing through the engine.

(*c*) There is no change in the chemical composition of the working fluid, it being assumed to be air at all sections of the flow path.

(*d*) The working fluid (air) behaves in accordance with the laws of perfect gases; the effect of temperature on the specific heat of the air is neglected.

The inaccuracies introduced by the foregoing assumptions are so small that for the practical purpose of obtaining a general insight into the behavior of the thermal-jet engine they are well justified. The advantage of this form of analysis is that general equations for the various performance characteristics can be derived.

Fig. 12 illustrates the thermodynamic process involved on the temperature-entropy (T-S) plane. The processes have been explained in the foregoing and are denoted on the diagram.

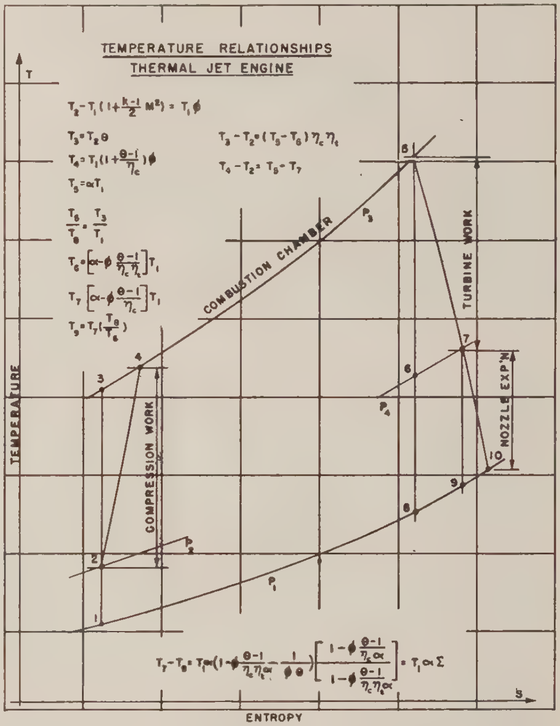

Fig. 12 Thermal-Jet Engine Cycle on Temperature-Entropy Plane

The object of the analysis is to obtain equations for the temperatures at the state points indicated on the diagram in terms of the temperature of the entering air and its Mach number. These equations are listed in the diagram. From them the equation for the temperature difference ($T_7 - T_9$), corresponding to an isentropic expansion through the nozzle, is readily obtained. Fig. 13 presents values of this temperature difference as a function of Mach number for five different altitudes ranging from sea level to 40,000 ft.

Since the temperature difference ($T_7 - T_9$) is proportional to the isentropic enthalpy change for the expansion in the nozzle, the exhaust velocity of the jet is readily calculated; thus

$$w = 223.7\sqrt{c_p\,(T_7 - T_9)} \times \text{nozzle coefficient} \quad \ldots. \quad [12]$$

where $c_p = 0.24$ Btu per lb per deg F.

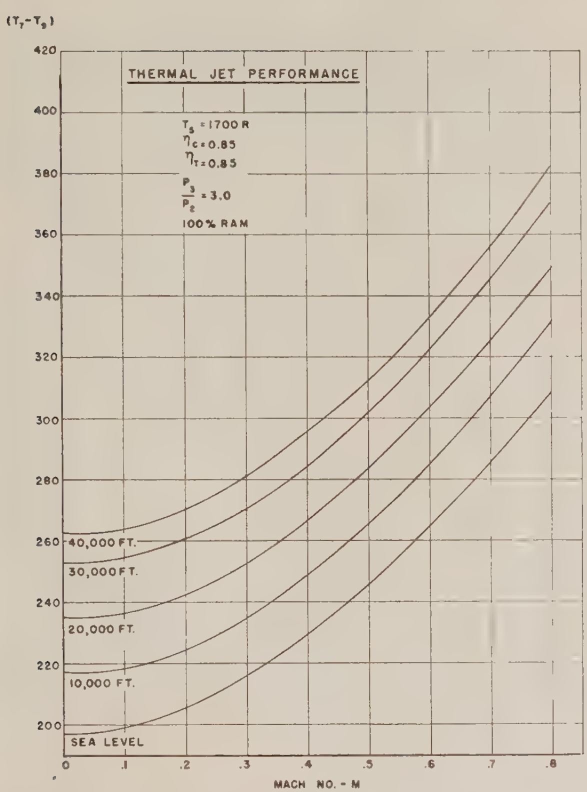

FIG. 13 TEMPERATURE DIFFERENCE (T_7 — T_9) AS A FUNCTION OF MACH NUMBER

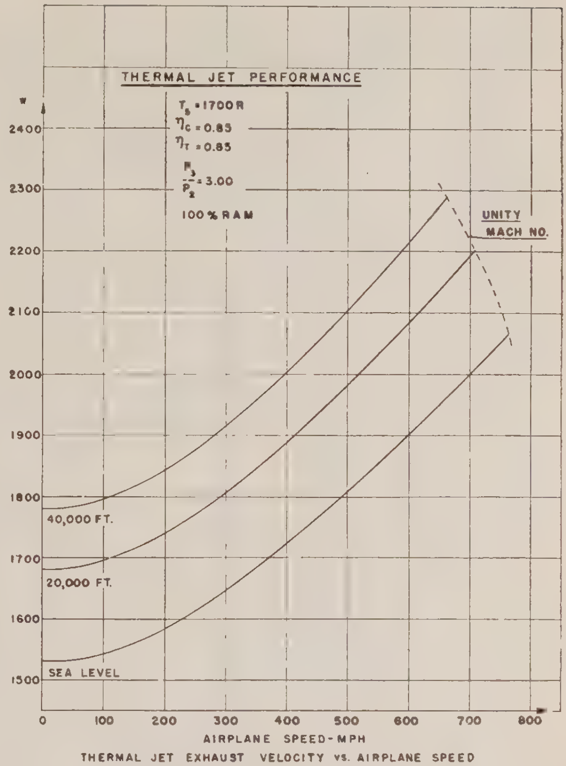

FIG. 14 THERMAL-JET VELOCITY VERSUS TRUE AIR SPEED IN MILES PER HOUR

In calculating the performance characteristics the nozzle velocity coefficient was assumed to be unity.

PERFORMANCE CHARACTERISTICS OF THERMAL-JET ENGINE

Fig. 14 illustrates how the jet velocity varies with the true air speed, in miles per hour, at different altitudes. The rapid increase in jet velocity with higher air speed is due to full recovery of the dynamic pressure of the air. Since the thrust developed by the engine depends upon the velocity difference (w — V), it is important to design the intake system so that the ram recovery is high.

Fig. 15 illustrates how the weight rate of air flow through the system varies with Mach number, with the compressor running at constant speed.

Fig. 16 shows the effect of true air speed on the thrust and the fuel consumption per pound of thrust. Assuming that the fuel has a calorific value of 18,000 Btu per lb, it is seen that the ratio of the static thrust to flight thrust is considerably less than it is for a variable-pitch, constant-speed, engine-driven propeller. As a result of the ram effect, the thrust increases at higher air speeds after passing through a minimum point. The fuel consumption per pound of thrust increases with flight velocity at all altitudes. Its rate of increase, however, diminishes somewhat with increasing altitude at speeds in excess of 250 mph.

Fig. 17 compares the thrust characteristics of the adjustable-pitch propeller with that of a thermal-jet engine. The basis of comparison is the fact that both propulsion systems provide equal thrusts at 375 mph.[13]

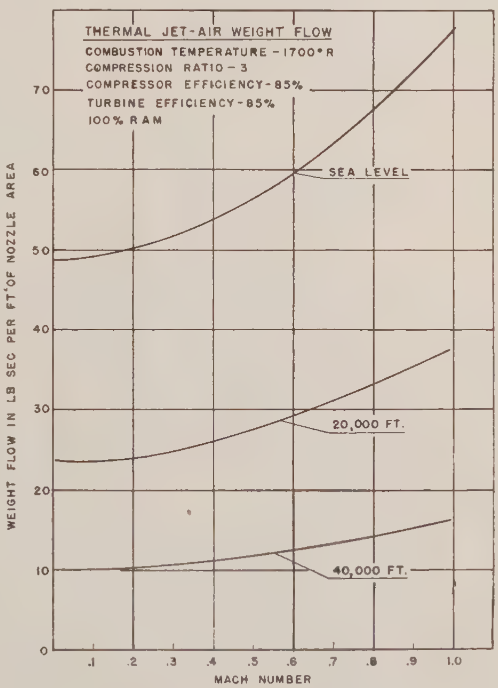

FIG. 15 WEIGHT RATE OF AIR FLOW VERSUS MACH NUMBER

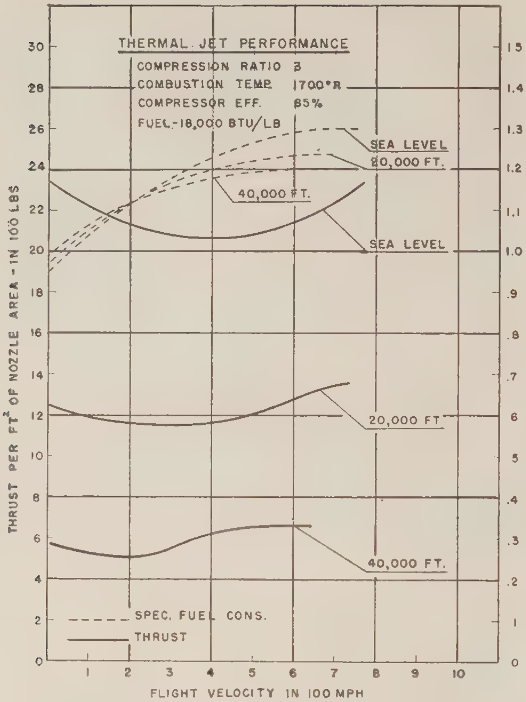

Fig. 16 Thrust and Fuel Consumption of Thermal-Jet Engine Versus True Air Speed

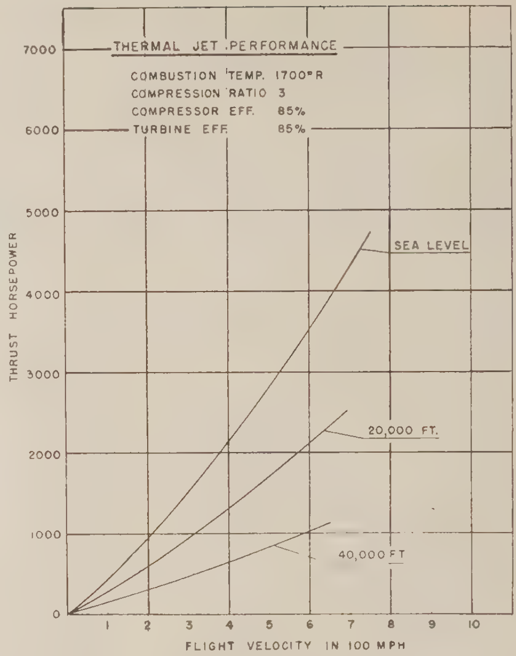

Fig. 18 Thrust Horsepower of Thermal-Jet Engine Versus Flight Speed

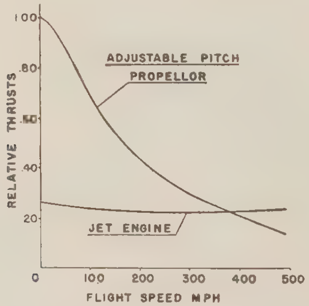

Fig. 17 Comparison of Propeller and Thermal-Jet Thrusts Versus True Air Speed

Fig. 18 shows how the thrust horsepower developed by the thermal jet varies with flight velocity and altitude.

Fig. 19 shows how increasing temperature of air leaving the combustion chamber affects static thrust and fuel consumption per pound of thrust. It is seen that raising the temperature greatly increases the static thrust at sea level but this is only at the expense of a slightly higher rate of fuel consumption per pound of thrust.

In the present state of the metallurgical art, operating temperatures as high as 1750 F are possible. If the present rate of improvement of refractory metals continues, operating temperatures as high as 2000 F appear to be probable.[14] As in the case of

[14] "The Gas Turbine in Aviation—Its Past and Future," by S. R. Puffer and J. S. Alford, presented at the Aviation War Conference, Los Angeles, Calif., June 11–14, 1945, of The American Society of Mechanical Engineers.

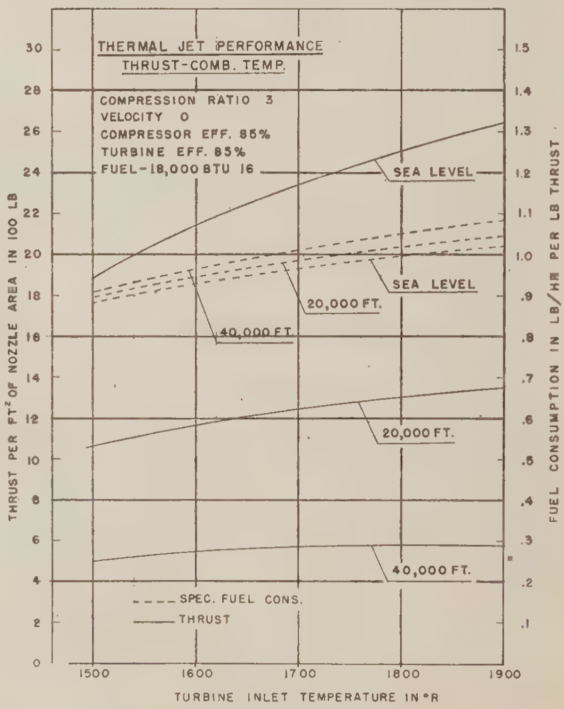

Fig. 19 Effect of Temperature on Static Thrust and Fuel Consumption of Thermal-Jet Engine

gas-turbine propulsion plants, the maximum benefits derivable from higher operating temperatures will necessitate using higher pressure ratios.[15]

Fig. 20 presents the static thrust and fuel consumption as functions of the pressure ratio of the air compressor for a constant temperature at the entrance to the turbine. Increasing the pressure ratio is effective in increasing the thrust and decreasing the fuel consumption.

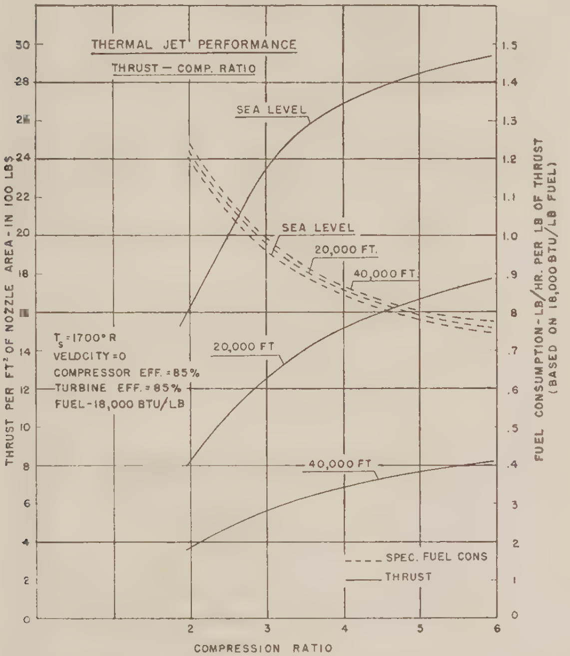

Fig. 20 Effect of Pressure Ratio on Static Thrust and Fuel Consumption of Thermal-Jet Engine

The efficiency of the unit, defined as the ratio of the thrust horsepower to the fuel supplied, is given by

$$\eta = \frac{2(\phi - 1)}{\alpha - \phi\left(1 + \dfrac{\theta - 1}{\eta_c}\right)}\left[\sqrt{\frac{\alpha\Sigma}{\phi - 1}} - 1\right] \ldots\ldots [13]$$

With the assumed machine efficiencies, $\eta_c = \eta_t = 0.85$, and a pressure of 3, the efficiency at 500 mph and 20,000 ft altitude is approximately 15 per cent. An engine-driven propeller with a propulsion efficiency of approximately 60 per cent would give the same over-all efficiency. The efficiency, as a function of true air speed for different altitudes, is presented in Fig. 21.

Fig. 22 illustrates the effect of the efficiency of the compressor upon the static thrust developed and the corresponding fuel consumption. It is seen that with a turbine efficiency of 0.85 and a pressure ratio of 3, no thrust is developed if the compressor efficiency is less than 49 per cent. Increasing the efficiency of the compressor greatly reduces the fuel consumption and increases the thrust output. As a matter of fact, the efficiency of the system is improved by making the ratio of the compression work to the available energy of combustion as small as possible.[16]

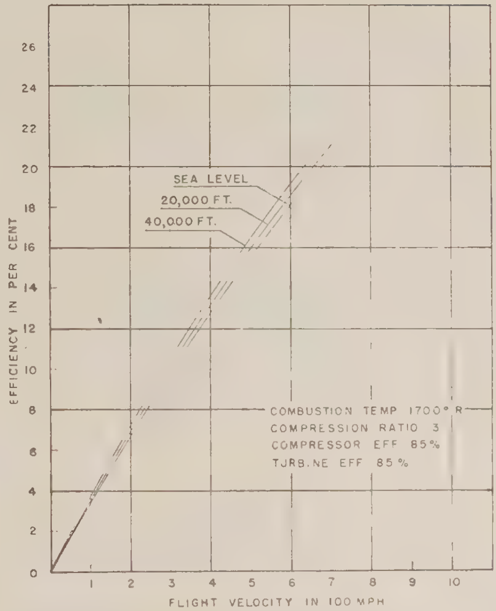

Fig. 21 Over-All Efficiency of Thermal-Jet Engine Versus True Air Speed

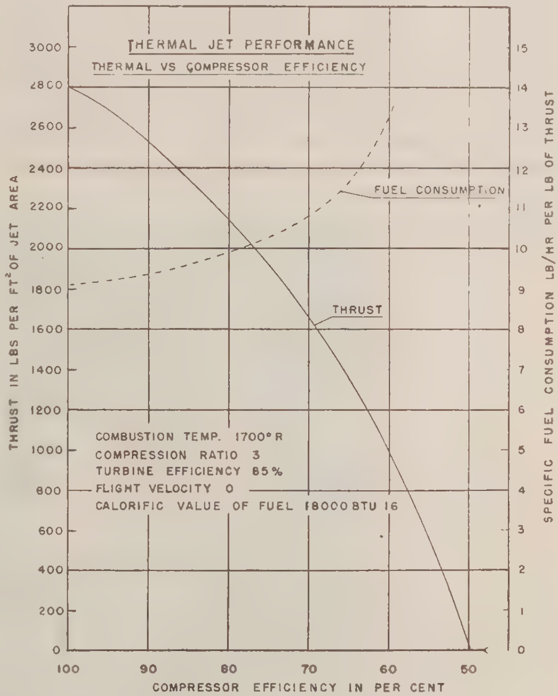

Fig. 22 Effect of Compressor Efficiency on Static Thrust and Fuel Consumption of Thermal-Jet Engine

The thermal-jet engine has made it possible to attain flight speeds higher than those obtainable with propeller propulsion. Because of its high fuel consumption, it has been widely held that its application will be restricted to short-endurance military

aircraft. Analyses of its commercial possibilities,[17] based on certain assumptions which have to be made at this stage in its development, indicate, however, that the jet-propelled transport should find a place in the postwar commercial field. These analyses indicate that for flights of the order of 500 miles, the jet-propelled transport provides economical transportation at high cruising speeds.[14] Until more of the operating data and actual performance characteristics of aircraft equipped with this form of power plant become available, the limits of the application of the thermal-jet engine to civilian aircraft cannot be stated with certainty.

Too much attention has been focused upon the apparent limitations of the thermal-jet engine, particularly upon its high fuel consumption; but these limitations appear to be related, to some extent at least, to the present state of the developments in the field of aerodynamics of high-speed flight. Thermal-jet propulsion imposes fewer restrictions upon the airplane designer. The commercial future of this method of propulsion depends to a large extent on the ability of airplane designers to produce airplanes with lower drag.

Perhaps the most attractive feature of the thermal-jet engine, apart from its ability to provide propulsion at high speeds, is its simplicity and low weight. Furthermore, this power plant is relatively free from vibration, permits using cheaper fuels than high-octane gasoline, and should require less frequent major overhauls.

Many problems are presented by the high operating temperatures required to obtain even fair fuel economy. Since weight and space are major considerations, the rate of heat liberation per cubic foot of combustion chamber has to be extremely high. For it to have reasonable life, its design must be arranged to give clean and reliable combustion, and the walls must be kept at safe operating temperatures. There are still metallurgical problems to be solved if higher operating temperatures are to be realized. In addition, there are problems in compensating for differences in thermal expansion. The fact that thermal-jet propulsion has become a practical reality is an indication, however, that great progress has been made in solving these problems.

[17] "Postwar Transport Aircraft," by E. P. Warner, *Aeronautical Engineering Review*, 1943, p. 7.

Rocket-Jet Application to Aircraft; Jato Units

The rocket has been developed to the stage where it should find a place as the power plant for short-duration high-speed aircraft (German ME 163); for long-range missiles (German V2 bomb); for superperformance at altitude, for torpedo drive, and for the assisted take-off of aircraft. Furthermore, the high-temperature high-pressure gas-producing capability of the rocket system should find application for short-duration turbine drives, or for any service where a temporary generation of such a gas can be employed for useful purposes.

In this country the principal application of rockets to aircraft apart from their use as weapons, is in the field of assisted take-off. Most of the applications have been to flying boats where the added thrust of the Jato units has made it possible to take off under conditions such that without them successful take-off would be problematical. This has increased the usefulness of such aircraft for rescue work in forward combat areas. Jato units have also been applied to carrier and land-based aircraft. As is to be expected, reductions in take-off time and/or distance have resulted from their use.[18]

Fig. 23 illustrates graphically the improvement in the sea level take-off characteristics of a DC-3 transport when equipped with a 1000-lb Jato unit having a duration of 14 sec. Fig. 24 is a similar comparison made at 6000 ft altitude. It is seen that the reduction in the distance to clear a 50-ft obstacle is from 4600 ft to 3250 ft at sea level and from 5800 ft to 3850 ft at 6000 ft altitude.

Two types of units have been applied; those employing liquid propellants, and those employing a solid propellant. To the author's knowledge, the solid-propellant units have found the greatest favor, owing to the ease of their installation, and the fewer logistic problems introduced by their use.

A liquid-propellant rocket system is ordinarily controlled from a single electric switch operated by the pilot. The switch actuates an electric control valve, thereby causing an inert pressurizing gas to communicate with the propellant tanks. The pressurizing gas passes through a regulating valve which main-

[18] "Take-Off Analysis for Flying Boats and Seaplanes," by E. G. Stout, *Aviation*, Oct., 1945, pp. 137–141; Nov., 1945, pp. 140–146, and Dec., 1945, pp. 163–166.

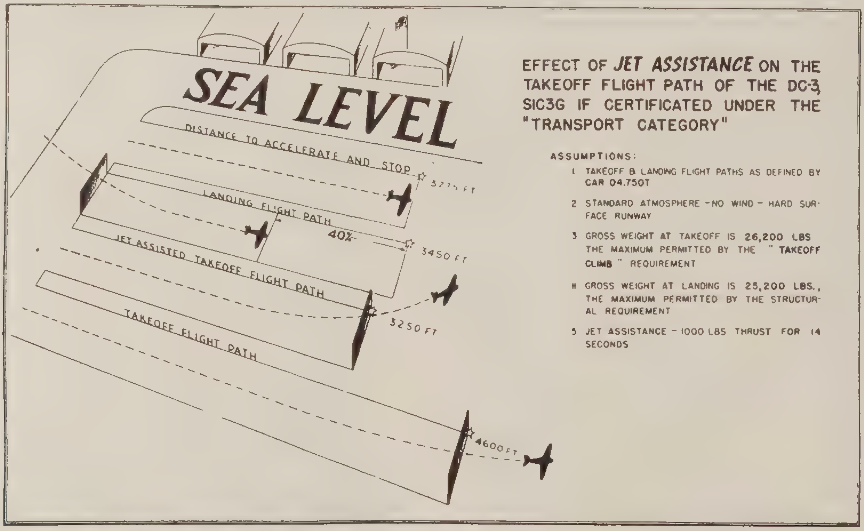

Fig. 23 Effect of Rocket-Jet Assistance on Take-Off Characteristics of DC-3 at Sea Level

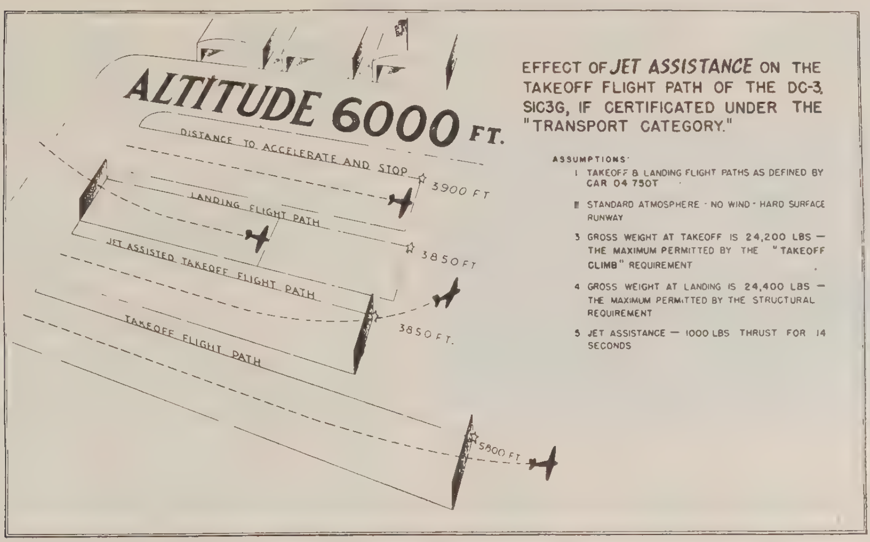

Fig. 24 Effect of Auxiliary Rocket-Jet Assistance on Take-Off Characteristics of DC-3 at 6000 Ft Altitude

tains the gas pressure on each propellant tank at a constant value. This gas is also utilized for actuating the propellant flow control valves located upstream relative to the injector which introduces the propellants into the motor. No ignition system is employed, since the propellants used with this unit react spontaneously upon contact with each other.

Liquid-propellant Jato units have been constructed so that they can be mounted either as fixed installations in the aircraft, or so that they can be dropped by parachute after use. Reliable liquid-propellant rocket motors have been developed that have operated without difficulty for continuous periods of several minutes. These motors are light in weight and are cooled by circulating one of the propellants around the combustion chamber and nozzle. For example, a rocket motor of this type developing 1500 to 2000 lb thrust can be built to weigh less than 45 lb. For security reasons, the design details of this type of motor cannot be released, nor can information be presented regarding the developments concerned with propellants or means for injecting the propellants into the motor.

Fig. 25 shows a typical solid-propellant Jato unit which delivers 1000 lb thrust for 12 sec. It is put into operation by means of the igniter which is fired electrically. Once the unit has been

Fig. 25 Typical Solid-Propellant Jato Unit for 1000 Lb Thrust, 12-Sec Duration

started it cannot be stopped and restarted, as can the liquid-propellant units.

Fig. 26 shows a PB2Y3 flying boat taking off with these units installed to supply additional thrust.

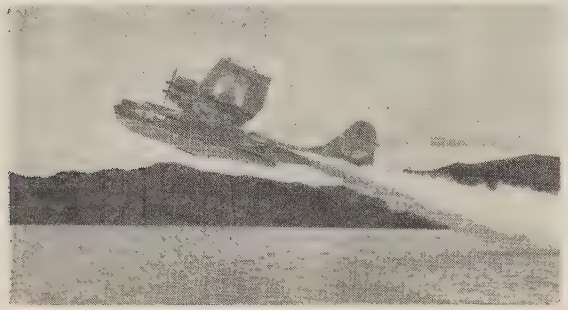

Fig. 26 Flying Boat Taking Off With Jato Assistance

Conclusions

Jet-propulsion devices have reached the development stage where they must be given serious consideration as a propulsion means. Where high-speed flight is of paramount importance, the thermal-jet engine has demonstrated its ability to accomplish that result. For shorter-duration high-speed flight, the rocket jet has potentialities.

In general, it appears that the future of jet propulsion in the postwar commercial field depends upon the success of the co-operative endeavors of airplane designers and jet-propulsion engineers in securing the maximum benefits offered by this mode of propulsion.

Acknowledgments

The author expresses his thanks to Mr. R. Sabersky, Aerojet Engineering Corporation, for his assistance in making some of the calculations for the performance characteristics of the thermal-jet engine.

(Owing to travel emergency conditions existing when this paper was presented, discussion will be accepted until May 10, 1946)

Free Heat Convection Through Enclosed Plane Gas Layers

By MAX JAKOB,[1] CHICAGO, ILL.

Fifteen years ago, Mull and Reiher published elaborate experiments on heat convection through enclosed plane air layers. In the present paper it is shown that the representation and evaluation of the results of these experiments can be simplified, improved, and generalized when, as for a single surface in an extended medium, a laminar and turbulent range are distinguished. Defining slightly modified Nusselt and Grashof numbers with the layer thickness L as characteristic length, the experimental results for horizontal and vertical layers can be expressed by $(N_{Nu})_L = C_b(N_{Gr})_L^n$, or $C_v(N_{Gr})_L^n(L/H)^{1/9}$, respectively, where $n = 1/4$ and $1/3$ for the laminar and turbulent ranges, respectively, and H is the height of vertical layer. Comparison with tests of other authors indicates that, due to the experimental elimination of any influences from the edge of the enclosed layer, Mull and Reiher obtained relatively low values of the constants C_b and C_v, whereas without particular precaution these influences may considerably increase the heat transfer.

Nomenclature

The following nomenclature is used in the paper:

$A = H \cdot W$ = area of gas layer
C = constant
D = diameter
g = gravitational acceleration
H = height of vertical gas layer
h = coefficient of heat transfer by convection
k = thermal conductivity of gas
k_c = equivalent thermal conductivity, including conduction and convection
k_r = equivalent thermal conductivity, superseding radiation
$k_e = k_c + k_r$ = equivalent thermal conductivity
L = thickness of gas layer
N_{Gr} = Grashof number
N_{Nu} = Nusselt number
n = constant
q = rate of heat flow
$q'' = q/A$
t = temperature
W = width of gas layer
β = coefficient of thermal expansion
ν = kinematic viscosity
Φ, Ψ = functions

Subscripts:

c = convection
D = diameter as characteristic length
d = heat flow downward
H = height as characteristic length
h = horizontal gas layer
L = thickness of gas layer as characteristic length
m = mean
u = heat flow upward
v = vertical gas layer
1 = warmer surface
2 = colder surface

1 Introduction

In his excellent survey on heat transmission, presented in 1932, King (1)[2] dealt only briefly with the subject of heat transfer in air layers as "too involved to allow a complete discussion here." In particular, he had in mind the experimental results for plane air layers, published by Mull and Reiher in a not widely known supplement to a German magazine (2). It will be seen that these results are less involved than they appear in the original paper. The present paper will bring them to a more general and simpler representation and show their close relation to equations for free convection on horizontal and vertical surfaces.

2 Mull and Reiher's Procedure and Results

As a measure for the heat exchange in a gas layer, Mull and Reiher used an equivalent thermal conductivity k_e, which combines the effect of convection and radiation and is defined by

$$k_e = k_c + k_r \qquad [1]$$

where k_c and k_r are themselves equivalent thermal conductivities, the first one including the effect of conduction and convection and the second one superseding the effect of radiation.

Whereas k_r can be simply calculated, using the laws of radiation, it requires special experiments to determine k_c. Mull and Reiher employed two parallel plates, each 40 in. long and 24 in. wide, which were separated by air layers. These could be divided in different ways so that it was possible to study enclosed air layers having areas of 30 to 960 sq in. Air layers of seven different thicknesses from $1/2$ to $7^3/_4$ in. were employed. One of the two plates was an electrical heating plate composed of five separate sections and surrounded by an electrical ring heater. A secondary heating plate at the rear side, insulated from the front plate and ring, was held at the same temperature as these. Thus the main heat flow was confined to the front side from where it first crossed the air layer under consideration and then a cork plate which served as an auxiliary heat flowmeter. Strips of poorly conducting balsa wood, only 80/1000 in. thick, separated the air layers from each other and from the surrounding air which was in contact with the ring heater. Zinc was the material of the heating and cooling surfaces (zinc-plated steel sheets). The whole system of plates was surrounded by granulated cork and fixed in a wooden frame. This was turnable in a horizontal bearing so that the air layer could be brought into horizontal, vertical, or oblique position.

Contributed by the Heat Transfer Division and presented at the Annual Meeting, New York, N. Y., Nov. 26–29, 1945, of The American Society of Mechanical Engineers.

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

The rate of heat flow by convection between a warmer surface (subscript 1) and a cooler surface (subscript 2) can be expressed by

$$q_c = k_c \frac{A}{L}(t_1 - t_2) \text{ or } q_c'' = \frac{k_c}{L}(t_1 - t_2) \quad [2]$$

where

L = the thickness of gas layer
A = $H \cdot W$, area of this layer
H = height of rectangular area A (when brought into vertical position)
W = width of this area
t_1 and t_2 are surface temperatures
$q_c'' = q_c/A$

Further, from the theory of similarity for air and probably also for any other diatomic gases (except under extreme conditions of state)

$$(N_{Nu})_L = \Phi[(N_{Gr})_L, H/L, W/L] \quad [3]$$

where slightly modified Nusselt and Grashof numbers are defined by

$$(N_{Nu})_L = \frac{q_c''}{(t_1 - t_2)} \cdot \frac{L}{k} = \frac{k_c}{k} \quad [4]$$

and

$$(N_{Gr})_L = \frac{\beta g}{\nu^2} L^3(t_1 - t_2) \quad [5]$$

with

g = gravitational acceleration
β = coefficient of thermal expansion of gas
k = its thermal conductivity
ν = its kinematic viscosity

the last two properties being taken at the mean temperature

$$t_m = {}^1/_2(t_1 + t_2)$$

From Equations [3] and [4]

$$k_c/k = \Phi[(N_{Gr})_L, H/L, W/L] \quad [6]$$

First considering horizontal layers (subscript h), the experiments, with heat flow upward, showed that $k_{c,h}/k$ is virtually independent of H and W. Then, from reasons of similitude, it will also be independent of H/L and W/L. Hence Equation [6] simplifies to

$$k_{c,h}/k = \Phi(N_{Gr})_L \quad [7]$$

Mull and Reiher represented their results by plotting $k_{c,h}/k$ versus log $(N_{Gr})_L$; obviously

$$k_{c,h}/k \longrightarrow 1 \text{ when } (N_{Gr})_L \longrightarrow 0$$

In the experimental range of $(N_{Gr})_L$ = 2112 to 8,890,000, a smooth curve of increasing steepness was obtained. Representation in bilogarithmic co-ordinates, however, will reveal that the curve has at least one bend in close relationship to other cases of free convection.

For vertical air layers (subscript v), the conditions are less simple than for horizontal layers because $k_{c,v}/k$ may not be independent of H and W. Mull and Reiher, in one of their tests, kept H/L and $(N_{Gr})_L$ constant, but reduced W/L from 25.7 to 12.8, that is, by 50 per cent. The term $(k_{c,v}/k)$ (H/L), however, changed only by 1.3 per cent. Hence, omitting W/L as independent variable and modifying Equation [6] slightly

$$\frac{k_{c,v}}{k} \cdot \frac{H}{L} = \Psi\left[(N_{Gr})_L \frac{H}{L}\right] \quad [8]$$

Similarly as for horizontal gas layers

$$k_{c,v}/k \longrightarrow 1 \quad \text{when } (N_{Gr})_L \longrightarrow 0$$

The problem also simplifies for very large Grashof numbers due to the vanishing of the frictional resistance between two parallel vertical surfaces with increasing distance; obviously

$$t_1 - t_m = t_m - t_2$$

and

$$q_{c,v}'' = h(t_1 - t_m) = h(t_m - t_2)$$

or

$$q_{c,v}'' = {}^1/_2 h(t_1 - t_2) \quad [9]$$

where h is the coefficient of convection for a single vertical surface. From Equations [2] and [9]

$$k_{c,v} = \frac{hL}{2} \quad \text{or} \quad \frac{k_{c,v}}{k} \cdot \frac{H}{L} = \frac{h}{k} \cdot \frac{H}{2} = \frac{1}{2} \cdot \frac{h}{k} \cdot \frac{H}{L} \cdot L \quad [10]$$

Hence, $k_{c,v}$ becomes proportional to L for very thick air layers and the resistance against thermal convection, $L/(k_{c,v}A)$ becomes constant. Since the resistance against heat transfer by radiation is also constant for given temperatures, it follows that the insulating power of an air layer cannot be increased infinitely by increasing the layer thickness as it would be with a solid layer, but is limited.

For layers of finite thickness, Mull and Reiher plotted $(k_{c,v}/k)$ (H/L), as measured, versus log $(N_{Gr})_L$ and built up 27 curves with H/L as parameter, making ample use of interpolation and extrapolation since a total of only 21 points from their own, and 3 from other experiments were available. Again, bilogarithmic representation will give a very much simpler and more reliable picture and will lead to simple equations for the laminar and turbulent ranges, analogous to those for single plane surfaces.

3 Dimensionless Equations for Free Convection on Vertical and Horizontal Surfaces

As already indicated, the heat convection on a plane plate is an extreme case of convection through a plane fluid layer.

The Nusselt and Grashof numbers for the free convection on a vertical surface of height H and temperature t_1 to a fluid of temperature t_m is usually defined by

$$(N_{Nu})_H = \frac{hH}{k} \quad [11]$$

and

$$(N_{Gr})_H = \frac{\beta g}{\nu^2} H^3(t_1 - t_m) \quad [12]$$

where arithmetic means, taken over the temperature difference $(t_1 - t_m)$, may be used for the properties of the fluid.

Employing the principle of similarity, Nusselt (3) showed that $(N_{Nu})_H$ is proportional to $H^{3/4}$, a result which had already been obtained analytically by Lorenz (4), 34 years before. This, however, is only a fair approximation to the actual much more complicated relation between h and H, as has been demonstrated later on by different workers, particularly by Schmidt and Beckmann (5) in a theoretical and experimental investigation. Moreover, Griffiths and Davis (6) had shown by experiments that above a certain height (about 2 ft for air) the coefficient h becomes independent of H and proportional to $(t_1 - t_m)$. They correctly

concluded that turbulence occurs above that height. It is worth noting that Nusselt (3) had already predicted an analogous phenomenon for horizontal cylinders placed in cooler air when $(N_{Gr})_D > 10^7$, the diameter D being used as characteristic length.

The occurrence of an exponent $n = 1/3$ in the equation

$$N_{Nu} = C(N_{Gr} \cdot N_{Pr})^n \qquad [13]$$

was later verified by a correlation of King (1) and by Jakob and Linke (7) in representing their own and Jakob and Fritz's experimental results (8) for not too vehemently boiling water. According to these investigations, the following equations can be used for vertical surfaces in an unrestricted fluid

$$(N_{Nu})_H = 0.555\,[(N_{Gr})_H N_{Pr}]^{1/4} \qquad [14]$$

for the laminar range and

$$(N_{Nu})_H = 0.129\,[(N_{Gr})_H N_{Pr}]^{1/3} \qquad [15]$$

for the turbulent range.

Jakob and Linke further showed that Equation [13] with $n = 1/3$ may also be used for the convection on the upper side of a horizontal plate (subscript u) on which water is boiling, and they concluded that in the range of their experiments, $q_{c,u}'' = 7$ to 5200 B hr^{-1} ft^{-2}, the coefficient of convection on a horizontal plate is independent of the size of the plate except for a possible effect of the edges. In fact, this had to be expected because it would not be understandable why the heat transfer on one place of a large horizontal plate should be different from that at any other place.

In other words, if Equation [13] is valid, then $n = 1/3$ must necessarily occur in all cases where no reason exists why h should depend upon a characteristic length. In a subsequent paper, Jakob and Linke (9) found by experiments with boiling water and carbon tetrachloride that the constant C of Equation [13] sensibly exceeds the values given in Equations [14] and [15]. For vertical surface, in the range where $n = 1/4$, $C_v = 0.61$ was found, compared to $C_v = 0.555$ in Equation [14]. This difference may be due to the action of the steam bubbles which is rather mild in the considered range, but increases rapidly at higher load (9, 10). With horizontal surface facing upward, $n = 1/3$ and $C_u = 0.16$ were observed to be compared with $C_v = 0.129$ for vertical surfaces according to Equation [15]. Here, in addition to the effect just mentioned, the difference of surface orientation seems to play a role. In fact, such an effect had previously been observed by Griffiths and Davis (6). From their tests on horizontal heating plates in air facing upward, the following equation can be derived

$$q_{c,u}'' = 0.275(t_1 - t_m)^{4/3} \qquad [16]$$

with

$q_{c,u}''$ in B hr^{-1} ft^{-2} and $(t_1 - t_m)$ in Fahrenheit units.

Combining this with their original values for vertical plates, 2 and $8^2/_3$ ft high

$$q_{c,u}''/q_{c,v}'' \approx 1.28 \qquad [17]$$

to be compared with $C_u/C_v = 0.16/0.129 = 1.24$.

For horizontal plates, facing downward (subscript d) where theoretically only conduction would be expected, Griffiths and Davis' measurements can be represented by

$$q_{c,d}'' = 0.50\,q_{c,u}'' \approx 0.64\,q_{c,v}'' \qquad [18]$$

It may be noted that

$$\frac{q_{c,u}'' + q_{c,d}''}{2} \approx \frac{1.28 + 0.64}{2}\,q_{c,v}'' = 0.96\,q_{c,v}'' \approx q_{c,v}'' \qquad [19]$$

Wilkes and Peterson (11), however, obtained about 1.6 instead of 1.28 (Equation [17]) and about 0.35 instead of 0.50 (Equation [18]). Their data are based on experiments with only 10 F temperature difference and therefore probably less exact.

4 New Equations for Free Convection Through Enclosed Plane Gas Layers

In the range of $(N_{Gr})_L$ = 10,000 to 10,000,000, Mull and Reiher's experimental data for horizontal air layers can be represented by two straight lines in bilogarithmic co-ordinates, Fig. 1. Intersection of these lines occurs at log $(N_{Gr})_L \approx 5.57$, corresponding to $(N_{Gr})_L \approx 370{,}000$. However, a state of transition may exist between $(N_{Gr})_L \approx 200{,}000$ and 800,000. In the

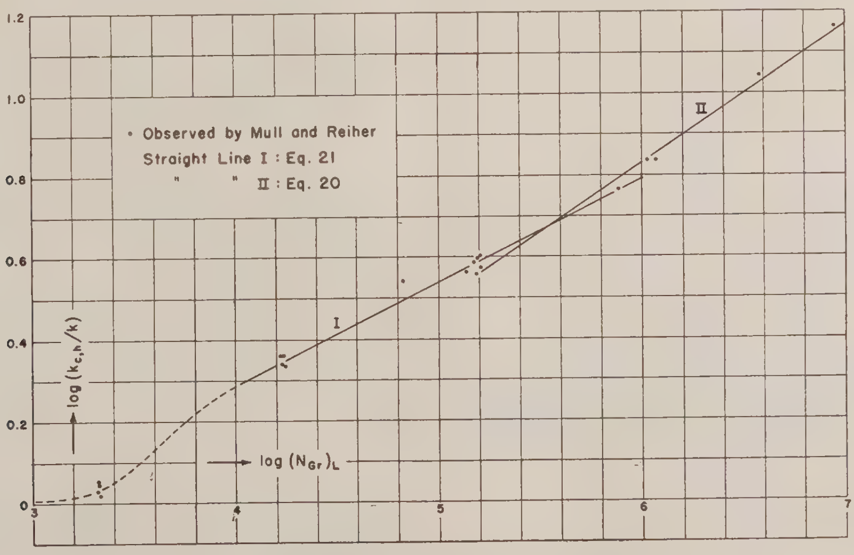

Fig. 1 Correlation for Horizontal Air Layers

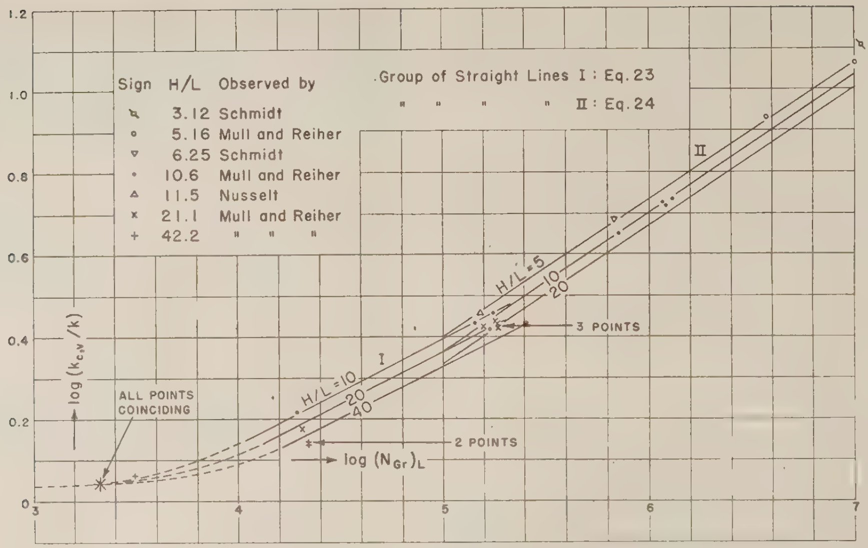

Fig. 2 Correlation for Vertical Air Layers

upper range,[3] similarly as for a heated surface, facing upward, or for a vertical surface

$$k_{c,h}/k = 0.068(N_{Gr})_L^{1/3} \quad \text{[20]}$$

In the lower range, in analogy to the behavior of vertical surfaces in a medium range of Grashof numbers

$$k_{c,h}/k = 0.195(N_{Gr})_L^{1/4} \quad \text{[21]}$$

For $(N_{Gr})_L \longrightarrow 0$, finally

$$k_{c,h}/k \longrightarrow 1 \quad \text{or} \quad \log(k_{c,h}/k) \longrightarrow 0 \quad \text{[22]}$$

as indicated by a dotted line in Fig. 1.

The meaning of Equation [20], obviously, is that above a certain thickness L the coefficient of heat transfer does not change any more, but should be the same as for a single horizontal plate, facing upward.

This may be checked by calculating an example: According to Equation [20]

$$q_{c,h}'' = 0.068k\left(\frac{\beta g}{\nu^2}\right)^{1/3}(t_1 - t_2)^{4/3}$$

For $t_1 = 75°$ C, $t_2 = 52°$ C, and 730 mm Hg atmospheric pressure, Mull and Reiher took $\beta g/\nu^2 = 0.110\,(10^9)$ m^{-3} C^{-1} and $k = 23.0\,(10^{-3})$ kcal hr^{-1}m^{-1}C^{-1}. Using these values and converting to British technical units

$$q_{c,h}'' = 0.068(23.0)10^{-3}(0.673)(0.110)^{1/3}(10^3)0.3048(1.8)(t_1 - t_2)^{4/3} = 0.277(t_1 - t_2)^{4/3}$$

in excellent agreement with Equation [16].

For vertical air layers, employing again bilogarithmic representation, all experimental points of Mull and Reiher and three points of other authors which they also used are plotted in Fig. 2.

At Grashof numbers as small as 2000, in analogy to Equation [7], no influence of H/L upon $k_{c,v}/k$ seems to exist in the range of the experiments (H/L = 10.6 to 42.2).

For still smaller Grashof numbers, the ratio $k_{c,v}/k$ approaches unity in analogy to Equation [22].

In the range of $(N_{Gr})_L$ = 20,000 to 200,000, the following equation represents the experimental data

$$k_{c,v}/k = 0.18(N_{Gr})_L^{1/4}(H/L)^{-1/9} \quad \text{[23]}$$

and in the range of $(N_{Gr})_L$ = 200,000 to 10,000,000

$$k_{c,v}/k = 0.065(N_{Gr})_L^{1/3}(H/L)^{-1/9} \quad \text{[24]}$$

Again the exponents, $1/4$ and $1/3$, of $(N_{Gr})_L$ are significant for laminar and turbulent flow. The exponent $-1/9$ of H/L, however, has been found empirically. The increase of $k_{c,v}/k$ with decreasing H/L is probably an effect of the lower and upper edge of the gas layer.

It is questionable how far beyond the range of the experiments Equations [23] and [24] are valid and, in particular, down to which smallest value of H/L Equation [24] can be used; certainly not down to $H/L = 0$, where it would yield an infinitely large heat transfer whereas the behavior of single vertical plates should be approached. However, the experimental point for $H/L = 3.12$ at N_{Gr} = 10,820,000 in Fig. 2 is in excellent agreement with the value calculated from Equation [24] ($\log[k_{c,v}/k]$ = 1.105, observed and 1.103, calculated) so that Equation [24] actually seems to be valid down to the ratio of $H/L \approx 3$.

Lines for H/L = 5; 10; 20; and 40 are drawn in Fig. 2, to facilitate interpolation. It is seen that they are in good agreement with the experimental points.

Mull and Reiher's paper includes one measurement for 45 deg inclination of the air layer. At H/L = 10.5 and $(N_{Gr})_L$ = 1,050,000 they obtained $k_c/k = 6.13$. Under the same conditions Equations [20] and [24] yield $k_{c,h}/k = 6.92$ and $k_{c,v}/k = 5.09$, the mean of which is 6.005. This result suggests that for angles from 0 to 90 deg linear interpolation between these equations may give reasonable results.

5 Discussion of Different Experimental Results

It must be mentioned that experiments, performed by Wilkes and Peterson (12), led to about 50 per cent higher values of q_c'' for vertical layers. An air layer with $L = 0.302$ and $H = W =$

[3] Particularly after correcting the highest point, at $(N_{Gr})_L$ = 8,890,000, for which Mull and Reiher erroneously have entered $k_{c,h}/k = 13.5$ (instead of 14.5) in their original graph.

2.667 ft was used, and it seems that the temperatures (t_1 = 60 deg F and t_2 = 40 deg F) were not varied either, so that the result would refer to $(N_{Gr})_L \approx 1{,}700{,}000$ only. The data given in the authors' paper do not allow one to check the accuracy of the results. The higher heat transfer obtained by them may be due to inclusion of the flow of heat through the studs confining the air layer and to the lack of a ring heater with air layer. Griffiths and Davis (6), employing a vertical layer with $L = ^1/_6$ ft and H/L = 24.8, arrived at almost 40 per cent higher heat transfer than Mull and Reiher, assumedly for the same reason. Experiments of Schmidt (13), on the other hand, performed with vertical layers, 0.263 or 0.526 ft thick, led to results in good agreement with those of Mull and Reiher (see Fig. 2). In these experiments a layer of 5-ft height was divided into three layers, each $1^2/_3$ ft high, by means of thin, horizontal strips of plywood, the adjacent layers giving some heat protection to each other. A test by Nusselt (14), on a vertical layer (L = 0.13 ft, H = 1.5 ft) led also to satisfactory agreement with our representation (see Fig. 2); this, however, may be accidental, considering the not too accurate experimental procedure.

With their air layer in horizontal position, Wilkes and Peterson, again at $(N_{Gr})_L \approx 1{,}700{,}000$, obtained a 40 per cent higher value than according to Mull and Reiher, whereas an experiment of Schmidt (13), at $(N_{Gr})_L \approx 30{,}000$, led to a 33 per cent smaller value than according to Mull and Reiher. This experiment was performed on a twin-plate device for measuring thermal conductivities, using a 1-in. air layer.

Considering the results of Wilkes and Peterson, and of Griffiths and Davis, the author looked for reasons why Mull and Reiher might have obtained too small values of convection. Referring to Equation [1], the value k_r was 27 to 49 per cent of k_e in their experiments. They determined k_r individually in each test by bringing the plates in horizontal position, heating the upper one, and assuming that no convection at all occurred in this case. According to Equation [20] or Fig. 1, this would mean that at $(N_{Gr})_L = 1{,}700{,}000$, after deduction of the radiated heat, the heat flow downward would amount to 12.3 per cent of that upward. This is not an unreasonable result, considering that Wilkes and Peterson found 23 per cent, without taking such precautions as the use of a heated air ring and thin balsa-wood strips to secure a strictly vertical heat flow downward. Anyway, k_r may have been found only a few per cent too large and k_c some per cent too small in Mull and Reiher's procedure. Incidentally, the emissivity of the zinc-plated steel sheet determined by them was rather too small than too large, according to the known values from literature, and there was no systematic influence of L on the measured value of that emissivity as would have been if convection had played a role.

Hence the only explanation for the mentioned differences is that, as just given, the Mull and Reiher values belong to the case of an enclosed partition, cut out somewhere in the middle of an extended gas layer between two parallel surfaces, each at uniform temperature, and with a practically nonconducting border strip, whereas in Griffiths' and Davis' results, as well as in those of Wilkes and Peterson, conduction effects on the edge of the layer are included. Therefore Equations [20], [21], [23], and [24] and Figs. 1 and 2 of the present paper yield values which may have to be increased by empirical factors if less ideal conditions exist at the edge of the air layer.

6 Free Convection Through Enclosed Plane Liquid Layers

According to the theory of similarity, Equations [20], [21], [23], and [24] should hold for any diatomic gases, except in such extreme ranges where the Prandtl number appreciably differs from $N_{Pr} = 0.72$, as assumed for air. Since for horizontal and vertical surfaces Equation [13] has been found to hold for gases and for liquids, even in the state of not too vehement boiling, with only moderately different values of C, the equations mentioned for confined layers may tentatively be used for other than diatomic gases and for liquids by multiplying the right sides by $(N_{Pr}/0.72)^n$, with $n = ^1/_4$ and $^1/_3$, respectively.

Discussion

W. J. King.[4] This paper constitutes a useful contribution to the literature of heat transmission, by making the data of Mull and Reiher available to American engineers in the form of a convenient and significant correlation.

The use of an "equivalent conductivity," k_e, has the advantage of expressing heat transfer through air spaces in the same units as for solid insulation or building materials, which may be convenient for combining terms. On the other hand, there is a disadvantage in that the conductivity of an air space is by no means a constant property of the material, as in the case of cork or brick, so that the actual relationship between heat transfer and thickness of the air space is somewhat obscured.

For example, it is shown that for certain conditions the conductivity is proportional to the $^3/_4$ power of the thickness. Actually, since the heat-transfer coefficient h (heat flow per unit time per unit area per degree temperature difference), is equal to the conductivity divided by the thickness, i.e.

$$h = \frac{k}{L}$$

[4] Research Engineer, Battelle Memorial Institute, Columbus, Ohio. Mem. A.S.M.E.

it turns out that the heat flow varies inversely with the $^1/_4$ power, or 4th root of the thickness, in this region.

It is also important to understand that for the wider air spaces or higher Grashof's numbers, where the conductivity is directly proportional to the thickness, the actual heat-transfer rate, as Btu per hour per square foot per degree temperature difference, is independent of the thickness.

Probably the most questionable feature of this correlation is the effect of height upon heat transfer across vertical air layers, as expressed by the term $(H/L)^{-1/}$ in Equations [23] and [24] of the paper. As the author points out, for the higher values of Grashof's number, to which Equation [24] applies, the heat transfer should be similar to free convection from exposed plane surfaces, in which case the effect of height is sometimes more pronounced. In fact, for vertical surfaces about 1 ft high, the effect of the height H, may be represented by the $-^1/_4$ exponent, under ordinary conditions.

Tests on enclosed air spaces made by E. R. Queer[5] in this country showed that the heat transfer across an air layer $4^1/_2$ in. high was about 80 per cent greater than for a height of 35 in. For a height ratio of 1 to 8, as in this case, the $-^1/_9$ exponent would give a 1.27 ratio of heat-transfer rates, instead of the 1.8 ratio observed by Queer. It is very likely that the effect of height becomes more pronounced as the height is decreased.

The author recognizes the fact that this exponent is not constant, pointing out that Equation [24] would give infinitely large heat-transfer rates for $H/L = 0$. This brings out the danger of applying such equations as these to conditions too far removed from those under which the original data were obtained.

Author's Closure

In discussing the concept of "equivalent conductivity," Mr. W. J. King uses the word "equivalent" only once and then omits it for brevity. Then, of course, all statements concerning that quantity become odd, as, for instance, the one that the conductivity be proportional to the 3/4 power of the thickness. The sense of introducing an "equivalent" conductivity, however, is only to show how much more heat is actually transferred than would be by conduction alone. The ratio $k_c/k = 1.5$, for instance, means that the heat transfer by convection is 50 per cent larger than the heat transfer by mere conduction.

This sort of representation is neither novel nor unique. The rate of heat exchange by radiation q_r, for instance, is often expressed by means of an "equivalent" coefficient of radiation, h_r. For black surfaces h_r is defined by the equation

$$q_r = \sigma A(T_1^4 - T_2^4) = h_r A(T_1 - T_2)$$

wherein

T = absolute temperature
σ = constant of Stefan-Boltzmann's law

It is seen that h_r is not a constant as σ, but depends upon T_1 and T_2 in a rather odd way. However, when convection and radiation occur in the same field, it is practical to use h_r, because the total coefficient of heat transfer simply becomes

$$h = h_c + h_r$$

Also the ratio k_c/k should just be considered as a practical form or as a Nusselt number (see Equation [4] of the paper).

The term $(H/L)^{-1/9}$ of Equations [23] and [24] was chosen empirically as best representing the points in Fig. 2 of the paper. However, its influence is small and it would have been possible to neglect it entirely and to represent each of the point groups I and II of Fig. 2, by a single straight line, yielding values of $k_{c,v}$ with extreme deviations of ± 10 per cent from the measured values. Doing so, Equation [23] would contain only the exponent $^1/_4$, in analogy to Equation [14].

Mr. King has further directed the author's attention to a paper of E. R. Queer,[5] who observed a much larger increase in heat transmission when the height H was reduced than did Mull and Reiher. This seems to be partly due to the heat conduction through the wooden strips which confined the air layers and the thick plates extending over the top and bottom of the apparatus. According to Fig. 2 of Queer's paper, these probably were thick enough to cause the large heat transfer observed by him for small ratios H/L. A part of the discrepancy, however, is due to the difference in the absolute values of heat transfer, observed in the two investigations for great ratios of H/L. For example, at $L = 1/12$ ft, $t_m \approx 75$ deg F, $t_1 - t_2 = 50$ F, the author's Equation [23] yields $q_{c,v}'' = 21.5$ Bhr^{-1} ft^{-2} for $H = 4.5/12$ ft, and $q_{c,v}'' = 17.2$ for $H = 35/12$ ft, in agreement with Mull and Reiher's experiments, whereas Queer obtained $q_{c,v}'' = 27.5$ and 15.3, respectively.

When the author by illness was prevented from presenting his paper personally, Mr. King kindly presented it for him, adding some interesting comments which form the subject of his discussion. The author wishes to express his appreciation for Mr. King's co-operation and valuable contribution.

A Graphical Determination of Unshielded-Thermocouple Thermal Correction

By W. M. ROHSENOW,[1] ANNAPOLIS, MD.

This paper presents a simple and rapid method for determining the thermal error of an unshielded thermocouple, with slide-rule precision.

Nomenclature

The following nomenclature is used in the paper:

Q = rate of heat transfer by convection
R = rate of heat transfer by radiation
C = rate of heat transfer by conduction
T_N = absolute temperature of N, deg R
t_N = temperature of N, deg F
h = film coefficient of heat transfer, Btu hr^{-1} ft^{-2} F^{-1}
k = thermal conductivity of thermocouple wire, Btu hr^{-1} ft^{-2} (F/ft)$^{-1}$
σ_b = Stefan-Boltzmann constant = 1.723×10^{-9} Btu hr^{-1} ft^{-2} R^{-4}
ϵ = emissivity
η = transmissivity
α = absorptivity
G = mass flow per unit cross section of duct area, lb ft^{-2} sec^{-1}
A = thermocouple bulb surface area, ft^2
D = thermocouple wire diameter, ft
d_0 = thermocouple bulb diameter, in.
b = exposed length of thermocouple, ft
T_m = $[(T_T^4 - T_W^4)/4(T_T - T_W)]^{1/3}$
T_a = average temperature between T_T and T_W = $1/2(T_T + T_W)$
θ = $(T_G - T_T)/(T_T - T_W)$

Subscripts:

G = gas
T = thermocouple
W = wall
S = thermocouple surface
GT = gas to thermocouple
TW = thermocouple to wall

Introduction

The problem of measuring the temperature of a gas stream by employing a thermocouple has been well treated by King (4),[2] Fishenden and Saunders (6), Bennett and Pirani (7), and Bosanquet (8). The accurate measurement of the temperature of a hot gas flowing in a duct is more difficult than the accurate measurement of the temperature of a solid or liquid. The temperature indicated by a thermocouple placed in the gas stream, Fig. 1, will always lie between the temperature of the gas itself and of the surrounding walls.

The thermocouple reading is in error because heat is exchanged between the thermocouple and the wall by radiation, and heat is transferred along the thermocouple wires by conduction. The analyses for the cases in which the gas is hotter than the wall and in which the wall is hotter than the gas are identical. When the gas is hotter than the wall, the thermocouple temperature is such that the rate of heat transfer by convection from the gas to the thermocouple plus the radiation from gas to thermocouple is equal to the radiation from the thermocouple to wall plus the conduction along the thermocouple wires. This may be stated in equation form

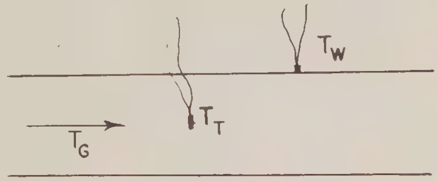

Fig. 1 Sketch of Duct With Temperatures Involved

$$Q_{GT} + R_{GT} = R_{TW} + C \quad [1]$$

The purpose of this paper is to present a simple and rapid solution of this equation in mathematical form and in chart form. The solution of Equation [1] involves solving a fourth-degree algebraic equation which is quite cumbersome to manipulate. The method of solution presented in this paper is simple and greatly reduces the time necessary to determine the thermocouple error. This method has slide-rule precision, which is more than sufficient when one realizes the inability to predict accurately emissivities and film coefficients of heat transfer.

Analysis

From the laws of convection and radiation, which may be found in McAdams (1), Equation [1] may be written in the form

$$Ah(T_G - T_T) + A\sigma\epsilon_g\left(\frac{1+\epsilon_s}{2}\right)(T_G^4 - T_T^4) = A\sigma\eta_G\epsilon_s(T_T^4 - T_W^4) \quad [2]$$

in which the conduction term is neglected. The conduction term is usually small; so it is neglected in the development of the equation from which the charts are constructed. Later a solution will be obtained for determining the magnitude of this conduction error.

The gaseous radiation term R_{GT}, and the gaseous emissivity ϵ_G of Equation [2] may be evaluated as indicated by McAdams,[3] and the thermocouple surface emissivity ϵ_s may be estimated as indicated by McAdams.[4]

If it is assumed that $\epsilon_G = \alpha_G$, then the transmissivity of the gas is

$$\eta_G = 1 - \epsilon_G$$

Dividing Equation [2] by $h(T_T - T_W)$ and simplifying

Note: Statements and opinions advanced in this paper are to be understood as individual expressions of the author and are not to be construed as official nor reflecting the views of the Navy Department or naval service at large.

[3] Reference (1), p. 68.

[4] Reference (1), p. 393.

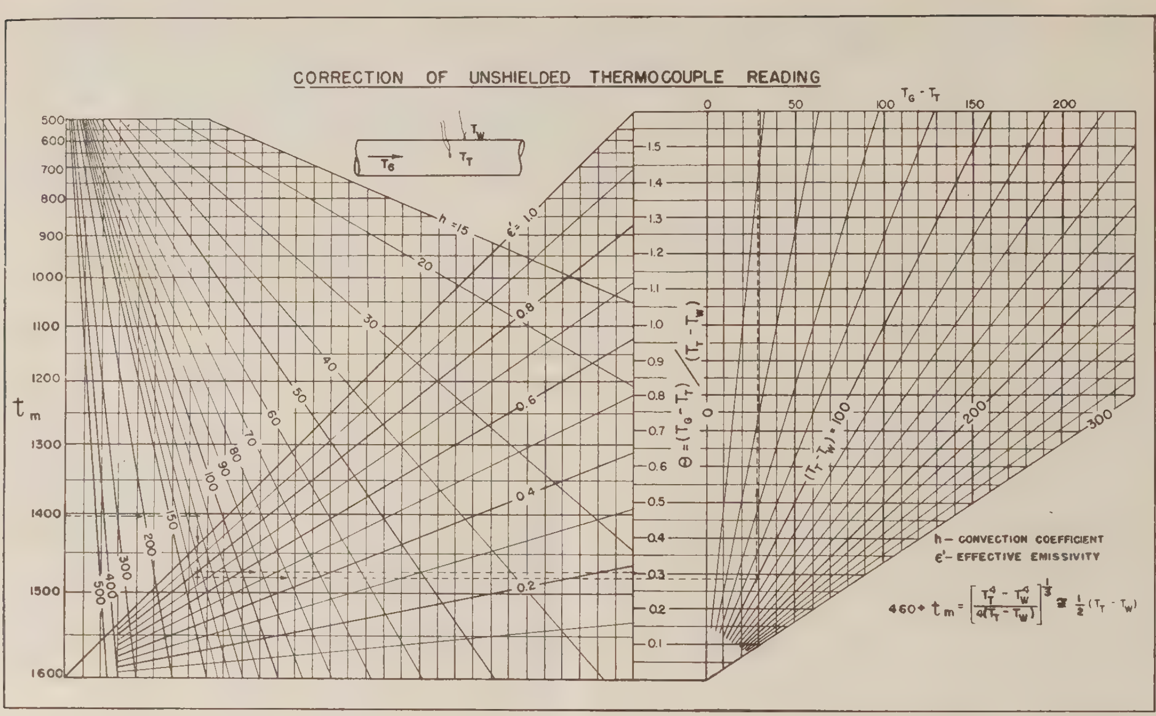

Fig. 2 Diagram for Unshielded-Thermocouple Correction

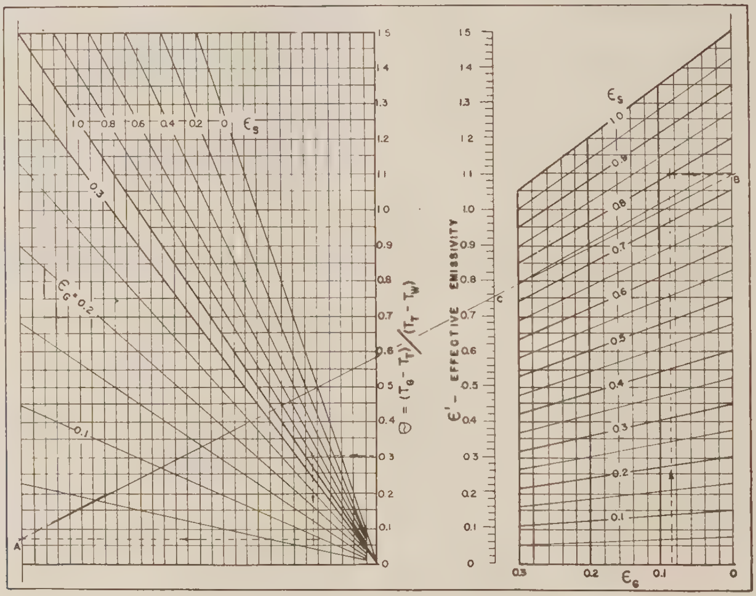

Fig. 3 Diagram for Determining Effective Emissivity

$$\frac{T_G - T_T}{T_T - T_W} = \frac{\sigma}{h} \cdot \frac{T_T^4 - T_W^4}{T_T - T_W} \left\{ \epsilon_s (1 - \epsilon_G) + {}^1/_2(1 + \epsilon_s) \cdot \epsilon_G \cdot \frac{T_G^4 - T_T^4}{T_T^4 - T_W^4} \right\} \ldots\ldots [3]$$

Now

$$\frac{T_G^4 - T_T^4}{T_T^4 - T_W^4} \equiv \frac{T_G - T_T}{T_T - T_W} \cdot \frac{T_G + T_T}{T_T + T_W} \cdot \frac{T_G^2 + T_T^2}{T_T^2 + T_W^2} \quad [4$$

Since T_G, T_T, and T_W are all large and of the same order of magnitude and their differences are small compared with the absolute magnitudes, the last two terms of the identity [4] are approximately equal to unity; hence

$$\frac{T_G^4 - T_T^4}{T_T^4 - T_W^4} \cong \frac{T_G - T_T}{T_T - T_W} \ldots\ldots [5]$$

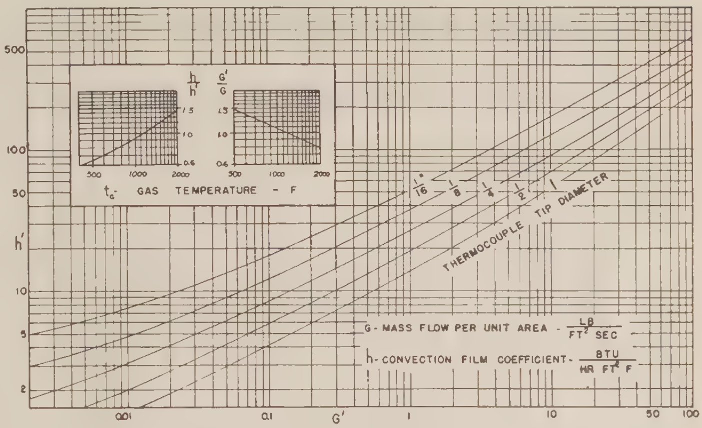

FIG. 5 DIAGRAM FOR DETERMINING FILM COEFFICIENT OF HEAT TRANSFER FOR SINGLE CYLINDERS NORMAL TO GAS STREAM

(Computed from Fig. 111, p. 221 of McAdams, Bibliographg reference 1.)

This approximation does not produce a serious error because it appears in the second term, in braces, of Equation [3]; and since ϵ_G is small compared with ϵ_s, the second term is much smaller than the first term.

Substituting Equation [5] in Equation [3]

$$\theta = 4 \frac{\sigma}{h} T_m^3 \epsilon' \ldots\ldots\ldots\ldots [6]$$

where the terms are defined in the nomenclature and where

$$\epsilon' = \left\{ \epsilon_s(1 - \epsilon_G) + {}^1/_2(1 + \epsilon_s)\epsilon_G \frac{T_G - T_T}{T_T - T_W} \right\} \ldots\ldots [7]$$

in which ϵ' is called the effective emissivity.

The solution of Equation [6] may be obtained from the diagram in Fig. 2, and ϵ' may be obtained from the diagram in Fig. 3.

Expand T_m as defined in the nomenclature

$$T_m^3 = \frac{T_T^4 - T_W^4}{4(T_T - T_W)} = \frac{T_T + T_W}{2} \cdot \frac{T_T^2 + T_W^2}{2} \ldots [8]$$

Since ${}^1/_2(T_T + T_W) = T_a$ and ${}^1/_2(T_T^2 + T_W^2) \cong T_a^2$, where T_a is the average temperature between T_T and T_W, Equation [8] indicates that

$$T_m \cong T_a \ldots\ldots\ldots [9]$$

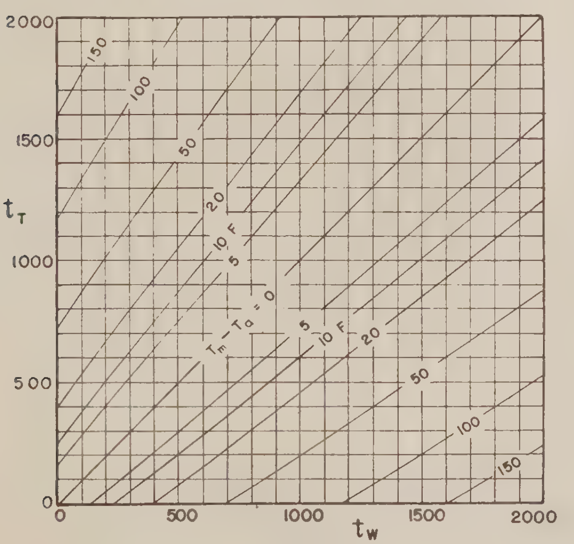

FIG. 4 DIAGRAM FOR DETERMINING $T_m - T_a$

The error in the assumption that $T_m = T_a$ is found in Fig. 4. Usually this error is less than 10 deg F and may be neglected.

If $\epsilon_G = 0$ then $\epsilon' = \epsilon_s$ and if T_m is assumed equal to T_a, Equation [6] becomes

$$\theta = 4 \frac{\sigma}{h} T_a^3 \epsilon_s \ldots\ldots\ldots\ldots [10]$$

For all practical purposes

$$\sigma = \sigma_b = 1.723 \times 10^{-9} \ldots\ldots [11]$$

USE OF THE DIAGRAMS

It is noted that a value of T is necessary to evaluate ϵ' in Fig. 3; hence the solution is of the trial-and-error type. First, solve for θ from Fig. 2, assuming $\epsilon' = \epsilon_s$. Then with this value of θ determine ϵ' from Fig. 3. This new value of ϵ' will be sufficiently close to the true value to obtain a solution. Now return to Fig. 2, with the new value of ϵ' and solve for θ and for $(T_G - T_W)$.

In order to obtain a solution of Equation [3] from Fig. 2, it is necessary to know h, the film coefficient of heat transfer between the flowing gas and the thermocouple. If the thermocouple approximates a cylinder normal to the gas stream, the curves in Fig. 5 may be used to estimate the value of h. For a given gas temperature, obtain from Fig. 5 the ratios G'/G and h/h'; then for any gas flow G, the value of G' is known. Now determine the value of h' for a given thermocouple tip diameter; then h is the product of h' and h/h'. The curves in Fig. 3 are computed from data presented by McAdams[5] for air flowing normal to a single cylinder. If this condition is not approximated, some other data must be used for estimating the value of h.

CONDUCTION ALONG THE LEADS

In the foregoing analysis the conduction heat-transfer term C of Equation [1] has been neglected. This term is usually small, but in order to determine its effect consider the conduction of heat to the cold wall along the two wires of the thermocouple in a gas stream as shown in Fig. 6. The differential equation is

$$\frac{d^2t}{d^2x} = \frac{4h}{kD}(t - t_G) \ldots\ldots\ldots\ldots [12]$$

[5] Reference (1), Fig. 111, p. 221.

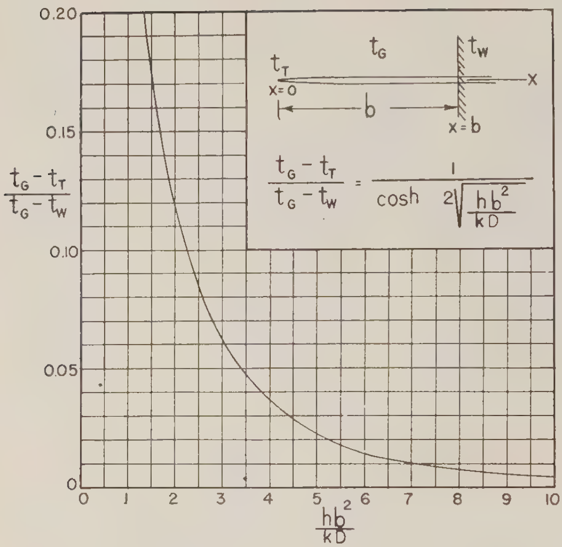

FIG. 6 DIAGRAM FOR DETERMINING CONDUCTION ERROR

whose solution[6] at $x = 0$ is

$$\frac{t_G - t_T}{t_G - t_W} = \frac{1}{\cosh 2\sqrt{\frac{hb^2}{kD}}} \quad [13]$$

This equation is shown graphically in Fig. 6.

ILLUSTRATIVE EXAMPLE

Determine the gas temperature of a gas flowing through a duct with the following conditions:

$G = 7.2$ lb sec^{-1} ft^{-2}
$t_T = 1450$ F
$t_W = 1350$ F
$D = 0.0675$ in. $= 0.005625$ ft
$d_0 = {}^1/_8$ in.
$b = 6$ in. $= 0.5$ ft
$k = 220$ (assuming copper)
$\epsilon_G = 0.085$
$\epsilon_s = 0.80$

Solution: From Fig. 5, $G'/G = 0.90$ and $h/h' = 1.20$ for a temperature of 1450 F; then $G' = 0.90 \times 7.2 = 6.48$ lb sec^{-1} ft^{-2}. For a ${}^1/_8$-in. tip diam, $h' = 100$ from Fig. 5, and $h = 1.2 \times 100$ or 120 Btu hr^{-1} ft^{-2} F^{-1}.

Now $t_a = {}^1/_2(t_T + t_W) = 1400$ F, and from Fig. 4, $(t_m - t_a) = 1^1/_2$ F; so $t_m = 1400 + 1^1/_2 = 1402$ F.

As a first approximation determine T from Fig. 2 by assuming $\epsilon' = \epsilon_s = 0.8$; enter the diagram in Fig. 2 at the left with $t_m = 1402$; then follow the dotted line in the direction of the arrows to $h = 120$, $\epsilon' = 0.8$, and to $\theta = 0.305$. Use this value of θ to determine ϵ' from Fig. 3. Enter Fig. 3 with $\theta = 0.305$; follow the arrows to $\epsilon_s = 0.80$, $\epsilon_G = 0.085$ and then to the left alignment line to locate point A. Locate point B by following the arrows from $\epsilon_G = 0.085$ to $\epsilon_s = 0.80$ to the right alignment line. Connect points A and B with a straight line to locate point C, reading $\epsilon' = 0.755$.

Return to Fig. 2 with the new value of ϵ' to obtain the new value of $\theta = 0.285$. Continue to $(t_T - t_W) = 1450 - 1350 = 100$ F and up to obtain the thermocouple correction $(t_G - t_T) = 28$ deg F; hence $t_G = 1450 + 28 = 1478$ F.

If gaseous radiation is neglected, $\epsilon_G = 0$ and $\epsilon' = \epsilon_s$, and if t_m is assumed to be equal to t_a, the solution from Fig. 2 yields $(t_G - t_T) = 30$ F, and $t_G = 1450 + 30 = 1480$ F.

An estimate of the effect of conduction along the thermocouple wires is obtained from Fig. 6. For this example

$$\frac{hb^2}{kD} = \frac{(120)(0.5)^2}{(220)(0.005625)} = 24.2$$

then from Fig. 6, the error term due to conduction alone is

$$\frac{t_G - t_T}{t_G - t_W} = \frac{t_G - 1450}{t_G - 1350} < 0.001$$

from which $t_G < 1451$ F. Hence the error due to conduction alone is less than 1 deg F in this case.

CONCLUSIONS

To determine the gas temperature solve Equation [6] mathematically or graphically by using the diagrams in Figs. 2, 3, and 4.

For a less precise solution solve Equation [10] mathematically or graphically by using only Fig. 2, with $\epsilon' = \epsilon_s$ and $t_m = t_a$.

Either of these methods will yield results which are better than our knowledge of surface and gaseous emissivities and heat-transfer film coefficients warrants.

Coaster Gate and Handling Equipment for River Outlet Conduits in Shasta Dam

By J. E. WARNOCK[1] and H. J. POUND,[2] DENVER, COLO.

At Shasta Dam, a coaster gate is used to close the intake of any one of the eighteen 102-in. conduits in the spillway section of the dam. Each conduit is provided with a control valve. The coaster gate is used to close the intake of each conduit whenever required for inspection and servicing of the control valve and conduit. It may also be used for emergency closure in the event of failure of a control valve. Since the gate design is predicated on emergency conditions of maximum head, when it is subjected to large unbalanced pressures, hydraulic model studies were conducted to determine the best shape of gate to minimize the downpull force to which it might be subjected in an emergency closing. The procedure followed in conducting the studies and the final installations are treated in this paper.

Introduction

Shasta Dam, one of the major features of the Central Valley Project, is located on the Sacramento River, 9 miles above Redding, Calif. It is designed as a multipurpose dam with facilities for flood control, river regulation, and power generation.

Release of stored water for river regulation in excess of the capacity of the powerhouse turbines is accomplished by eighteen 102-in-diam conduits in the spillway section of the dam. Each of these conduits is provided with a control valve. A coaster gate is used to close the intake of any one of the 18 conduits whenever required for inspection and servicing of the control valves and conduits. The gate may also be used for emergency closure in the event of failure of a control valve.

Normally the gate is operated under balanced hydrostatic pressures with no flow in the conduits. However, design conditions were taken as those which exist during emergency closure under maximum head when the gate is subjected to large unbalanced pressures.

As the gate is lowered under emergency conditions, the increase in velocity under the gate acts to decrease the pressures on the downstream face while those on the upstream face remain substantially constant. The frame of the gate must resist the resultant force which pushes it against the face of the dam, and the rollers supporting the gate must have a low frictional resistance or the gate cannot be lowered into the closed position by its own weight. Another effect of the high-velocity flow is the reduction in pressure on the bottom of the gate which creates an additional force, referred to as downpull. Consideration of this force is important as it may be equal to or greater than the weight of the gate.

The hydrostatic pressures on the top of the gate can be calculated readily; but unfortunately, calculations of the downpull force can be only approximate without detailed hydraulic-laboratory studies. The pressures on the bottom of the gate are a function of the flow velocity under the gate, the shape of the gate bottom, and the gate opening, and they may vary from full hydrostatic pressure to the vapor tension of water. The value of the downpull force is therefore dependent upon the velocity distribution and flow pattern beneath the gate, since the pressure reduction at any point on the gate bottom is equal to the velocity head at that point.

In previous designs an approximation of the downpull force was considered satisfactory, but at Shasta Dam the estimated downpull on the coaster gate was so large that the total load on the handling equipment was about 60,000 lb in excess of the permissible load. The gate was to be handled by a 125-ton gantry crane, operating on the bridge across the spillway section of the dam. The capacity of this bridge was the limiting factor. Such a circumstance arose from the fact that the original plan was to handle the coaster gates from a barge and the bridge was designed for normal traffic load. When later in the design the handling equipment was transferred from the barge to the bridge, it was necessary to determine more accurately the downpull force and to reduce it, if possible, to avoid a drastic change in the design of the bridge across the spillway.

Hydraulic Model Studies

Hydraulic model studies were made to check the computed downpull and to develop a new shape for the gate bottom. Various shapes were tested and a satisfactory design was developed. A combination of this design and a properly proportioned recess in the face of the dam above the inlet reduced the downpull from the original value of 260,000 pounds to 70,000 lb.

The studies were made with a model of the conduit and coaster gate built to a scale of 1 to 17. Test data included pressure measurements on the gate and in the outlet for several heads and gate openings. The downpull was determined by integrating the pressure curves shown in Fig. 1. In the tests of the final design, the value obtained by pressure integration was verified by direct measurement with a spring scale.

With the gate of the original design in the full-open position, and a head representing the maximum of 323 ft, the downpull was approximately 75,000 lb. As the gate was lowered the downpull gradually increased to a maximum of 260,000 lb at an opening of about 8 ft 6 in. and then decreased gradually to zero for the closed position.

The typical variation of downpull with gate opening, which is shown graphically in Fig. 3, may be explained by a consideration of the variation in magnitude and distribution of velocity under the gate. When the gate was fully opened the discharge was a function of the size of the outlet conduit and its frictional resistance. As the gate was lowered it created a restriction in conduit cross section; and since the discharge was not reduced in the same proportion, there was an increase in velocity and a reduction in pressure under the gate and for a short distance downstream. The decrease in pressure caused an increase in downpull.

Since the conduit was vented downstream from the gate, air re-

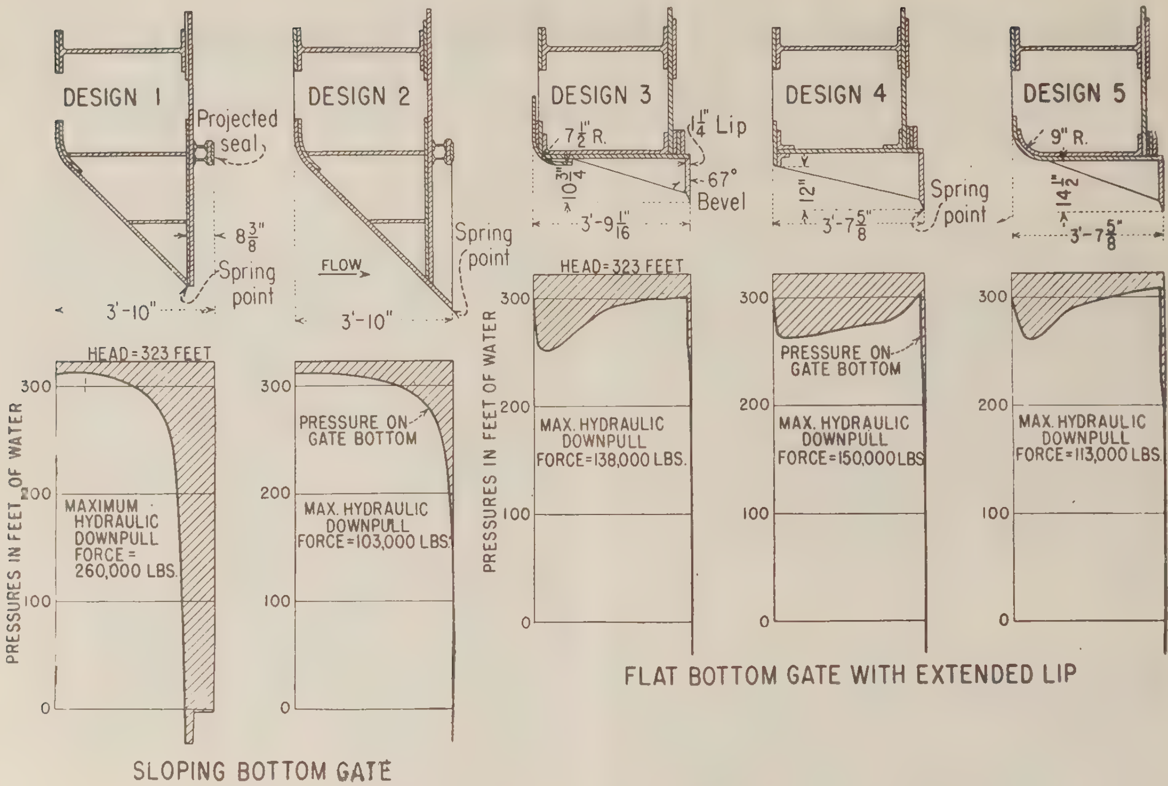

Fig. 1 Pressure Studies of Gate Bottom

lief was obtained when the restriction in area was sufficient to lower the pressure at that point to atmospheric pressure. When the pressure downstream from the gate was restrained from decreasing to any appreciable extent by the presence of air relief, it may be said that the gate became a control. The discharge under this condition became a function of gate opening and head and was not affected by the conduit. At the gate opening corresponding to maximum downpull, the gate became a control and the velocity along its bottom reached its maximum value. For lesser gate openings, the velocity at the downstream edge of the bottom was increased slightly by a minor decrease in pressure downstream from the gate. However, at these openings the proportions and shape of the gate bottom relative to the size of the opening changed in such a manner that the velocity along it actually decreased and pressures increased enough to lower the value of downpull.

At small openings on the original design the jet under the gate impinged on the top of the conduit and interfered with proper action of the vent.

Reduction of Downpull in Original Design

The hydraulic downpull force of 260,000 lb, as determined by the pressure tests, did not agree with the original analytical estimate of 160,000 lb. A review of the original calculations indicated that the estimate of 160,000 lb considered only the pressure reduction on the sloping portion of the gate bottom and assumed that a recess in the face of the dam above the outlet entrance would balance the pressures on the projected seals. The model test was made without a recess, and the unbalanced pressures on the top seal contributed at least 100,000 lb to the total downpull of 260,000 lb. A recess in the model of the original design would have tended to balance the pressures on the top seal, and it was possible that a closer agreement might have been obtained. However, the downpull would still have been excessive; therefore consideration was given to reduction of the force by revision of the shape of the gate bottom. The effectiveness of a recess in the face of the dam was determined only for the most satisfactory gate bottom and will be discussed subsequently.

Studies of the flow under the gate and the pressure on its bottom indicated that a large reduction of downpull could be obtained by a simple revision of the bottom. The flow under the gate and into the outlet was studied by observing the movements of paper particles in the head tank through a window. The particles approached the outlet from all directions, moving slowly until they were within a few inches of the outlet, where they appeared to be drawn instantaneously into it, indicating a rapid increase in velocity close to the outlet entrance. This rapid increase in velocity was also shown by the pressure gradient across the 45-deg sloping portion of the bottom of the gate, Fig. 1, design 1. At the upstream edge the pressures were practically hydrostatic. On approaching the outlet the pressure reduction was gradual at first, but it became rapid close to the downstream edge. At the point where the 45-deg slope ended, the pressure reached a minimum. This was the spring point of the gate, that is, the point where the water normally sprang free of the gate bottom to form a jet in the conduit.

The face of the gate projected a distance of $8^3/_8$ in. beyond the spring point as shown in Fig. 1. The pressure forces acting upward on this projection were much lower than those acting downward so that it contributed an excessively large part of the downpull when its relatively narrow width was considered. By comparison, the much larger area of the 45-deg sloping bottom played

only a minor role because the low pressure prevailed only in the vicinity of the spring point. The original bottom design was revised by extending the sloping portion until it underlay the projecting seal, as shown in Fig. 1, design 2. This change placed the spring point close to the face of the dam and eliminated the undesirable projecting area. The pressure distribution on the revised gate bottom is shown in Fig. 1, design 2. The shape of the pressure curve remained the same but the elimination of the projection and its unbalanced loading reduced the downpull from 260,000 to 103,000 lb.

In contrast to the original design, where the maximum downpull occurred when the conduit was not completely filled with water, the maximum value with the revised gate occurred while the conduit was filled with water, just before a slight additional closure would lower the pressures so that the conduit would take some air through the vent. In addition to reducing the downpull, this revised design changed the shape of the jet flowing into the outlet so that the jet at no time impinged on top of the conduit to restrict the air vent, as was the case in the original design when the gate was open between 2 and $3^1/_2$ ft.

Effect of Extended Lip Below Downstream Edge of Flat-Bottom Gate

Although the revision of the bottom accomplished the desired reduction in downpull, the gate was not satisfactory structurally. The sloping bottom would have been difficult to fabricate and heavy plates would have been required to withstand the loads on its downstream edge. Thus it was necessary to make further tests to develop some other type of gate which would have even less downpull or at least a more acceptable structural design for the bottom.

The original tests indicated that a gate having a minimum downpull would be one with a lip placed at the downstream edge of the bottom and extended vertically below the gate. This would place the spring point at a greater distance from the bottom and the effect of the rapid drop in pressure which occurs near the spring point would be exerted on the vertical plane of the extended lip and would not contribute to downpull. To verify these indications, tests were made with an extended lip. The length of the lip was varied in successive steps, from zero to a length nearly equal to the thickness of the gate.

The complete shape of the gate bottom which will be referred to hereafter as the basic shape is shown in Fig. 2. The bottom was faired into the upstream plate on a 9-in. radius, to minimize the local reduction of pressure on the bottom where the flow down the upstream face of the gate changes direction below the gate. The extended lip was $^3/_4$ in. thick, and its bottom was beveled at 45 deg to place the spring point at the downstream edge of the lip and reduce the effect of the thickness on the downpull. The extended lip was supported by gusset plates attached to the bottom of the gate. These plates were in the plane of flow so that their effect on the downpull would be small and could be ignored.

The pressure gradients, as determined in what will be referred to as general tests, were similar to those of design 5, Fig. 1, except that negative pressures occurred on the bottom of the lip. There was some reduction of pressure near the upstream plane, as was anticipated, since the flow down the upstream face of the gate had to change its direction. However, the pressure increased rapidly, becoming a maximum at the downstream corner where the lip joins the gate bottom. This effect indicated that not only does the extended lip keep the rapid reduction in pressure near the spring point on the vertical plane of the lip where it cannot cause downpull, but it also tends to form a stagnation point which increases in the downstream corner.

Although the bottom of the lip was beveled at 45 deg to place the spring point on its downstream edge, the spring point actually occurred at the upstream edge of the lip. The resulting negative pressures on the bottom of the lip would cause a downpull of approximately 15,000 lb when the lip was $^3/_4$ in. thick, as indicated in Fig. 2.

The variation of maximum downpull force with length of lip extension is shown graphically in Fig. 2. The longest extension considered was approximately equal to the thickness of the gate,

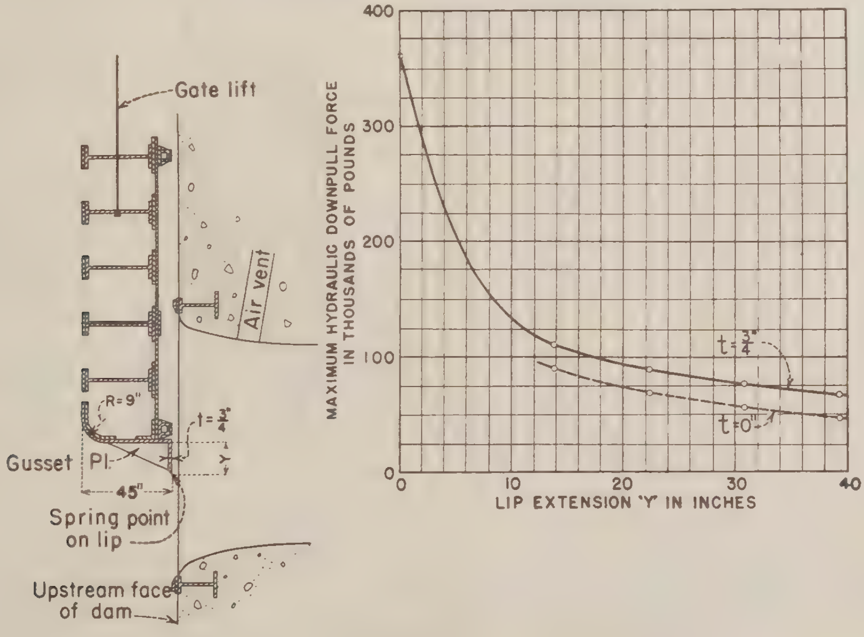

Fig. 2 Effect of Lip Extension on Hydraulic Downpull

as a greater extension would be impractical structurally. The graph shows that an extension of 40 in. would reduce the downpull to approximately 65,000 lb. As the extension was decreased, the downpull increased gradually until, at a lip extension of 14 in., the value was 110,000 lb. A further decrease in the extension caused a more rapid increase in downpull which finally became 360,000 lb when there was no extension.

Structural Designs of Flat-Bottom Gate With Extended Lip

A flat-bottom gate with an extended lip below its downstream edge, which would develop a downpull equal to that of the sloping-bottom gate of design 2, Fig. 1, or about 100,000 lb, would require a lip extension of 17 in. This was not practical, since the horizontal forces on it would be excessive. Nevertheless, a flat-bottom gate having an extended lip was a simple design compared with the sloping bottom of design 2.

Design 3 was more acceptable than the basic shape from a structural viewpoint, having a lip extension of $10^3/_4$ in. which, from the curve in Fig. 2, corresponds to a downpull of approximately 130,000 lb. The radius of the curved portion of the bottom was made $7^1/_2$ in. instead of 9 in., and the thickness of the lip was made $1^1/_4$ instead of $^3/_4$ in. It was anticipated that the smaller radius would increase the downpull a small amount. The bottom of the lip was beveled at a steeper angle, 67 deg, which placed the spring point at its downstream edge and reduced the downpull on the lip, Fig. 1. The tests showed that the downpull would be approximately 138,000 lb. Piezometers placed on the lip to determine pressures indicated that the portion of the downpull due to the $1^1/_4$-in. lip was nearly equal to that of the $^3/_4$-in. lip of the general test in which the spring point was at its upstream edge. Accordingly, the curve in Fig. 2 was used to predict the downpull of a gate having $1^1/_4$-in. lip with a 67-deg bevel at its bottom.

In design 4, Fig. 1, a simplification of the structural details was made by using flat plates and angles to eliminate the curved section of the gate bottom. The end of the plate at the upstream edge was rounded to avoid a sharp corner at that point. A $1^1/_4$-in. lip having a steep bevel, similar to design 3, was extended 12 in. below the upstream edge. The downpull was 150,000 lb, which represented a 25 per cent increase over that obtained in the general test with a 9-in. radius and a 12-in. lip extension. Neither design 3 nor 4 was satisfactory for the Shasta Dam outlet coaster gates because their downpulls, of 138,000 and 150,000 lb, respectively, exceeded the allowable limit.

A new analysis of the stresses on the bottom of a gate with the basic shape used in the general test, Fig. 2, revealed that it would be structurally sound if the lip extension did not exceed $14^1/_2$ in. Fig. 2 indicated that such a design would develop a downpull of 110,000 lb. Since this value was not excessive, design 5 was constructed and tested, Fig. 1. It differed from the gate of the general test in that a $1^1/_4$-in. lip with a 67-deg bevel at its bottom was used instead of $^3/_4$-in. lip with a 45-deg bevel. The measured downpull of 112,000 lb checked the predicted value of 110,000 lb.

The final design of the Shasta outlet coaster gate was developed from design 5. The width was increased from $43^5/_8$ to $44^{11}/_{16}$ in. for structural reasons, and a clearance of $^1/_2$ in. between the lip and the seal seats was introduced to facilitate operation of the gate. The maximum downpull as determined by pressure measurements was increased to 122,000 lb by these changes. An independent check of the downpull by direct measurement with a spring scale indicated that a slightly larger downpull of 131,000 lb occurred at a gate opening of 55 per cent. The latter value was accepted as the more accurate one as it was impractical to take the number of pressure measurements required for a comparable accuracy.

The over-all effect of the gusset plates was determined by a test with the plates removed. No appreciable difference in downpull could be detected. If plates were terminated at the point where the bevel of the lip begins as shown in Fig. 1, their effect on downpull was negligible.

Effect of Recess in Face of Dam

It had been appreciated that any one of the various designs of the gate could have been improved from the standpoint of downpull by introducing a recess in the face of the dam. This improvement was deliberately withheld until the best shape of gate bottom was determined.

To understand the action of the recess, it must be noted that the seals of the gate project beyond the skin plate. With no recess, the pressures on the top seal were unbalanced when the gate was partially closed. The full reservoir head acted on the outside, or topside, while the low

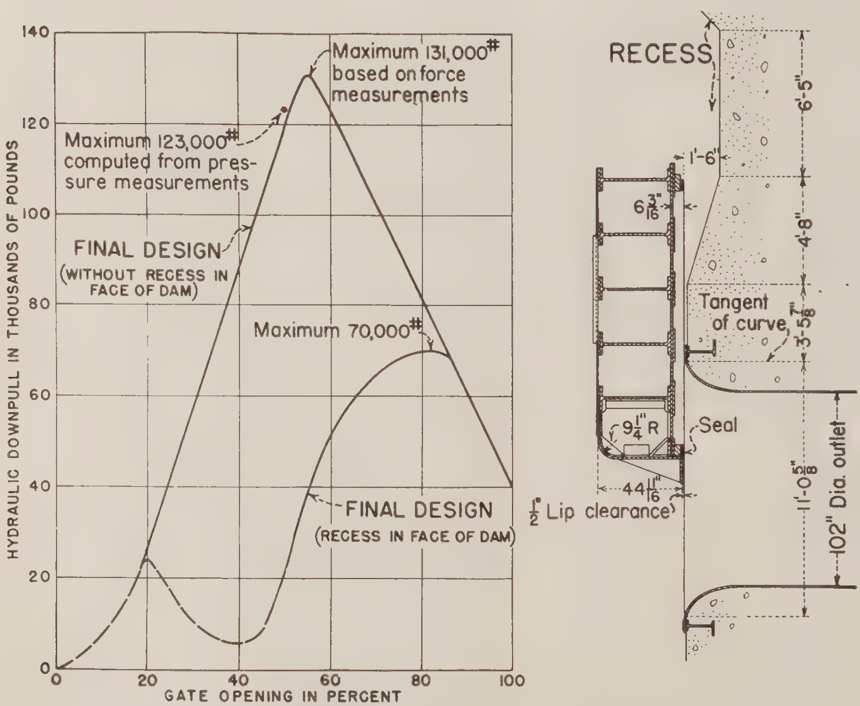

Fig. 3 Hydraulic Downpull of Final Design

pressure which prevailed downstream from the gate was exerted on the inside, or lower side. The resulting downward force, which at times was as large as 100,000 lb, depending on the pressure in the outlet entrance downstream from the gate, contributed a large portion of the downpull on the gate. With a recess, starting a short distance above the gate seat, the increase in the clearance between the seal and the face of the recess lessened the velocity of flow around the seal and reduced the pressure differential.

Tests showed that the recess performed its desired function of reducing the maximum downpull if its depth was made several times larger than the seal extension. At all openings the pressures on the upper seal were nearly balanced. For gate openings less than 40 per cent, the presence of a recess with a uniform depth introduced an undesirable complication. With the downpull force on the top seal eliminated by the recess, the increase in pressure which occurred at small gate openings over that portion of the bottom which underlay the seal was large enough to reverse the direction of the net hydraulic load. The gate was actually subjected to an uplift force large enough to offset its weight.

The effectiveness of the recess in balancing the pressures on the top seal was directly proportional to its depth. By varying the depth in the manner shown in Fig. 3, the reversal of net force on the gate was eliminated and the downpull varied as shown in Fig. 3. The maximum downpull of 70,000 lb occurred at a gate opening of 80 per cent.

Since the dead weight of the gate and lifting mechanism is 90,000, and 10,000 lb, respectively, the maximum total load on the gantry crane, including a downpull of 70,000 lb, will be 170,000 pounds. This is less than the permissible load on the bridge, so the design was accepted as being satisfactory.

The Coaster Gate

The coaster gate is mounted on endless roller trains and is lowered by its own weight in structural guides provided in the face of the dam to an accurate position over the intakes, Fig. 4. The gate consists primarily of a downstream skin plate mounted on horizontal beams which are supported by vertical girders at the sides.

The roller trains around each vertical girder transmit the water load on the gate to tracks on the face of the dam at the inlet. The tracks are fastened to large CB-sections embedded in blockouts provided in the original concrete of the dam, Fig. 5. A rectangular steel framework embedded in the concrete around the circular inlet supports accurately finished seal seats which project slightly from the face of the dam.

When the gate is used to close one of the conduits on the lower tier, it is subjected to a head of some 330 ft, equivalent to 22,000 psf or a total load of approximately 2,750,000 lb. As the gate weighs only 90,000 lb, roller trains were selected to minimize the friction forces so that the gate would close under its own dead weight.

Metal-covered rubber "music-note" seals, Fig. 5, are provided on the downstream face of the skin plate. The design utilizes the flexibility of a rubber hinge which permits close local adjustment but retains the rigidity of metal to support the load of approximately 125 lb per linear in. to which the seals are subjected when the gate is in the closed position. The rubber core also permits simple butt and miter joints to be used in the seal as the load on the seal is converted to axial compression which acts to seal the joints.

Advantage is taken of the pressure differential across the gate to retract the seals when the gate is closing under flow. This eliminates drag on the seals and materially reduces the force resisting closure just as the gate is seated. To accomplish retrac-

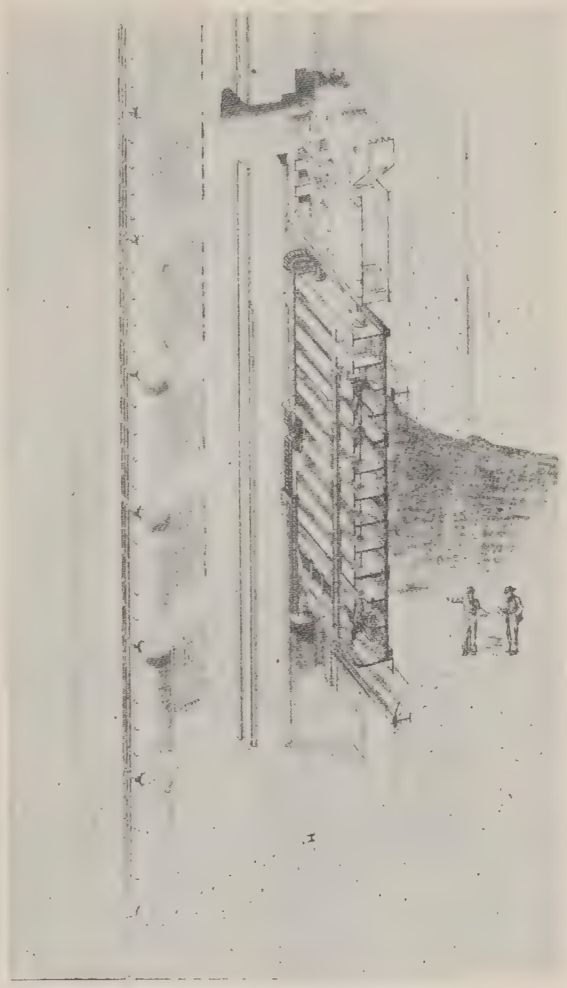

Fig. 4 Typical Coaster-Gate Installation

tion the area immediately back of the seals is closed at the sides. This forms a continuous watertight rectangular chamber having the movable portion of the rubber seal for one of the sides. Pipes connect this chamber, through a two-way valve, to either the reservoir pressure on the upstream side of the gate or to the reduced pressure on the downstream side of the gate.

The valve is operated by the overtravel of the relatively heavy gate-lifting stem. While the gate is supported by the lifting stem, the valve position admits the downstream pressure to the seal chamber and the seal retracts approximately $^3/_{16}$ in. As soon as the gate is seated in the closed position over the inlet, a 4-in. overtravel of the lifting stem reverses the valve to admit reservoir pressure to the seal chamber and the seals are forced into contact with the seat.

Channel-shaped guide shoes at each corner of the gate engage tongues on the guides in the face of the dam, Fig. 5. The distance, face to face, of the guide tongues is held accurately during installation to a clearance of $^1/_4$ in. in each shoe, except for a short distance near the conduit opening. Below an elevation slightly greater than one gate height above the top of the conduit opening the clearance is reduced practically to zero by making longer tongues on the guides. This causes the gate to be squared

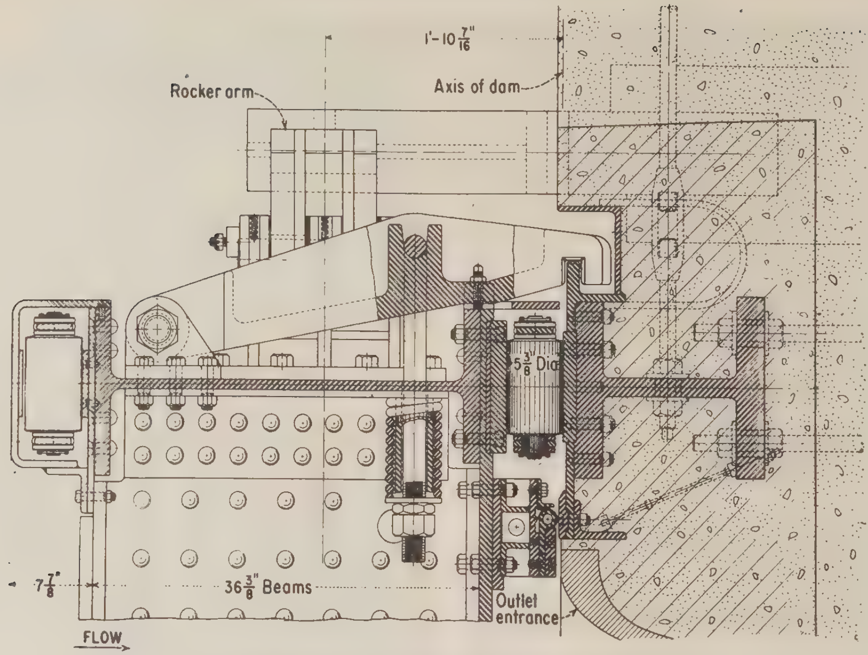

Fig. 5 Shasta Dam Outlet Coaster Gate Slot Section

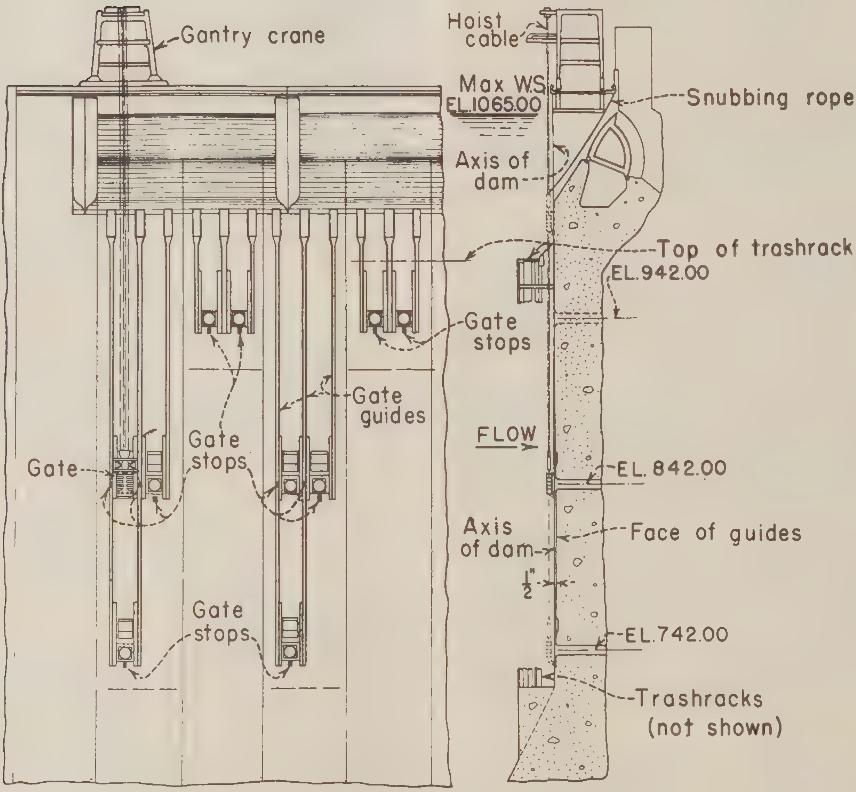

Fig. 6 Location of Outlets and Guides on Upstream Face of Dam

as accurately as possible with the tracks just before it receives the water load when closing under emergency-flow conditions. The shoes are spring-loaded with snubbed springs set with an initial compression sufficient to prevent deflection during this operation.

After the gate receives water load, it is practically impossible to guide the rollers or the gate, because of the extremely high unit contact pressure between the rollers and the track. The spring-loading of the shoes allows the gate to move laterally as much as $^1/_2$ in. in either direction, while closing under load, without excessive binding or probable breaking of the shoes. When the load on the gate is removed, the capacity of the springs is sufficient to square it again.

Operation of Gate

The gate is stored in a covered pit in the top of the dam. Except in case of emergency, it is used only during a few months of the year, when conditions are most favorable for inspection and servicing of the control valves and conduits.

The inlets to the conduits through the dam are arranged so that fourteen sets of guides serve the eighteen conduits. The four conduits of the lower tier, which are 335 ft below the spillway bridge, are served by the same set of guides as four of the conduits of the intermediate tier, which are 235 ft below the spillway bridge, Fig. 6. The other ten conduits are served by individual sets of guides.

The placing of the gate in the guides on the face of the dam requires careful handling. The gate must be lowered approximately 90 ft below the bridge, and 75 ft below the normal water surface before engaging the guides. The upper ends of each set of guides are tapered in the plane parallel to the face of the dam in such a way that in the event the gate is lowered slightly off-center, it is forced to correct itself and allow the channel-shaped shoes on the gate to engage the tongues on the vertical guides.

Engagement of the shoes in the direction normal to the face of the dam is provided for in the following manner:

The gate is lowered in a plane slightly upstream from the face of the dam until it is below the sloping face of the spillway crest. It is then snubbed back into contact with the face of the dam by snubbing ropes, Fig. 6, from the downstream edge of the bridge structure. Continued lowering will then cause the gate shoes to engage the guides and the operation can continue.

A gate-lifting frame, Fig. 7, with a semiautomatic grappling mechanism is used to handle the gate. After the gate is seated in front of a conduit, the lifting frame may be released from the gate and hoisted to the bridge. This arrangement is necessary as the gate is required to remain in place in front of a conduit for several weeks at a time and the crane must be free to perform its other functions.

The position of the gate cannot be observed after it is lowered into the water. Consequently, a safety device is provided to indicate proper engagement of the gate shoes. This device consists of ropes attached to a tripping mechanism at each lower corner of the gate. When the shoes engage the tongues of the guides, the rope is released by the tripping mechanism. Two men are stationed on the bridge to pay out the telltale ropes as the gate is lowered. If both ropes are released after lowering the gate a reasonable distance below the top of the guides, it is evident that the guides have been engaged properly.

Lowering is continued until the gate is supported by stops on the guides at the inlet of the conduit. The stops are located so that the gate comes to rest exactly in the closed position in front of the inlet. The lifting frame continues downward approximately 4 in. until it comes to rest on the top of the gate. The 4-in. travel of the lifting stem down into the gate causes the gate seals to close. The same motion causes the grappling mechanism in the lifting frame to release and a slack-cable limit switch, located on the crane, stops the lowering motion of the hoist.

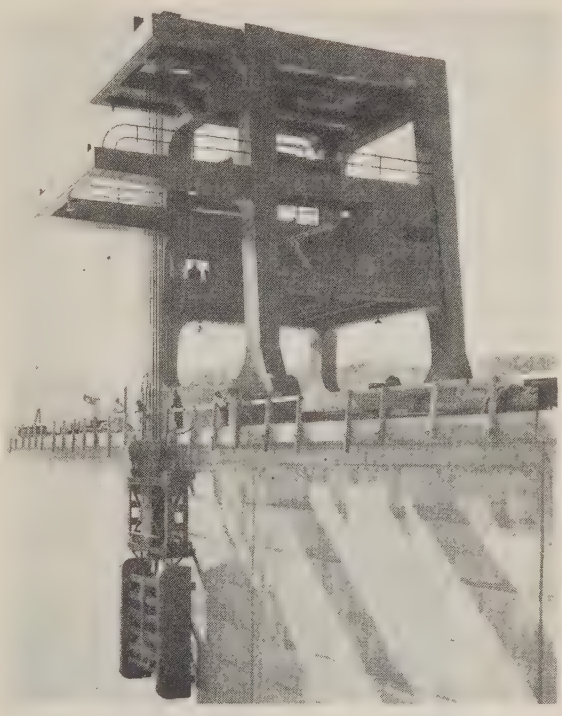

Fig. 7 Outlet Conduit Coaster Gate and Gate-Lifting Frame With Semiautomatic Grappling Mechanism

If only one conduit is served by a set of guides, a single stop is provided in the face of the dam directly below the conduit opening. Where two conduits are served by the same set of guides, that is, where one conduit is located above the other, a single stop is provided directly under the lower one. Stops for the upper one are located at the sides of the conduit, Fig. 6. Rocker arms, or pawls, are provided at each side of the gate and are interconnected by a linked tension bar. When it is desired to close the upper conduit, the bar is extended and the rocker arms are pushed outward to a position where they will contact the stops at the sides of the upper conduit and act as an equalizer as the gate comes to rest. If the lower conduit is to be closed, the bar is retracted so that the rocker arms, Fig. 7, will clear the stops at the side of the upper conduit, and the gate comes to rest on the signal stop below the lower conduit.

To remove the gate the operations described are reversed, except that the telltale ropes are attached to the tripping mechanism at each lower corner of the lifting frame.

Gantry Crane

The crane, an outdoor, traveling, gantry type, Fig. 8, is electrically operated and is provided with a 125-ton fixed hoist which handles the gates, and a 25-ton trolley hoist which handles parts of gates during assembly. The latter is also used infrequently to install stop logs in front of the power penstocks. The 125-ton capacity was determined by the installation and servicing conditions of the coaster gates for the main power-penstock inlets. These inlets are located in the curved portion of the dam, where the solid construction will support practically any crane load.

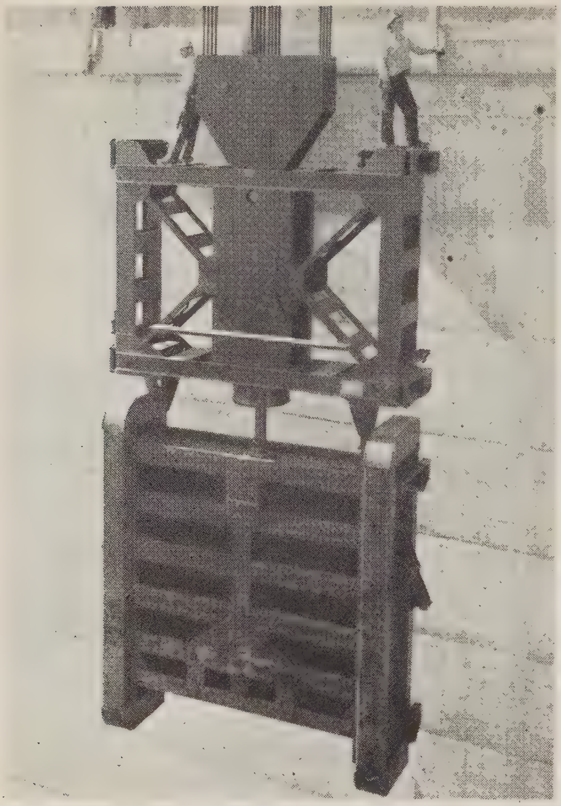

Fig. 8 Gantry Crane in Use With Lifting Mechanism and Outlet Conduit Coaster Gate Suspended From 125-Ton Fixed Hoist

As previously mentioned, the bridge structure over the spillway portion of the dam in which the river outlets are located made it economically desirable to limit the crane load at this point to only a fraction of the hoist capacity in order to avoid a heavy and expensive structure which would not be otherwise required. The crane can transfer a load from any point on the dam to the overhung position upstream from the face of the dam. All gates are installed and operated from the overhung position.

The crane operates on 27-ft-gage tracks. The tracks are straight for approximately 375 ft on the bridge structure over the spillway section at the center of the dam. The remainder of the track has a 2500 ft radius of curvature for a distance of 1425 ft along the roadway on top of the right abutment.

The combination of straight and curved track made it impractical to use the conventional drive with one motor driving a shaft leading to the trucks on either side. Instead, separate motors were mounted on each of four trucks with 50 per cent of the track wheels driving. Direct current for operation of the four 8-hp shunt-wound motors is provided by a generator set. The use of direct current was made necessary by the unequal loading of the motors.

Accurate spotting of the gates is provided by direct-current-motor-operated hoists and Maxspeed control. In case the gate should encounter some obstruction in the guides, a special type of control was provided for the hoist. This control limits the maximum lifting effort when the crane is located on the bridge. If a conventional hoist with alternating-current motor and standard control had been provided, the maximum lifting effort on the crane hook under a 275 per cent breakdown torque of the motor would have been approximately 350 tons. The modified Maxspeed control limits the lifting effort at the hook to 175 tons. The control is the full-magnetic, reversing, master type. It has definite time-limit acceleration relays and six speeds in each direction of operation. Due to the extremely long lift of 360 ft, a mechanical load brake was not considered feasible and direct-current dynamic braking was provided.

A panel of indicating lights in the operator's cage warns him when the gate is approximately 16 ft above the closed position in front of any conduit. A lighting system, including floodlights, was installed on the crane so that the gates could be operated at night.

Speed and Feed Selection in Carbide Milling With Respect to Production, Cost, and Accuracy

By HANS ERNST[1] AND MICHAEL FIELD[2]

The present paper reports findings of a research on milling cast iron with carbide-tipped cutters in addition to those presented previously in 1945 by Michael Field and W. E. Bullock.[3] An important finding of the earlier work was the existence of a definite maximum tool-life point, i.e., at 290 fpm, in relationship of cutting speed to tool life, when milling a cast iron of medium hardness (Bhn 190). Subsequently, it was found that a similar maximum tool-life point, i.e., 200 fpm, occurs when milling a considerably harder and less machinable cast iron (Bhn 240). An important outcome of the earlier phases of the research was the development of a combination of tool angles which gave much greater tool life and a considerably higher production rate. The original work was done with single-point tools, whereas a multitooth cutter was subsequently developed, details of which and the results obtained are included in the paper. A comprehensive account is given of the recent studies, illustrated by numerous test curves, and a practical analysis of milling costs.

In a previous paper[3] by Michael Field and W. E. Bullock, results were given in part of a research on the milling of cast iron with carbide-tipped cutters, which had been conducted at the University of Cincinnati. The present paper covers certain subsequent findings of this research, together with a further elaboration and application of earlier findings.

One of the important findings reported in the previous paper was the existence of a definite maximum tool-life point in the relationship of cutting speed to tool life, when milling a cast iron of medium hardness (190 Bhn), designated as Meehanite A. This relationship is reproduced in the upper curve of Fig. 1. Here it will be seen that the average of the tool-life values for 210 fpm falls well to the left of the average of the values for 290 fpm. At higher cutting speeds all the values of tool life are also to the left of the value for 290 fpm and fall approximately on a line representing the equation $VL^{0.55} = 7800$, where V = cutting speed (ft per min) and L = tool life (cu in. of metal removed).

In a subsequent series of tests, it has now been found that a similar maximum tool-life point occurs when milling a considerably harder and much less readily machinable special grade of alloy cast iron, designated as Meehanite C-304B. The Brinell hardness of this material was 240; its chemical composition is given in Table 1, together with that of Meehanite A.

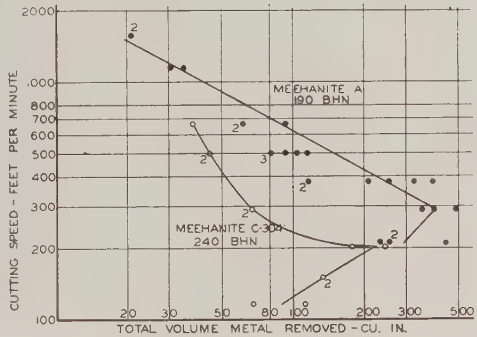

Fig. 1 Cutting Speed Versus Total Volume of Metal Removed to Dull Tooth With Axial Rake of +3 Deg, Radial Rake of +3 Deg, and Corner Angle of 30 Deg

(Width of cut = 6 in.; depth of cut = 0.187 in.; feed per tooth = 0.015 in.; carbide, 44A.)

TABLE 1 CHEMICAL PROPERTIES OF CAST IRONS USED IN CUTTING TESTS

	Meehanite A, per cent	Meehanite C-304B, per cent
Total carbon	2 85-3.15	2.90 3 20
Silicon	1 20-1.50	2.45-3 00
Phosphorus	0.12 Max	0.18 Max
Sulphur	0.20 Max	0.20 Max
Manganese	0.80-1.20	0.75-1.00
Chromium	....	1.00
Copper	....	
Molybdenum	....	0.50

The tool-life values for Meehanite C-304B, expressed in cubic inches per tool grind, are shown by the lower curve in Fig. 1. The maximum tool-life point here occurs at about 200 fpm in contrast to 290 fpm for the softer Meehanite A. The portion of the line to the left of this point is quite definitely curved, again in contrast to the straight line of Meehanite A.

The existence of a rather critical maximum tool-life point (which has now been found in a considerable number of tests) is a matter of real importance in practical milling. It indicates clearly the impossibility of predicting tool-life values in the normal speed range by extrapolation from the results of tests above 500 fpm.

Another important outcome of the work[3] previously reported, was the development of a combination of tool angles which gave a much greater tool life (in terms of metal removed per grind), and a considerably higher production rate, than could be obtained with the angles used in conventional practice. The initial work was done with single-point tools in which the effective angles could be readily changed. In later work a multitooth cutter was used. One such cutter is shown in Fig. 2.

The basis for this development was established in 1937, in an investigation covering the performance of face-milling cutters with very large corner angles. In a report of this investigation by M. Kronenberg,[4] it was shown that very large corner angles had

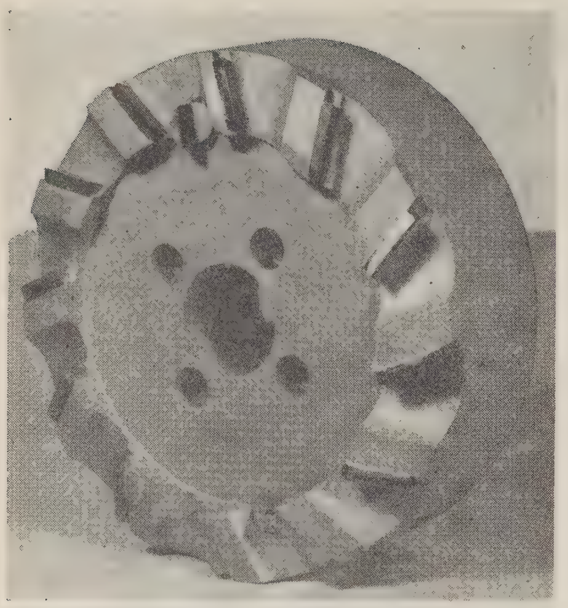

Fig. 2 Cutter Developed in Research, Capable of Operating at Extremely High Feed Rates

(The 12 major teeth have an axial rake of +15 deg, a radial rake of —30 deg, a 75 deg corner angle, a true rake of +6 deg, and a face angle of 5 deg. The finished surface is produced by a separate tooth which has a face $^3/_4$ in. long and extends axially several thousandths of an inch beyond the roughing teeth.)

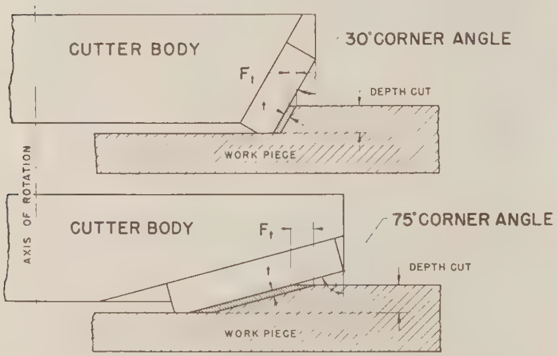

Fig. 3 Effect of Corner Angle on Feed per Tooth for a Constant Value of Undeformed Chip Thickness

the unique property of distributing the work of chip removal over a much greater length of cutting edge than conventional corner angles of zero to 45 deg, thus permitting the use of a very high feed per tooth, and a consequent high rate of metal removal.

The upper view in Fig. 3 shows in diagrammatic fashion a face-milling cutter with a conventional 30 deg corner angle. In this figure the workpiece is assumed to be feeding to the left, and the small cross-hatched area represents the cross section of the metal which will be removed by the next tooth. Thus for a given feed per tooth F_t, the thickness of the undeformed chip will have the value t.

In the lower view in Fig. 3 the corner angle of the cutter is 75 deg. For the same value of the undeformed chip thickness t, it is evident that in this case the feed per tooth F_t must have a much larger value. It is also clear that the length of cutting edge engaged with the work is here much greater, even though the depth of cut is the same as in the upper view. Thus for a given value of t, the cross-sectional area of metal removed per tooth will be much greater even though the load on each element of length of the cutting edge remains virtually unchanged.

In the numerical example, illustrated in Fig. 4, it is shown that for a constant value of 0.013 in. for the undeformed chip thickness, the feed per tooth with the 30 deg corner angle cutter is 0.015 in., while with the 75 deg corner angle it is 0.050 in. This represents a rate of production 333 per cent that of the lower corner angle.

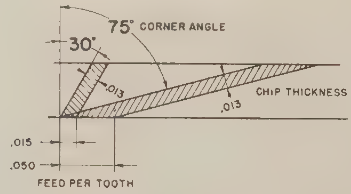

Fig. 4 Example Showing Increase of Feed per Tooth From 0.015 In. to 0.050 In. as Corner Angle Is Increased From 30 to 75 Deg for a Constant Undeformed Chip Thickness of 0.013 In.

In practice it is difficult to utilize such large corner angles and high potential feed rates with the present commercially used numerically small values of axial and radial rake angle (either positive-positive, negative-negative, or positive-negative). Problems of chip disposal, high impact loads, smoothness of finish, flatness, etc., are all limiting factors. These difficulties have been overcome to a high degree of satisfaction with the combination of angles and arrangement developed in this investigation; viz., large negative radial rake (—30 deg to —45 deg); large positive axial rake (+15 deg to +20 deg), and large corner angle (70 deg to 80 deg). In the 12-tooth cutter, shown in Fig. 2, the values used are axial rake, +15 deg; radial rake, —30 deg; and corner angle 75 deg, giving a true (or resultant) rake of +6 deg. This designation may be abbreviated, +15, —30, 75, +6. (a, r, c, t).

The very large feed per revolution obtainable with such a cutter ($^1/_2$ in. to 1 in. or more, depending on number of teeth and material cut) presents a difficult problem in surface finish. This is particularly true with large carbide-tipped cutters owing to the difficulty of grinding the ends of all teeth exactly alike. This problem has been solved in the present instance by providing a separate finishing tooth with fine axial adjustment and a face sufficiently broad to cover at least the feed per revolution; it is set so as to extend a few thousandths of an inch beyond the "highest" of the roughing teeth. This separate finishing tooth is shown at the top in Fig. 2.

With this arrangement, the main teeth are ground so as to cut on their angularly disposed edges only. The adjacent edges do not lie in a radial plane but are sharply relieved so as to clear the finished surface, the latter being produced entirely by the separate finishing tooth. By separating the functions of roughing and finishing, it is also possible to use for the finishing tooth a very hard and abrasion-resistant grade of carbide; and if desired, a large positive axial rake angle, as this tooth does not have to withstand an impact load.

A characteristic feature of this cutter is the large positive angle of inclination (32 deg in the cutter shown in Fig. 2). The angle of inclination is the angle between the cutting edge and a plane normal to the path of motion. This large positive angle produces a helically curled chip which flows radially out of the cutter body, even with very high values of feed per tooth. The electronic flash photographs of a single-tooth cutter with this

(In *b*, the chip is somewhat further developed than in *a*.)

angle combination, Figs. 5 (*a*) and 5 (*b*), made with an exposure time of about 0.000004 sec, clearly show this helical chip formation.

In early tests with the multitooth cutter, cast-iron test blocks were milled at feed rates of over 100 ipm. Such a cut is shown by the high-speed flash photograph, Fig. 6.

SELECTION OF FEED AND SPEED IN PRODUCTION MILLING

In practical applications of carbide milling, the question naturally arises as to what factors actually determine the speeds and feeds which can properly be used. The performance illustrated in Fig. 6, although spectacular, may not be possible, or desirable, on a given job. In any milling operation certain quality specifications such as flatness, breakout, and surface finish must first be satisfied; any of these requirements may limit the feed rate to a value appreciably lower than the maximum capacity of the machine or cutter.

In order to study the quality of surface obtainable when milling with the cutter shown in Fig. 2, the head and pan surfaces of an automobile cylinder block were milled on a special fixed-bed milling machine, Fig. 7. This machine was provided with a hydraulic feeding mechanism by means of which the table could be operated at feed rates up to 300 ipm. The spindle was driven by a separate 40-hp motor. The cylinder block was held in a fabricated fixture. The cylinder-block head surface was $7^1/_4$ in. wide × $23^1/_2$ in. long, while the pan sur-

(Width of cut = 6 in.; depth of cut = 0.150 in.; cutter, $9^5/_8$ in. diam, 12 teeth, +15, —30, 75, +6; cutting speed, 350 fpm.)

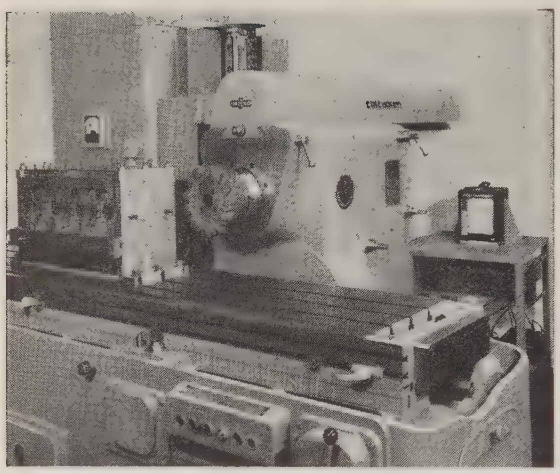

Fig. 7 Fixed-Bed Milling Machine Used for Milling Tests on Cylinder Blocks With Special Cutter Shown in Fig. 2

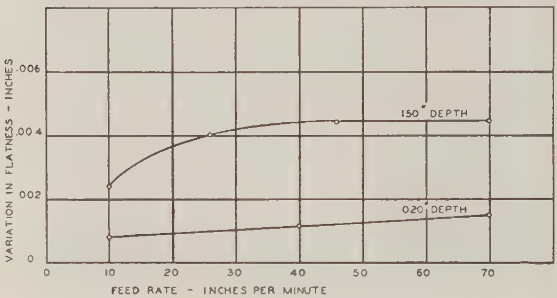

Fig. 8 Variation in Flatness Versus Feed Rate
(Milling head surface of cast-iron cylinder block with special cutter shown in Fig. 2.)

face was $11^1/_4$ in. wide × 25 in. long. Cuts were made at 280 fpm, at feed rates up to 70 ipm. The thin wall sections and cored openings in the block presented a difficult test for these high feed rates.

Flatness. The variations in flatness obtained in milling the head surface of the block at both 0.150-in. and 0.020-in. depths are shown in Fig. 8. Taking a roughing cut 0.150 in. deep, the departure from surface flatness was 0.0044 in. at a feed rate of 70 ipm. This may be considered satisfactory, since such a heavy cut would always be followed by a finishing cut. At 0.020 in. depth, the flatness error never exceeded 0.0015 in. at any feed rate up to 70 ipm.

Breakout. In milling cast iron, the breakout on the work at the side where the cutter teeth emerge from the cut may possibly limit the maximum feed. The relation of breakout to feed rate, measured at the cylinder bores while taking a 0.150-in-depth cut, is shown in Fig. 9. The cylinder bores had 0.125-in. finishing stock, so that the 0.070-in. breakout at 70 ipm left a comfortable margin of safety.

Surface Finish. The surface finish obtained in milling the pan surface of the cylinder block is shown in Fig. 10. The surface finish improved somewhat as the feed rate was reduced. However, even the worst surface finish (230 microinches at 70 ipm, with a depth of 0.150 in.) would be satisfactory as a roughing cut. Figs. 11 (*a*) and (*b*) are reproductions of Faxfilm replicas showing the finish obtained at 70 and 26 ipm, respectively. By careful attention to the shape and smoothness of the cutting edge on the finishing tooth, a very high quality of surface can be obtained on finishing cuts.

Tool Life. There are, of course, other factors than quality specifications that influence the choice of speed and feed. Chief among these is tool life.

Fig. 12 shows the relationship between tool life (measured in terms of cubic inches of metal removed per sharpening) for a single-tooth cutter having the combination of angles developed in this investigation, and used in the multitooth cutter, Fig. 2. In this case the work material was Meehanite A. Here again a definite maximum tool-life point occurs at about 300 fpm; both above and below this speed the tool life rapidly decreases. Higher cutting speeds permit higher feed rates, and, conse-

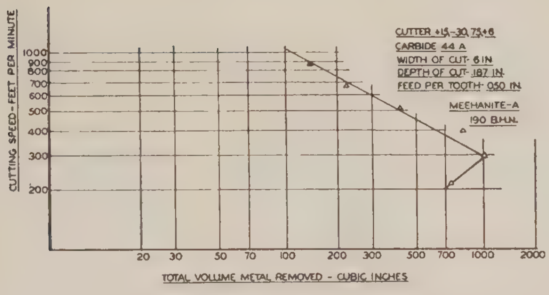

Fig. 12 Cutting Speed Versus Total Volume of Metal Removed to Dull Tooth With Axial Rake of +15 Deg, Radial Rake of —30 Deg, and Corner Angle of 75 Deg

quently, higher production, but as is evident from the curve, this can be gained only at the expense of cutter life.

Cost of Milling and Rate of Production

From the foregoing discussion it is evident that the selection of speed and feed in milling must take into consideration a number of factors such as tool life, surface quality, production rate, breakout of trailing edge of work, etc., any one of which may be of paramount importance in a particular case. In the final analysis, the best combination must be determined by economic considerations; in other words, by the best balance between production rate and cost per piece. Hence it is necessary first to study in detail all of the elements entering into the cost of production.

In the paper[3] previously mentioned, the factors that determine milling cost were combined into the following equation

$$C = \underbrace{\left[\left(M_{LO}\right)\left(T_m + \frac{T_o}{N_L} + \frac{T_r}{N_S}\right)\right]}_{\text{Milling cost}} + \underbrace{\left[C_u\right]}_{\text{Initial cost of cutter}} + \underbrace{\left[\left(G_{LO}\right)\left(\frac{T_S}{N_S} + \frac{T_B}{N_B}\right) + C_a + W\right]}_{\text{Cutter preparation cost}}$$

where

C = total cost to mill one piece, dollars
M_{LO} = labor + overhead on milling machine, \$/min
G_{LO} = labor + overhead on cutter grinder, \$/min
B_{LO} = labor + overhead on brazing unit (assumed = G_{LO}), \$/min
T_m = total time to mill one piece, min
= feeding time + rapid traverse time + loading and unloading time
T_o = original set-up time on milling machine, min
N_L = total number of pieces in lot
T_r = time to change and reset cutter, min
T_s = time to resharpen cutter, min
N_s = number of pieces milled per cutter sharpening
T_B = time to rebraze teeth (or reset blades), min
N_B = number pieces milled per brazing (or resetting)
C_u = original cutter cost per workpiece
C_a = carbide (or blade) cost per workpiece
W = wheel (diamond or abrasive) cost per sharpening

From this equation the production rate in pieces milled per 60-min hr (P) can be derived

$$P = \frac{60}{T_m + \frac{T_o}{N_L} + \frac{T_r}{N_s}}$$

The cost equation also indicates that the two major factors which determine the cost of milling are the actual milling cost (or metal-removal cost), and the cutter preparation cost. The original cutter cost per piece milled is generally negligible, except for short jobs that require special cutters.

In order to illustrate the application of a cost analysis to speed and feed selection in practical cases, specific examples will be presented to show the effect of such factors as work material, cutting speed, feed per tooth, number of teeth in the cutter, loading and unloading time, number of pieces in the lot, and the length of cut. The following assumptions will be common to all of the examples:

Operation: Face mill cast-iron block
Cut dimensions: 6 in. wide, $^3/_{16}$ in. deep, 20 in. long (except where noted)
Cutter: 10 in. diam, +15 deg axial rake, —30 deg radial rake, 75 deg corner angle, +6 deg true rake, 12 teeth (except where noted)
Feed per tooth: 0.050 in. (except where noted)
Approach to work: 10 in.
Overtravel of cutter past work: 10 in.
Number of pieces in lot: 10,000 (except where noted)
Time to load and unload: 1 min (except where noted)

Labor cost on milling machine..................	\$1.00 per hr
Overhead on milling machine..................	\$4.00 per hr
Labor cost on cutter grinder..................	\$1.00 per hr
Overhead on cutter grinder..................	\$1.25 per hr

Then M_{LO} = \$.0832 per min
G_{LO} = \$.0374 per min

Rapid traverse rate = 300 ipm

T_o = 60 min
T_r = 10 min
T_s = 20 min per tooth
T_B = 5 min per tooth
$N_B = 4\ N_s$

$$C_u = \frac{\text{Original cutter cost}}{\text{No. of pieces milled with cutter}} = \frac{\$200}{50{,}000} = \$0.004$$

$$C_a = \frac{\$2.00 \times \text{No. teeth}}{3\ N_B}$$

$$W = \frac{\$0.20 \times \text{No. teeth}}{N_s} \text{ (for diamond grinding wheel)}$$

The time to mill one piece T_m will then be

$$T_m = \frac{10 + l}{f} + \frac{10 + l + 20}{r} + T_L$$

where

l = length of cut, in.
f = feed rate, ipm
r = rapid traverse rate, ipm
T_L = time to load and unload, min.

The number of pieces milled before the cutter has to be resharpened, N_s, will be

$$N_s = \frac{\text{No. teeth} \times L}{\text{Cubic inches removed per piece}}$$

where

L = tool life, cu in. removed to dull one tooth, obtained from cutting-speed versus tool-life curves (such as Fig. 12)

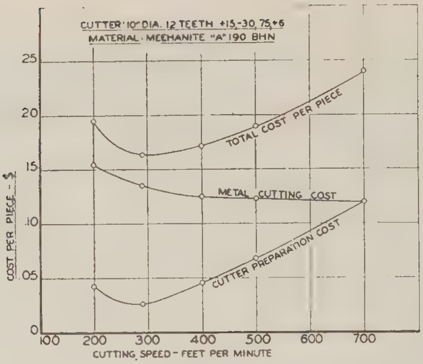

Fig. 13 Analysis of Total Milling Cost in Terms of Its Principal Components

(Dimensions of cut: $^3/_{16}$ in. deep, 6 in. wide, 20 in. long.)

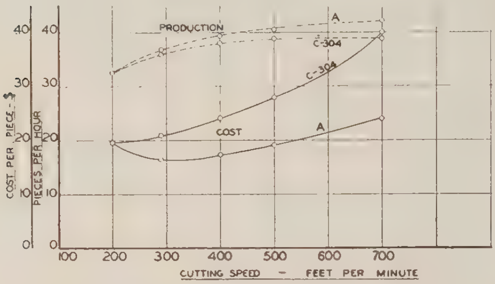

Fig. 14 Production Rate and Cost per Piece Versus Cutting Speed

(Dimensions of cut: $^3/_{16}$ in. deep, 6 in. wide, 20 in. long.)

The manner in which the cutting cost components vary with cutting speed, in milling Meehanite A, is shown in Fig. 13. The cutter preparation cost is a minimum at 290 fpm, because at this speed the tool life was a maximum (see Fig. 12). The metal-cutting cost drops rapidly as the speed is increased from 200 to 400 fpm, but at higher speeds the milling cost remains practically constant because the increase in feed rate is offset by the time lost in changing and resetting cutters which results from the decreased tool life. The total cost per piece is the sum of the cutter preparation cost and the metal-cutting cost. This total cost is likewise seen to be a minimum at 290 fpm.

But the cost per piece may not be the most important factor. Under certain conditions, the production rate may be equally important as the cost per piece, and in some cases may be even more important. The production rate required on a machine may be determined by the capital investment and by the inconvenience or delay in obtaining additional equipment. For example, it may be desirable to sacrifice tool life by operating at higher cutting speeds in order to obtain a definite production rate with a given number of milling machines.

The production rate, measured in number of pieces milled per 60-min hr, and the cost per piece, vary with cutting speed as shown in Fig. 14. The production rate for both of the materials tested (Meehanite A and Meehanite C-304) rises rapidly as the speed is increased from 200 to 400 fpm, but at the higher speeds these increases are less pronounced owing to the increase in time lost when changing cutters. The total cost per piece for Meehanite C-304 is practically constant between 200 and 300 fpm, but at the higher speeds the cost rises rapidly. The differences in cost and production between the two grades of Meehanite are due to the differences in their machinability characteristics. From Fig. 14 the speed which gives the best combination of cost and production can be readily determined. In milling Meehanite A it is obvious that 300 or 400 fpm would be a more economical speed than 200 fpm.

Quantitative comparisons may also be made. Thus in milling Meehanite C-304, the cost at 300 fpm would be 1.07 times as high as at 200 fpm, whereas the production rate at 300 fpm would be 1.11 times as high. Thus at 300 fpm, for a 7 per cent increase in cost, one could obtain a production increase of 11 per cent. In a like manner, the economy of operation at other cutting speeds can be compared.

In the case just discussed, the feed per tooth was held constant at 0.050 in. A thorough analysis of cost and production, however, must take into consideration a wide range of feeds per tooth as well as cutting speeds.

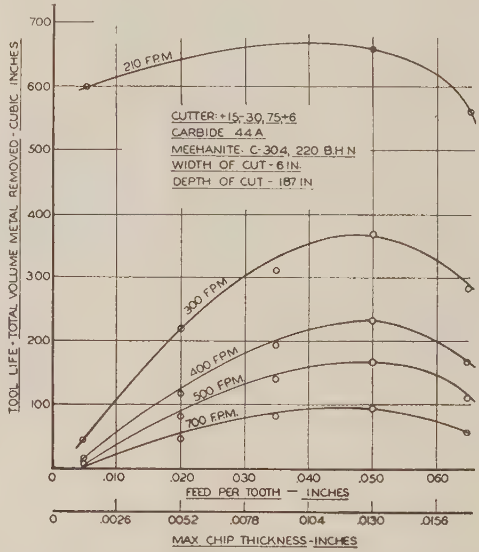

Fig. 15 Tool Life, in Terms of Total Volume of Metal Removed Versus Feed per Tooth, at Constant Cutting Speed

In Fig. 18 of the paper by Field and Bullock[3] (reproduced here as Fig. 15), the interrelation of feed per tooth and cutting speed, with tool life, is shown for the 75-deg corner angle cutter when milling Meehanite C-304. Here the tool life (expressed in cubic inches of metal removed per tooth) is plotted against feed per tooth at constant cutting speeds. Note that here the maximum tool life occurs at 0.050 in. feed per tooth, regardless of the cutting speed. In Fig. 16 the cost and production rate have been plotted against feed per tooth, at constant cutting speeds, using the tool-life data from Fig. 15. Inspection of Fig. 16 shows that the minimum cost likewise occurs at 0.050 in. feed per tooth for all cutting speeds.

Many interesting facts are revealed by a study of the curves in Fig. 16. For instance, it will be noted that for cutting speeds of 200 to 400 fpm, the cost curves are relatively flat with feeds per tooth between 0.040 in. and 0.060 in., but rise rapidly with feeds per tooth below 0.040 in. For cutting speeds above 400 fpm, the cost curves show a sharp minimum at about 0.050 in. feed per tooth. In contrast, all the production-rate curves rise rapidly with feeds per tooth up to 0.040 in., while above 0.040 in. only those for cutting speeds of 400 fpm and under continue to rise appreciably. At 500 fpm the production-rate curve is rela-

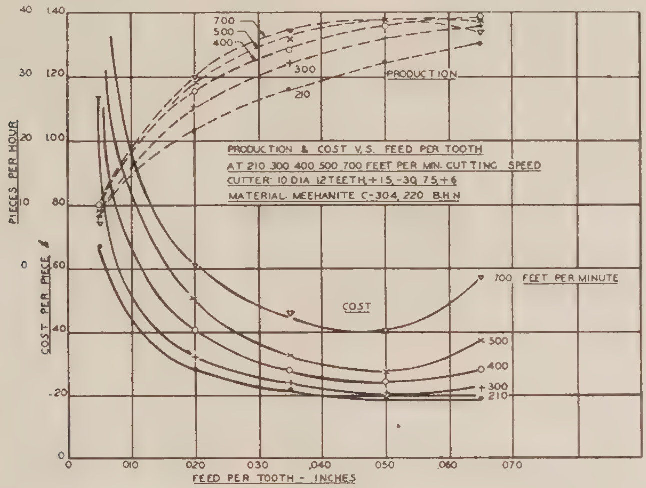

Fig. 16 Pieces per Hour and Cost per Piece Versus Feed per Tooth at Constant Cutting Speeds
(Dimensions of cut: $^3/_{16}$ in. deep, 6 in. wide, 20 in. long.)

tively flat above 0.040 in. feed per tooth, while at 700 fpm, the curve actually peaks at a feed per tooth of 0.050 in. In this neighborhood the vertical interval between the production-rate curves decreases as the speed is increased, while the interval between the cost curves rapidly increases.

From the curves in Fig. 16 it is therefore apparent that for this particular example of cutter and work, the most desirable combination, from the standpoint of both cost and production, is with a cutting speed of about 300 fpm, and a feed per tooth of about 0.050 in. to 0.055 in. If the cutting speed were increased from 300 to 400 fpm, the cost per piece would be increased 10 per cent, while the production rate would increase only 5 per cent. On the other hand, if the cutting speed were reduced from 300 to 200 fpm, the cost would be decreased only 5 per cent, while the production rate would decline 10 per cent.

With a cutter of $9^5/_8$ in. mean diam, (as in Fig. 2), a 300-fpm cutting speed would correspond to a rotation of 120 rpm. With 12 teeth in the cutter and a feed per tooth of 0.055 in., the feed rate would then be 120 × 12 × 0.055, or 80 ipm. Under these conditions, the total volume of cast iron, Meehanite C-304, which could be removed before the cutter would need resharpening (using the data from Fig. 15), would be about 4200 cu in. or approximately 1200 lb.

If a cutting speed of 400 fpm were used, the feed rate would be 107 ipm, but the total volume of metal removed before sharpening would be reduced to 2640 cu in. Under these conditions, using the data from the curves in Fig. 16, it can be shown that the production rate would be increased 5.4 per cent while the cost per piece would be increased 22 per cent.

From the tool-life curve in Fig. 12, it is interesting to note that if Meehanite A had been used instead of Meehanite C-304, the volume of metal removed before sharpening, at a cutting speed of 300 fpm, would be 12,000 cu in., or approximately 3100 lb.

Other Factors Influencing Production Rate and Milling Cost

There are still other important factors than quality specifications and tool life, however, that influence production rate and cost of milling.

Number of Teeth in Cutter. In Fig. 17 is shown the effect of the number of teeth in the cutter when using an optimum combination of cutting speed and feed per tooth. Here it will be

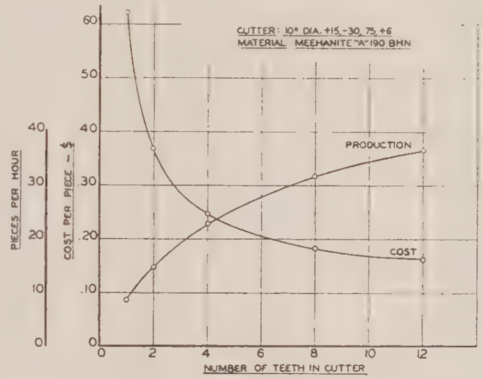

Fig. 17 Pieces per Hour and Cost per Piece Versus Number of Teeth in Cutter
(Dimensions of cut: $^3/_{16}$ in. deep, 6 in. wide, 20 in. long.)

seen that there is a rapid drop in cost and a rapid rise in production rate as the number of teeth is increased from 1 to 4 in this 10-in-diam cutter. As the number of teeth is further increased, both the cost and the production curves flatten out because the feeding time eventually becomes small in comparison with other fixed portions of the cycle time, such as the rapid traversing time, and the loading and unloading time.

Loading Time. The effect of loading and unloading time on cost and production is shown in Fig. 18, for two conditions: (*a*) 280 fpm cutting speed and 65 ipm feed rate; and (*b*) 500 fpm cutting speed, and 105 ipm feed. From this chart it will be seen that the cost at 500 fpm is a constant amount higher than at 280 fpm, regardless of the loading time. Furthermore, the cost per piece is a linear function of the loading time. The production-rate curves are flat at a high loading time because the feeding time here is short compared to the time to load and unload. However, when the loading time is decreased below one min, the production rates increase sharply. It will also be noted that no appreciable increase in production will be obtained by selecting the high speed and feed, unless the loading time is decreased. For example, at 0.1 min loading time, 102 pieces per hr could be milled at 500 fpm, compared to 80 pieces per hr at

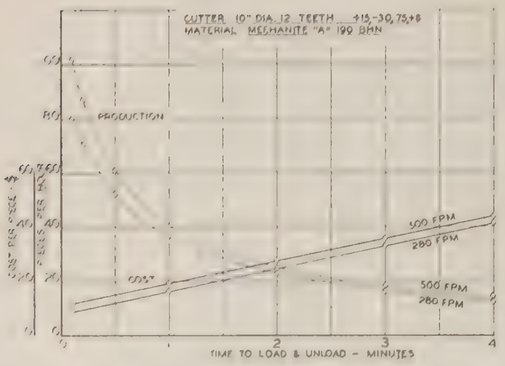

FIG. 18 PIECES PER HOUR AND COST PER PIECE VERSUS TIME TO LOAD AND UNLOAD
(Dimensions of cut: $^3/_{16}$ in. deep, 6 in. wide, 20 in. long.)

280 fpm. This is an increase of about 27 per cent. In contrast, for a 2-min loading time, 22.5 pieces per hr could be milled with the high speed and feed, compared to 21 pieces per hr with the low speed and feed; an increase of only 7 per cent.

Number of Pieces in Lot. The effect of the number of pieces in the lot being milled is shown in Fig. 19. If the number of pieces in the lot is small, the original setup time may seriously decrease the production rate and may add appreciably to the cost of milling. In the example chosen, it is seen that the cost and production curves change rapidly if there are fewer than 200 pieces in the lot. However, for larger lots the changes in the curves are very small. It is furthermore interesting to note the small difference between 800- and 10,000-piece lots. There is a constant difference in cost per piece between the 500- and 280-fpm curve. The difference in production rates between the two cutting speeds is small for very small lots. However, this difference increases and eventually becomes practically constant above a 300-piece lot.

Length of Cut. The effect of the length of cut on cost and production is shown in Fig. 20. The cost was about the same for both cutting speeds for a 5-in. length of cut. As the length of cut increased, the cost per piece to mill at the higher cutting speed increased over that of the lower cutting speed. However, the production rate at 500 fpm was substantially higher than at 280 fpm for lengths of cuts of 5 to 30 in.

MILLING OF STEEL

Turning now to the milling of steel, we may cite as an example an analysis made of an actual production milling job performed in the authors' plant. The workpiece was a steel forging (S.A.E. 4340, 415 Bhn) used as a "drag link" on the landing gear of the B-29 Superfortress. Two major milling operations were performed on this forging, namely, milling the inside and outside surfaces of the yoke on each end. The inside of the yoke was milled, with the setup shown in Fig. 21, on a Cincinnati horizontal Hydrotel using two staggered-tooth slotting cutters, 14 in. diam, having 8 teeth, tipped with a steel-cutting grade of carbide. The teeth were ground with an axial rake of —20 deg, a radial rake of —20 deg, and $^1/_4$ in. radius. Each cutter took a cut $^5/_{16}$ in. deep and $3^3/_4$ in. wide. The work was fed into the cutter at a rate sufficient to provide a feed per tooth of 0.008 in. The return feed was made at the same rate so as to reduce the dimensional error due to springing of the workpiece, and to avoid marring the work, as a finish under 50 microinches (rms) had to be obtained.

Three cutting speeds were chosen, 235, 290, and 370 fpm, respectively. From Fig. 22 it is seen that minimum cost and maximum production were obtained at 290 fpm. Designating the cost and production rates at this optimum speed 100 per cent, it is seen from the curves that, at a cutting speed of 235 fpm, the cost increased to 104 per cent while the production dropped to 94 per cent, whereas at 370 fpm, the production remained at 100 per cent while the cost rose to 107 per cent. Obviously, a cutting speed in the neighborhood of 300 fpm was the best for this particular operation.

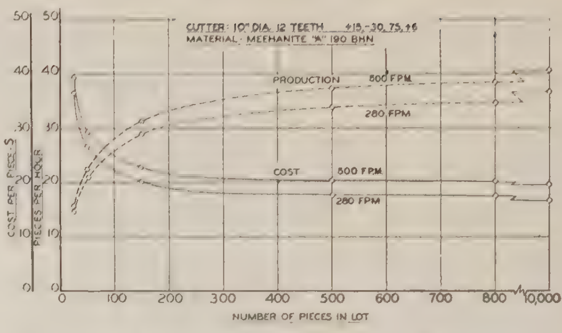

FIG. 19 PIECES PER HOUR AND COST PER PIECE VERSUS NUMBER OF PIECES IN LOT
(Dimensions of cut: $^3/_{16}$ in. deep, 6 in. wide, 20 in. long.)

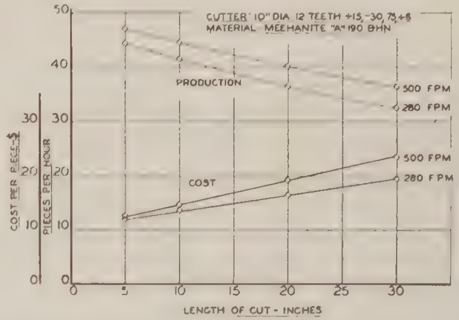

FIG. 20 PIECES PER HOUR AND COST PER PIECE VERSUS LENGTH OF CUT
(Dimensions of cut: $^3/_{16}$ in. deep, 6 in. wide.)

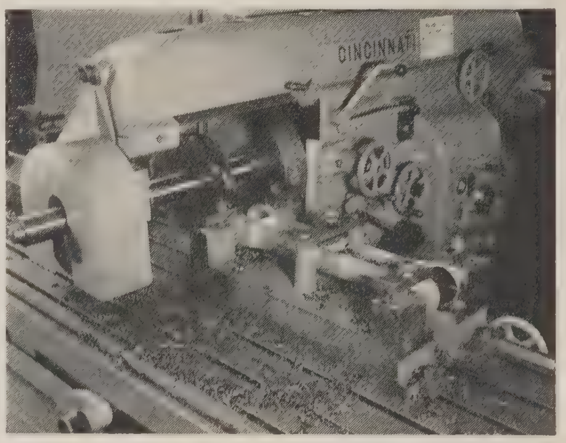

FIG. 21 SETUP FOR MILLING INSIDE OF YOKE ON ALLOY STEEL FORGING
("Drag link" for B-29 Superfortress.)

The second major operation analyzed was the straddle-milling operation on the outsides of the yoke. This operation was performed on a Cincinnati 4-48 duplex Hydromatic miller, with the setup shown in Fig. 23, using a pair of right- and left-hand, 6-in-diam 6-tooth shell-end mills. The cutters had an axial rake of —20 deg, a radial rake of —20 deg, and a corner angle of 30 deg. These cutters also took a cut $^5/_{16}$ in. deep and $3^3/_4$ in. wide. Again, in order to obtain the specified surface finish and accuracy, the cutters were fed fully across each yoke surface. As shown in Fig. 24, the minimum cost per piece and maximum production rate occurred at 285 fpm. Designating this condition as 100 per cent, it is seen that at 210 fpm the cost remained at 100 per cent, while the production dropped to 88 per cent. At 380 fpm, however, the cost jumped to 181 per cent while the production rate dropped to 88 per cent. It is therefore evident that a cutting speed of about 300 fpm was the optimum for this operation.

Conclusions

The following conclusions can be drawn from the results of the work done thus far:

1 It is not possible to extrapolate tool-life curves into the low-speed range from the results of tests made at cutting speeds over 500 fpm, for the following reasons:

(*a*) From the results of tests made thus far it appears that the cutting-speed versus tool-life curve may often contain a maximum tool-life point toward the lower end of the speed range. This point seems to exist at a lower value for the harder grades of cast iron.

(*b*) In certain cases the curve of cutting speed versus tool life is not a straight line in the lower speed range when drawn on log-log paper.

2 Practical tests of multitooth cutters with the combination of very large corner angle (70 to 80 deg), large negative radial rake (—30 to —45 deg), and large positive axial rake (+15 to +20 deg), have shown that this combination has unusually long life in terms of volume of metal removed before grinding. It also permits the use of very high feed rates and consequent high production without clogging of chips, and yet meets normal quality specifications of flatness, surface finish, and breakout.

3 Curves showing the relationship between cutting speed, feed, and tool life are essential for an intelligent selection of speed and feed. However, selection of speed and feed for practical milling operations cannot be made directly from these tool-life curves, but must take into consideration also the effect of tool life on both cost and production. Proper balance between these two factors can be made only on the basis of a complete cost analysis.

4 Selection of speed and feed must also be made on the basis of meeting quality specifications, such as flatness, surface finish, and breakout.

5 Cost and rate of production are also affected by number of teeth in the cutter, loading time, length of cut, and number of pieces in the lot. A complete analysis of a milling operation should take into consideration the relationship between these factors and cutting speed and feed.

Acknowledgment

The authors wish to express their appreciation to Dr. M. E. Merchant and Mr. Norman Zlatin of the research department of the Cincinnati Milling Machine Co., for their aid in the preparation of this paper, and to Mr. Walter Deer of the engineering service department, who helped in conducting the shop tests.

(Owing to travel emergency conditions existing when this paper was presented, discussion will be accepted until May 10, 1946)

Analysis of Initial Contact of Milling Cutter and Work in Relation to Tool Life

By M. KRONENBERG,[1] CINCINNATI, OHIO

Sintered-carbide tools, made of the hardest metal man has ever produced, have played a predominant role in speeding up war production. While appreciable experience has been acquired in connection with the turning of artillery shells and other implements of war, the application of sintered-carbide tools is often more difficult in milling than in turning operations because face-milling cutters, end mills, straddle mills, side mills, etc. are subjected to several hundred impacts per minute, which may destroy the tools prematurely due to their brittleness. Control of impact is therefore vital, a problem not encountered with high-speed steel tools.

It is the purpose of this paper to present methods for determining readily the impact conditions for any shape of the cutting edge as a function of positive and negative rake angles, corner angle, cutter diameter, position of the cutter relative to the workpiece, feed per tooth, and depth of cut. Furthermore, tests are discussed indicating a variation in the wear of sintered-carbide tools with a variation of impact conditions obtained by altering the relative position of cutter and work.

Introduction

While carbide-tipped tools with negative rake angles have been successfully employed for a number of years in intermittent turning operations, this technique is a relatively recent development in the case of milling operations. The reason for this may well lie in the more complex nature of initial contact of milling cutter and work compared with that of a turning tool and work.

In the simple case of machining a slotted flange in a plunge-cut operation, the location of the initial contact can be easily controlled. As shown in Fig. 1, a negative back rake is the only requirement for shifting the initial contact from the sharp point "S" of the tool to a point farther back, where the tool is stronger.

Turning a shaft with a keyway, using a longitudinal feed, is a more difficult case in that three tool angles affect the location of the initial contact when the tool is "on center," namely, back rake, side rake, and side-cutting-edge angle.

In the case of milling operations, a fourth quantity, which is not a property of the tool itself, must be taken into consideration; it depends on the position of the milling cutter relative to the work. This fourth quantity, later referred to as the "angle of engagement," plays a significant part in the location and magnitude of impact.

Three questions present themselves for the analysis of the impact problem. They can conveniently be used for subdividing the subject of this paper as follows:

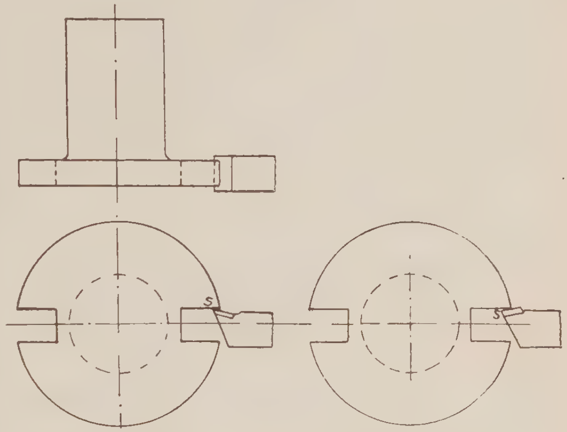

Fig. 1 Initial Contact Produced by Positive and Negative Back Rake, When Turning a Slotted Flange

1 Where does the impact of tooth and work occur? That is, what point on the tool face hits the work first? (Location of impact.)

2 How great is the impact? (Magnitude of impact.)

3 How is tool wear affected by location and magnitude of impact?

1—LOCATION OF IMPACT

Model, Demonstrating Location of Contact

A face-milling cutter is shown in Fig. 2 at an instant shortly before the tooth engages the side wall of the work, termed "plane of engagement." This plane is always assumed parallel to the cutter axis and extending in the direction of feed motion. It is evident from the close-up in the upper corner of Fig. 2 that the material removed by a tooth with a straight cutting edge is indicated by a parallelogram *S-T-U-V*. Its height depends on the depth of cut, while the width is determined by the feed per tooth represented by a dotted line on the top of the work. This parallelogram *S-T-U-V* develops gradually as the tooth enters the work, and the question arises, what spot on the contour of the parallelogram is generated first. This spot will obviously be the point of initial contact.

It will be seen from Fig. 2 that the tooth, before contacting the work, passes through the removed portion of the plane of engagement. This happens when the cutter axis is on the "workside" of the plane of engagement, as shown in Fig. 2.

In the analysis of initial contact, it is necessary to consider only the region of cutter and work indicated in the close-up, Fig. 2. This same region is represented in Fig. 3 as a large-scale model, seen in the direction of the arrow of cutter rotation, Fig. 2.

In Fig. 3 the "tool face" is a glass plate shaped to the contour of a tooth, intersecting the "plane of engagement" in line *L-M*.

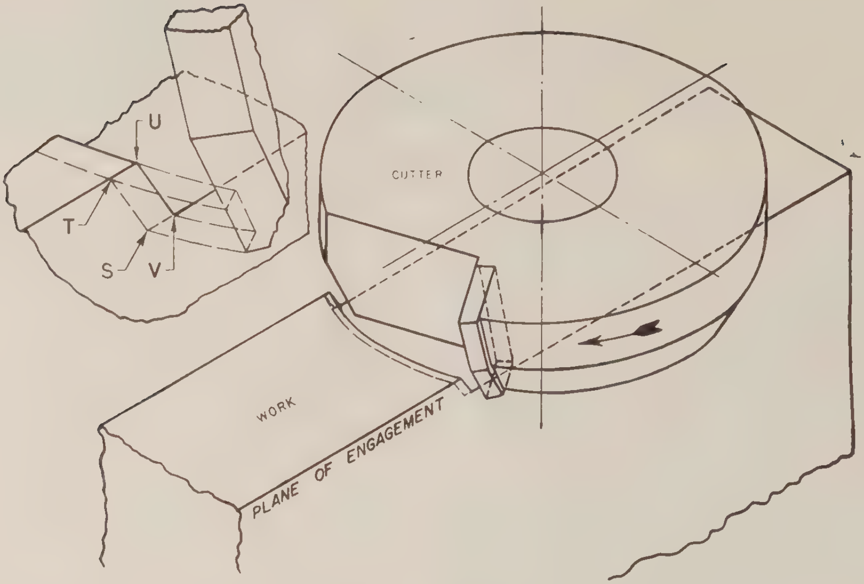

Fig. 2 Diagrammatic View of Cutter and Work, Illustrating an Instant Shortly Before Initial Contact

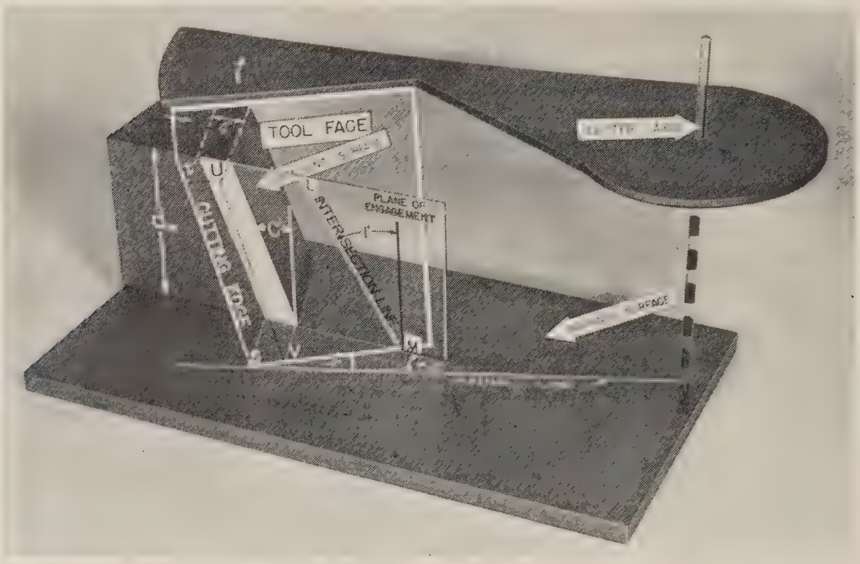

Fig. 3 Model of Cutter and Work Illustrating Intersection Line of Tool Face and Plane of Engagement

The axial rake and the radial rake are both negative and the cutting edge is a straight line in this model.

The direction of cutter rotation is indicated by an arrow pointing into the workpiece.

The "cutter axis" is connected with the tool face by a top piece symbolizing the face of the cutter body. The cutter axis is actually more distant from the tool face than shown in the model.

On the workpiece, dimension d_m is the depth of cut, while dimension f_t represents the feed per tooth.

The chip cross-sectional area is indicated by a white parallelogram on the workpiece. The corresponding points on the tool face are marked S, T, U, and V, in clockwise order.

The distance traveled by the tooth from the instant shown, to the instant of contact, is very short and it may therefore be assumed that the tool moves in a straight line during this very short interval of time, instead of traveling in a circular path. In other words, the tool face is assumed to advance parallel to itself in the direction of the white dotted lines which connect the points, S, T, U, V, on the tool face with the white parallelogram. The white lines are continued on the top of the work because the cutter movement is also considered straight for a short distance within the workpiece.

Point S is the sharp point of the tool and its weakest spot. Initial contact there is undesirable.

Point T is the top point of the active cutting edge and is located at a height above the machined surface equal to the depth of cut (d_m).

Point U indicates a point on the tool face, at the same height as point T, but remote from the cutting edge by approximately the feed per tooth.

Point V is a point on the face edge, located at a distance from point S approximately equal to the feed per tooth.

It is evident from Fig. 3 that in the case of this model, point U on the tool face will contact the work first, because this point is nearest to the white parallelogram. This can be judged by comparing the length of the four dotted white lines connecting points, S, T, U, and V with the work. Point U has the shortest distance. This type of contact is called "U-contact."

If the tool face would be inclined at a positive axial rake, point V would have the shortest distance on the model and contact first (V contact).

It shall now be assumed that the tool face in Fig. 3 is advancing parallel to itself, in the direction of the white dotted lines toward the workpiece. Point U on the tool face will then travel toward the upper right corner of the white parallelogram; simultaneously point L of the intersection line will likewise move toward the upper right corner on the workpiece. At the instant when point U contacts the white parallelogram at its upper right corner, point L of the intersection line must have arrived at that same point also.

If the tool face would be inclined at a positive axial rake and the angle i' would be to the right of the vertical line in the plane of engagement, it would be points V and M which would arrive at the same instant but at the lower right corner of the white parallelogram.

Consequently, the spot on the tool face which contacts the work first is indicated by the point of the intersection line LM, which first contacts the white parallelogram.

This is an important finding, because it furnishes not only the basis for the derivation of mathematical formulas for contact conditions in the case of straight cutting edges but also principles for a graphical solution of the more involved problems connected with nonstraight cutting edges and with the magnitude of impact.

Mathematical Conditions for Location of Initial Contact

Mathematical formulas are required for preparing diagrams and for other graphical methods which can directly be employed by production and tool engineers in their daily work.

The following nomenclature will be used in connection with the derivation of formulas:

a = axial rake
A' = distance of cutter axis from plane of engagement (see Fig. 4)
c = corner angle of tool
c' = slope of transient surface produced by corner angle c ($\tan c' = \tan c/\cos \epsilon$)
c_a = chamfer angle of tool
d_m = depth of cut
D = cutter diameter
ϵ = angle of engagement
f_t = feed per tooth
i = index angle
i' = intersection angle of tool face and plane of engagement ($\tan i' = \tan i/\cos \epsilon$)
I = impact factor (rate of increase of chip cross-sectional area) sq in. per sec
L_d = distance traveled by index line in direction of depth of cut during penetration time
L_f = distance traveled by index line in the direction of feed during penetration time
r = radial rake
T_p = penetration time, i.e., time elapsing between instant of initial contact and instant when both cutting edge and face edge of tool have engaged the work
T_e = exit time, i.e., time elapsing between instant when first point of tool leaves work and instant when both cutting edge and face edge are disengaged

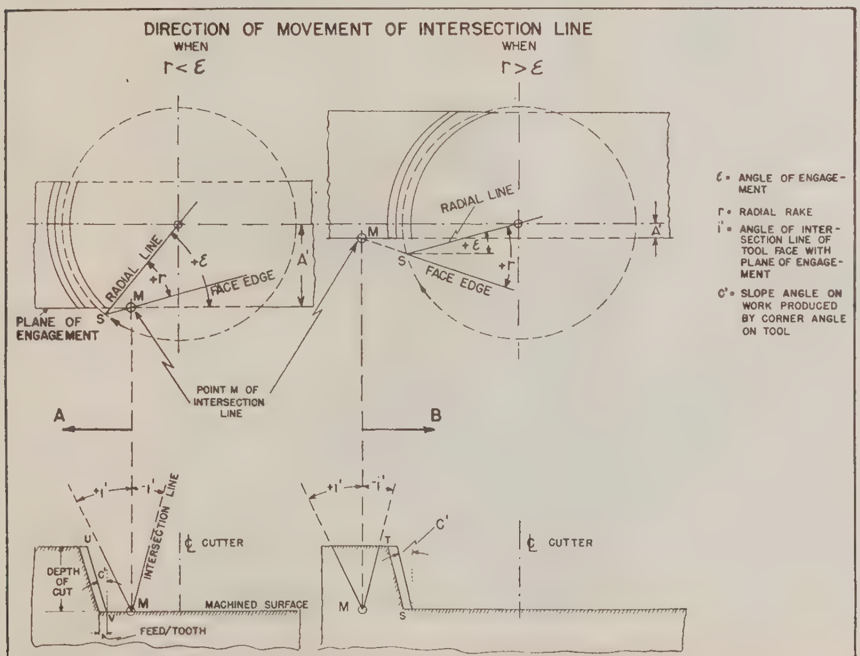

Fig. 4 Direction of Movement of Intersection Line

Referring to Fig. 3, two important angles, c' and i', will be seen in the plane of engagement.

Angle c' is the slope of the "transient surface" measured in the plane of engagement. This angle has been produced by the preceding tooth and depends therefore on the shape of the cutting edge and on the angle of engagement, as will become evident later.

Angle i' is an angle formed by line LM (which is the intersection line of tool face and plane of engagement) and a line parallel to the cutter axis. Angle i' is called "intersection angle."

The model, Fig. 3, refers only to the case where the intersection line is outwardly inclined with respect to the cutter axis and where the cutter axis is on the workside of the plane of engagement.

For a more general consideration, reference is made to Fig. 4. It will be seen from the lower sketches that the intersection angle i' can be positive or negative with respect to the vertical line parallel to the cutter axis, that is, it can be outwardly or inwardly inclined. Furthermore, the radial rake, formed by the face edge and a radial line, is shown in Fig. 4, marked r. In addition, the angle formed by the plane of engagement and the radial line is indicated; it is the angle of engagement (ϵ).

For determination of the direction of movement of the intersection line, it is sufficient to consider only its lower point M which is also a point of the face edge of the tool. In the case of the left-hand sketch in Fig. 4, point M moves toward the left as the cutter continues to rotate. Hence the intersection line will always move "away" from the cutter axis, due to cutter rotation, when $r < \epsilon$. Consequently, in cases where $r < \epsilon$, initial contact can occur only at the right-hand contour of the chip cross-sectional area, that is, in the case of a straight cutting edge, either at point U, or along line U-V or at point V, depending on the relationship of the two angles c' and i'.

Changing the setup (right-hand sketch in Fig. 4), by moving the workpiece into a different position with respect to the cutter axis, will change the relationship between the angles r and ϵ.

Point M of the intersection line is now located on the other side and will move "toward" the cutter axis, as the cutter continues to rotate. Consequently, in cases where $r > \epsilon$, initial contact can occur only at the left-hand contour of the chip cross-sectional area, that is, in the case of a straight cutting edge, either at point S, or T, or along line ST.

The following mathematical relationships for initial contact of straight cutting edges can therefore be derived from inspection of Fig. 4

S = contact occurs when $r > \epsilon$ and $i' > c'$........[1a]

S-T (line) = contact occurs when $r > \epsilon$ and $i' = c'$........[1b]

T = contact occurs when $r > \epsilon$ and $i' < c'$........[1c]

U = contact occurs when $r < \epsilon$ and $i' > c'$........[1d]

U-V (line) = contact occurs when $r < \epsilon$ and $i' = c'$........[1e]

V = contact occurs when $r < \epsilon$ and $i' < c'$........[1f]

There are three more types of initial contact possible in the case of straight cutting edges, namely, when $r = \epsilon$. In these special cases, the intersection line and therefore point M is at infinity because the face edge enters the work parallel to the plane of engagement. The mathematical conditions for these cases will be discussed later.

In order to express the contact conditions as functions of axial rake, radial rake, angle of engagement, it is now necessary to find the relationship between these three angles and the intersection angle i'.

Referring to Fig. 5: Dropping a perpendicular line from point L of the intersection line L-M, produces a vertical triangle L-N-M

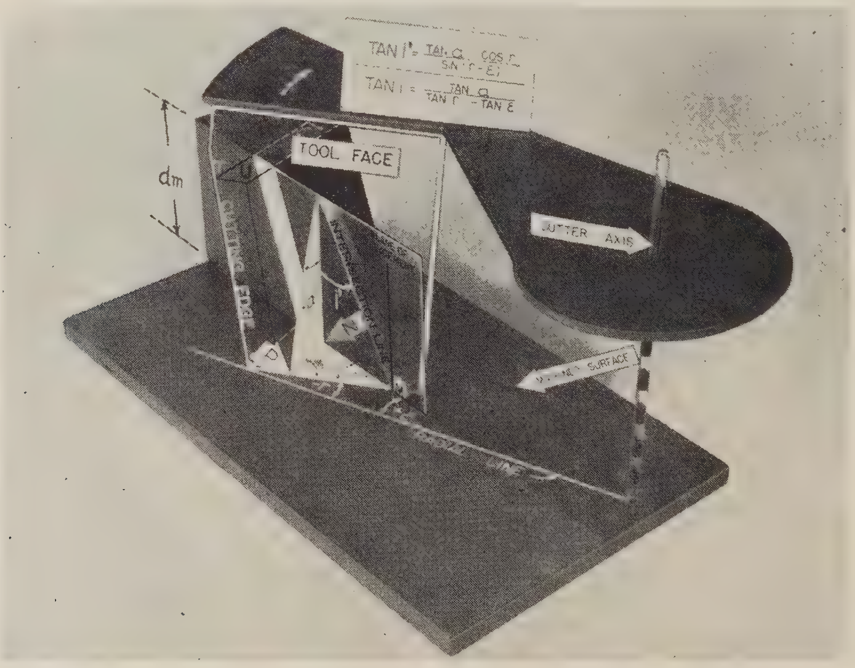

Fig. 5 Model of Cutter and Work Illustrating Relationship Between Axial Rake, Radial Rake, Angle of Engagement, and Intersection Angle

TABLE 1 MATHEMATICAL CONDITIONS FOR THE NINE TYPES OF INITIAL CONTACT FOR STRAIGHT CUTTING EDGES

	TYPE OF CONTACT	Relationship: radial rake (r) & angle of engagement (ϵ)	Relationship: corner angle (c) and index angle (i)	Relationship corner angle (c) axial rake (a) radial rake (r) and angle of engagement (ϵ)
1	 S	$r > \epsilon$	$c < i$	$\tan c < \frac{\tan a}{\tan r - \tan \epsilon}$
2	 T	"	$c > i$	$\tan c > \frac{\tan a}{\tan r - \tan \epsilon}$
3	 U	$r < \epsilon$	$c < i$	$\tan c < \frac{\tan a}{\tan r - \tan \epsilon}$
4	 V	"	$c > i$	$\tan c > \frac{\tan a}{\tan r - \tan \epsilon}$
5	 ST	$r > \epsilon$	$c = i$	$\tan c = \frac{\tan a}{\tan r - \tan \epsilon}$
6	 UV	$r < \epsilon$	$c = i$	$\tan c = \frac{\tan a}{\tan r - \tan \epsilon}$
7	 VS	$r = \epsilon$	$i = 90°$	$a = +$
8	 UT	"	"	$a = -$
9	 FACE	"	NO LINE INTERSECTION	$a = 0$

in the plane of engagement. This triangle L-N-M contains angle i'. The base line N-M equals

$$d_m \cdot \tan i'$$

The axial rake is measured, according to definition, in a plane located in the direction of cutter rotation, that is, in a plane perpendicular to the radial line. Such a plane is represented in Fig. 5 by the white vertical triangle L-N-P, containing the axial rake ($-a$) which is shown negative. The base line N-P equals

$$d_m \cdot (-\tan a)$$

The two base lines N-M and N-P, together with portion P-M of the face edge, form the horizontal, white triangle P-N-M, with the angles

$$(90 + r)$$

and

$$(\epsilon - r)$$

Applying the sine law to the horizontal triangle results in the formula

$$\tan i' = \frac{\tan a \cdot \cos r}{\sin (r - \epsilon)} \quad \ldots\ldots\ldots\ldots [2]$$

Equation [2], however, is inconvenient for use in a diagram, because the radial rake r appears twice.

A simplification can be obtained by multiplying both sides by $\cos \epsilon$. This transformation gives

$$\boxed{\tan i = \frac{\tan a}{\tan r - \tan \epsilon}} \quad \ldots\ldots\ldots\ldots [3]$$

It will be noticed that Equation [3] refers to an angle i instead of angle i'. This is due to the multiplication of Equation [2] by $\cos \epsilon$. Equation [3] represents therefore a different angle, called "index angle" (i).

The relationship between the intersection angle (i') and the index angle (i) follows from

$$\tan i = \tan i' \cos \epsilon \ldots\ldots\ldots\ldots [4]$$

Index angle i is a projection of intersection angle i', on a vertical plane which can be erected in the radial line. This plane, called reference plane, forms the angle ϵ with the plane of engagement, but is not shown in the model.

In order to maintain the mathematical relationship between slope angle c' and intersection angle i' when determining the location of initial contact (see formulas [1a] to [1f], inclusive), it is necessary to multiply the slope angle c' also by $\cos \epsilon$ as was done with angle i'. The slope angle c' is thus substituted by the corner angle c (or bevel angle) as ground to the tool itself, which is measured in the reference plane. The corner angle c is mathematically a projection of the slope angle c' on the reference plane. The relationship between slope angle c' and corner angle c is given by

$$\tan c = \tan c' \cdot \cos \epsilon \ldots\ldots\ldots\ldots [5]$$

The multiplication of Equation [2] by $\cos \epsilon$ does not only simplify the formula, but allows using the corner angle c of the tool instead of the slope angle c' on the work.

The following general equation is obtained for initial contact in the case of straight cutting edges by substituting Equations [3] and [5] into formulas [1a] to [1f]

$$\tan c \overset{>}{\underset{<}{=}} \frac{\tan a}{\tan r - \tan \epsilon} \ldots\ldots\ldots\ldots [6]$$

The individual formulas for the nine possible contacts in case of straight cutting edges are summarized in Table 1. The last three cases, where $r = \epsilon$, follow if Equation [6] is solved for $\tan a$

$$\tan a \overset{>}{\underset{<}{=}} \tan c (\tan r - \tan \epsilon) \ldots\ldots\ldots\ldots [6a]$$

The right side becomes zero if $r = \epsilon$, indicating that these three contact conditions are determined by the fact as to whether the axial rake "a" is positive, zero, or negative.

Cutter-Engagement Diagram

For practical use in engineering offices a "cutter-engagement diagram," Fig. 6, has been prepared, based on the foregoing mathematical analysis. It refers primarily to cases where the cutting edge is a straight line and where only a determination of the location of initial contact is desired.

A more general method is described later on in this paper which includes the determination of the progress of engagement and of the magnitude of impact, in addition to the location of impact.

Four fields will be seen in Fig. 6, marked in counterclockwise order; S-contact, T-contact, U-contact, and V-contact. Three smaller rectangles flanked by these four fields refer to three types of line contacts as indicated on the diagram. The two remaining types of contact, S-T line-contact and U-V line-contact are determined by the border lines between the S-field and T-field, and the U-field and V-field, respectively.

The type of contact can easily be determined by tracing along horizontal and vertical straight lines. This is indicated by a dot and dash line marked "example."

The example refers to a case where, at a distance of 2 in., a cutter with a diameter of 12 in. is located on the workside, which is the usual condition with face mills, end mills, etc. The radial rake and the axial rake are assumed 10 deg negative. Following

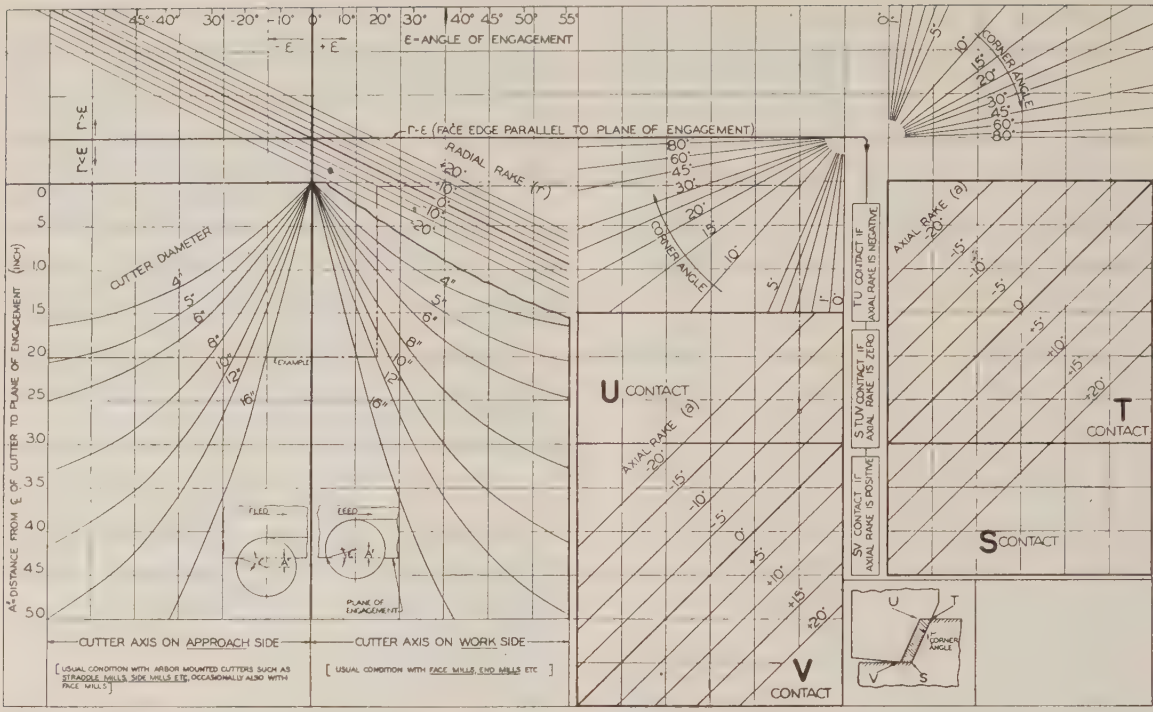

Fig. 6 Cutter-Engagement Diagram

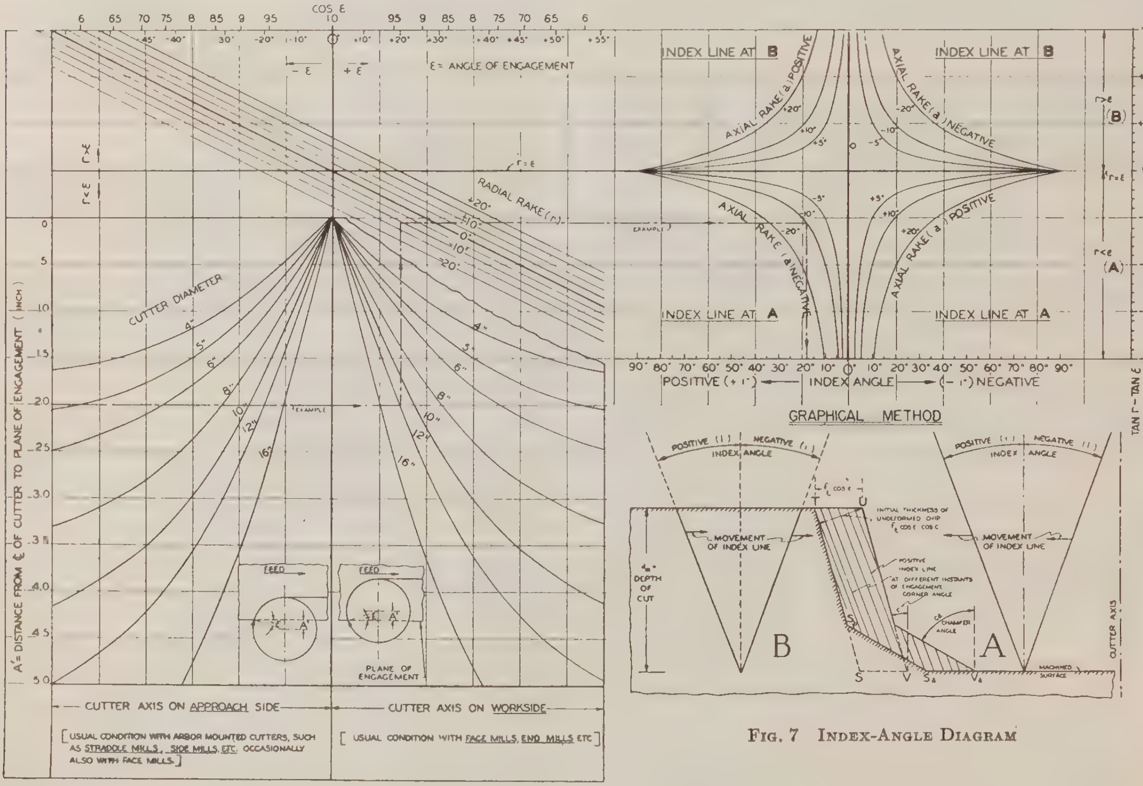

Fig. 7 Index-Angle Diagram

the dot-and-dash line leads to the U-field. Hence U-contact will ensue from this combination of rake angles, corner angle, cutter distance A', and cutter diameter.

The angle of engagement can be read at the top of the cutter-engagement diagram ($\epsilon = 20$ deg); it is however, not necessary to read this angle when using the diagram.

Graphical Solution of Contact Problems for any Shape of Cutting Edge

Complex formulas for the contact conditions result if the cutting edge is chamfered or rounded. However, a graphical method which gives, also, a mental picture of the engagement of cutter and work has been developed for solving such cases on the drawing board. The graphical method covers a broad field in that it includes the progress of engagement and disengagement, and also the magnitude of impact in addition to solving problems of initial contact for any shape of the cutting edge. Exit conditions existing when the cutter leaves the work can likewise be solved with the graphical method.

It has already been stated, in connection with Fig. 3, that the spot on the tool which contacts the work first is indicated by the point where the intersection line first contacts the white parallelogram.

Thus in order to determine graphically the location of initial contact, it is only necessary to draw the chip cross-sectional area (white parallelogram) to scale and to move a line at angle i' toward it. Where this line touches the chip cross-sectional area first, initial contact occurs.

It is, however, more convenient to move a line at angle i (index line) instead of the intersection line at angle i', because the corner angle c can then be used when drawing the chip cross-sectional area instead of the slope angle c'.

Furthermore, referring to Equation [3], it will be seen that the index angle i is independent of the corner angle c and therefore independent of the contour of the cutting edge.

Hence initial contact can be determined graphically by moving a straight line at index angle i toward a chip cross-sectional area of any shape, not only a parallelogram.

The index angle i, which is the compound angle of axial rake, radial rake, and angle of engagement, can either be calculated from Equation [3] or be determined without use of mathematics by means of the "index-angle diagram," Fig. 7. The left-hand portion of this diagram is identical with the left-hand portion of the "cutter-engagement diagram," Fig. 6, while the right-hand part of Fig. 7 is different, having curves for the axial rake, instead of the contact fields. The example in Fig. 7 corresponds to that on the cutter-engagement diagram. Tracing along the dash-dotted example line, however, leads, in Fig. 7, to an index angle of +18 deg and to the instruction that the index line must be placed at A, meaning that it moves away from the cutter axis (because $r < \epsilon$). Compare arrow "A" in Fig. 4.

The graphical solution (see Fig. 8) includes the following:

1 Construct a figure proportional to the initial chip cross section, indicated by the cross-hatched area, where d_m is proportional to the depth of cut, distances TU, SV, S_aV_a proportional to the feed per tooth $\cdot \cos \epsilon$ and where c = corner angle, c_a = chamfer angle.

2 Draw index line at index angle i at A (or B) of cross-hatched area, as determined from diagram. [A is indicated if $r < \epsilon$, and B if $r > \epsilon$.]

3 Move index line toward cross-hatched area. (If $r = \epsilon$ the index line is moved vertically; upward when the axial rake is positive, or downward when the axial rake is negative. No index line exists for face contact, i.e., when $r = \epsilon$ and the axial rake is zero.)

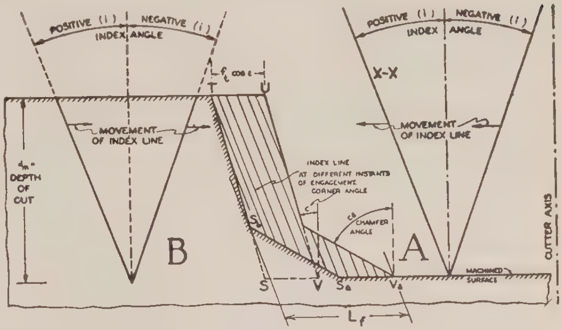

Fig. 8 Graphical Method for Determining Initial Contact of Cutter and Work, and Also the Progress of Their Engagement for Any Shape of the Cutting Edge

4 *Initial contact of cutter and work is indicated by the point or line where the moving index line touches the contour of the cross-hatched area first.*

In the given example when moving an index line x-x at +18 deg the initial contact occurs at point V_a.

5 Progress of engagement: The graphical method, however, permits not only determination of initial contact, but also the progress of engagement. Continuing the movement of the index line, x-x it, will be seen that

2nd point to engage is S_a
3rd point to engage is U
4th point to engage is T
5th point to engage is S_b

A closer inspection, by slowly moving the index line across the cross-hatched area, reveals even more details about the progress of engagement, for example, the fact that the engagement of point U follows very closely the engagement of point S_a. It will also be seen that a chip develops at first by deforming a triangle with the base V_aS_a, while later on a second chip develops from point U. Both chips unite at the instant when the vertex of the obtuse angle (i.e., the point opposite S_b) engages.

If the cutting edge is straight, the chip cross-sectional area is represented by parallelogram S-T-U-V in Fig. 8. Initial contact occurs in the case of $i = +18$ deg at point U instead of at V_a as was the case in the foregoing example for a chamfered cutting edge.

In the case of this example, chamfering of the cutting edge changes the initial contact from U to V_a. Chamfering, however, does not always have this effect. If the conditions for radial rake, axial rake, and angle of engagement are such as to give a negative angle i, initial contact of a tool having a straight cutting edge would occur at V, not at U, and the change due to chamfering would then be only a shifting of the initial contact from V to V_a.

Exit conditions when the cutter leaves the work can likewise be determined by the graphical method. Only one modification is necessary. Instead of using the distance of the cutter axis from the plane of engagement, the distance of the cutter axis from the exit plane must be used, when determining the index angle i in diagram Fig. 7. The terms "cutter axis on approach side" and "cutter axis on workside" are then to be used with reference to the exit plane.

2 Magnitude of Impact

The second problem, namely, the question, "How great is the impact?" is important because it may well be that the magnitude

of impact is a vital factor in cutter life. The magnitude of impact can be determined by further expanding the graphical method, used previously for determining the location and progress of engagement.

From the graphical method, Fig. 8, it will be realized that a chip does not exist at the instant of contact; that is, at the instant when the index line touches the contour of the cross-hatched area. However, as the index line travels across the cross-hatched area, the chip develops gradually, reaching its full size when the index line has moved all the way across the cross-hatched area. At that instant, all points of the tool face that take part in the metal removal have engaged the work.

For instance, in the example where $i = +18$ deg, no chip exists when the index line touches point V_a, but the full chip has been generated when the index line has arrived at point S_b of the cross-hatched area.

Conclusion: During the period of time in which the index line travels across the chip cross-sectional area, the chip has developed from zero to full size. This time interval is called "penetration time."

The shorter the penetration time, i.e., the faster the chip develops, the larger the impact.

The rate of increase of chip cross-sectional area can therefore be used as an "impact factor."

$$\text{Impact factor} = \frac{\text{Chip cross-sectional area}}{\text{Penetration time}} \quad \ldots\ldots\ldots [7]$$

In order to find the impact factor, it is necessary to determine only the penetration time and to divide it into the chip cross-sectional area. The impact factor has the dimension of square inch per sec.

Since "time" is the ratio of "distance traveled" to "velocity," it is possible to determine the penetration time T_p by dividing the distance L_f, which the index line has traveled across the cross-hatched area, by the velocity of this travel v_f.

As shown in Fig. 8, distance L_f can be measured directly from the graph between the contact position and end position of the index line when the graph is drawn to scale.

It remains to find the velocity of travel of the index line.

The velocity of travel v_f can be determined from the model shown in Fig. 9. In the horizontal triangle N-P-M, dimension P-N lies in the direction of cutter rotation and can therefore be taken as the "cutting speed vector." Dimension M-N lies in the direction of travel of the intersection line L-M, and represents therefore the "velocity vector" of the intersection line.

From the geometry of the horizontal triangle N-P-M

$$v'_f = \frac{\tan i'}{-\tan a} v_c \quad \ldots\ldots\ldots [8]$$

The same conversion as before is necessary in order to find the velocity of the index line instead of the intersection line. The result is

$$v_f = \frac{-v_c}{\tan r - \tan \epsilon} \quad \ldots\ldots\ldots [9]$$

It will be seen that the travel velocity v_f of the index line is a function of the cutting speed v_c, the radial rake, and the angle of engagement.

The minus sign in Equations [8] and [9] indicates the direction of travel, i.e., v_f is counted positive when the index line moves away from the cutter axis.

The penetration time in seconds is therefore

$$\boxed{T_p = \frac{5L_f}{v_f} = \pm \frac{5\,L_f\,(\tan r - \tan \epsilon)}{v_c}} \text{ sec} \quad \ldots\ldots [10]$$

where the factor 5 is due to conversion from feet per minute to inches per second.

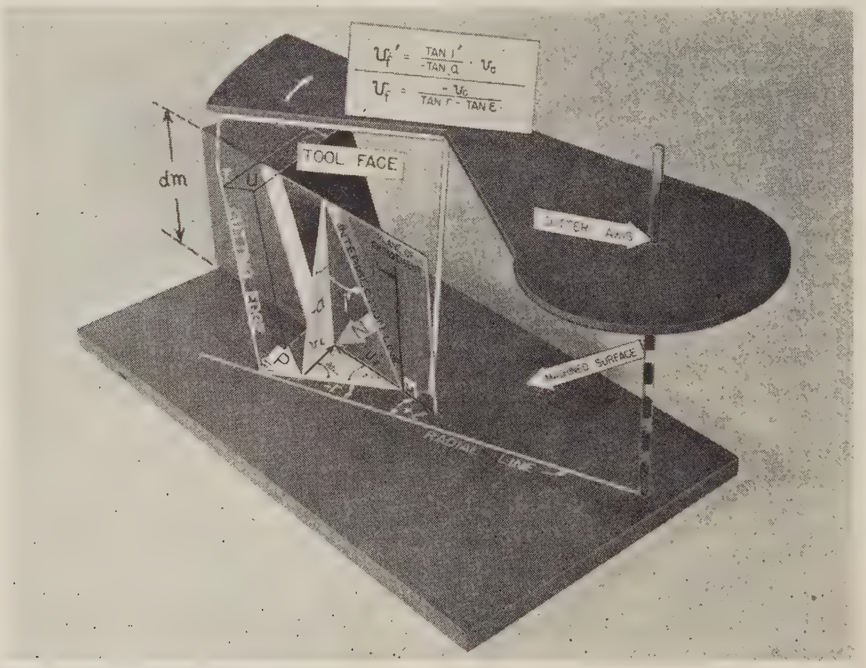

Fig. 9 Model of Cutter and Work Illustrating Relationship Between Cutting Speed and Travel Velocity of Intersection Line

When dimension L_f is very large, it is more convenient to use dimension L_d, Fig. 10, and the velocity (v_d) of the apparent travel in this direction.

Since this velocity, v_d is perpendicular to velocity v_f, their relationship is expressed by

$$v_d = \frac{v_f}{\tan i} = \frac{v_f\,(\tan r - \tan \epsilon)}{\tan a} \quad \ldots\ldots\ldots\ldots [11]$$

Upon substitution of Equation [9], the following formula results for the penetration time

$$\boxed{T_p = \pm\frac{5L_d \cdot \tan a}{v_c}} \quad \ldots [12]$$

When comparing the magnitude of impact for various tool-angle combinations, it is often *not* necessary to determine penetration time and impact factor from Equations [10], [12], and [7], but it is sufficient to compare only the dimensions L_f (or L_d), obtained graphically as the travel distance of the index line across the chip cross-sectional area from contact position to end position.

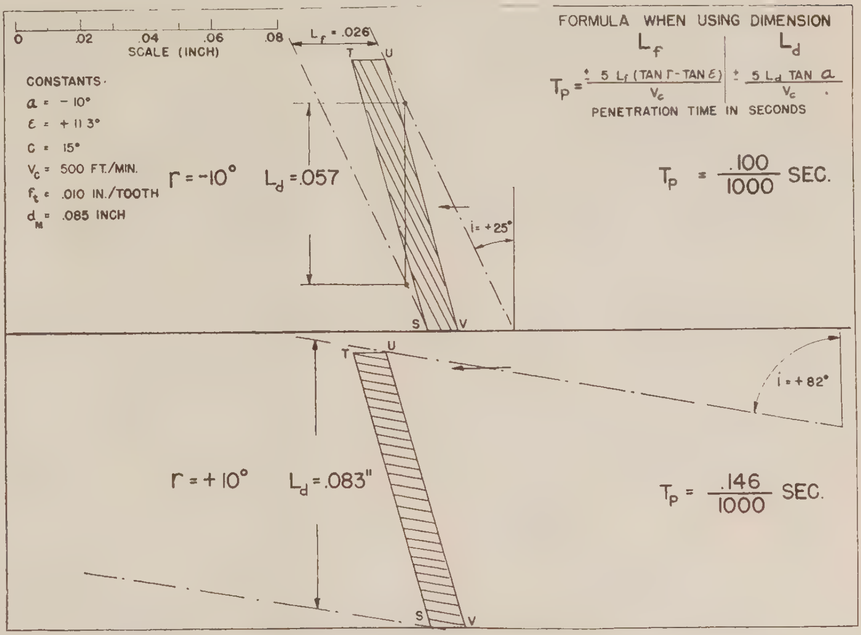

Fig. 10 Determination of Penetration Time and Magnitude of Impact

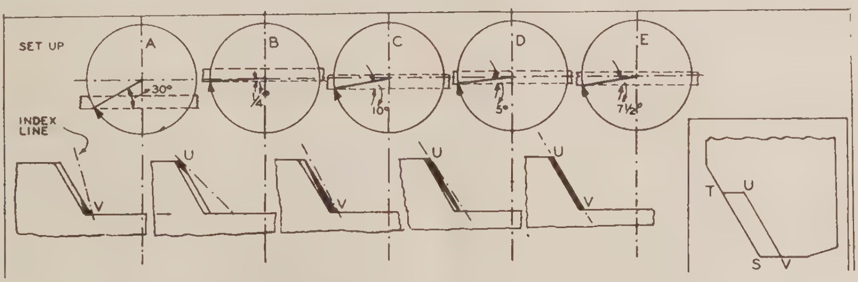

Fig. 11 Setup of Cutter and Work Used in Tool-Wear Tests

Setup	Distance of cutter axis from plane of engagement, in.	Angle of engagement, deg	Location of impact	Magnitude of impact (impact factor) sq in. per sec
A	2.000	30	V	3.4
B	0.020	1/4	U	12.3
C	0.700	10	V	19.5
D	0.360	5	U	24.5
E	0.520	7 1/2	UV	44.5

Constants:

Axial and radial rake, deg	10 negative
Corner angle, deg	30
Feed per tooth, in	0.009
Depth of cut, in	1/8
Cutting speed, fpm	490

The following rules apply:

(*a*) The longer distance L_f, the less the impact, provided that the axial rake is the only variable involved in a comparison of impact.

(*b*) The longer distance L_d, the less the impact, provided that the radial rake or the angle of engagement is the variable involved in the comparison.

(*c*) The longer either distance L_f or L_d, the less the impact, provided that the corner angle c is the only variable involved in the comparison of impact.

The two examples shown in Fig. 10 indicate that the impact will be smaller in the lower case, because L_d is here longer than in the upper case. The L_d comparison is used because the radial rake is the variable in the examples. The ratio of impact is inversely proportional to the distance L_d, i.e., the impact is 46 per cent greater in the upper case than in the lower one.

3 HOW IS TOOL WEAR AFFECTED BY IMPACT?

Tool-life tests have been carried out in order to determine the relationship between impact and tool wear.

A single-tooth cutter was employed for each run, changing the tooth after 13,300 impacts. Tests were also made with 20,000 impacts, and 26,600 impacts.

The location and magnitude of impact were varied by changing the distance of the cutter axis from the plane of engagement, that is, by changing the angle of engagement (ϵ). It was necessary only to adjust the knee of a horizontal milling machine up or down for each setup. Five different setups were tested as indicated in Fig. 11.

It will be noticed that the variation in the angle of engagement (ϵ) was small; this was done in order to keep the initial chip thickness and the exit conditions of the cutter as constant as possible.

The width of the workpiece was only $^3/_4$ in. in order to reduce tool wear due to cutting, in comparison with the wear due to impact.

The average depth of the crater on the tool face, measured

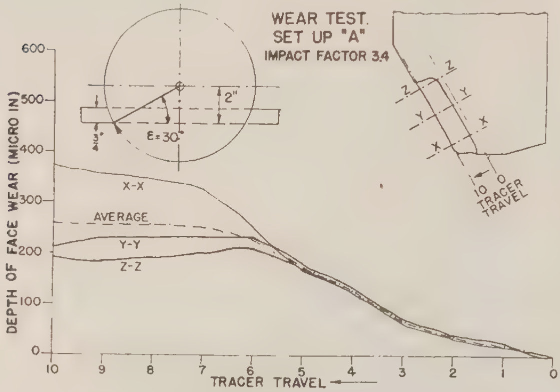

Fig. 12 Wear Test, Setup A; Smallest Impact Factor

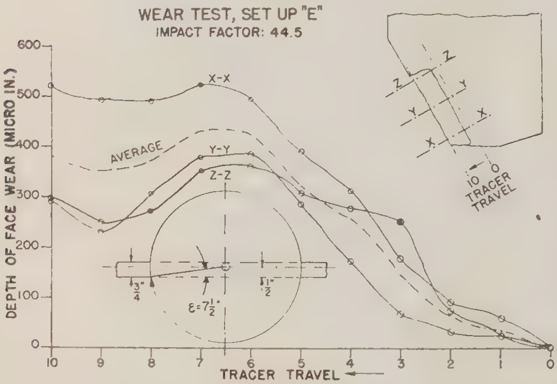

Fig. 13 Wear Test, Setup E; Largest Impact Factor

after the same number of impacts, was taken as the basis for comparison of tool wear. The results are indicated in Figs. 12 to 16, inclusive.

Fig. 12 shows the results of the wear test for setup A where the distance from cutter axis to plane of engagement was 2 in., corresponding to an angle of engagement of 30 deg.

The wear was measured at ten points in each of the three planes

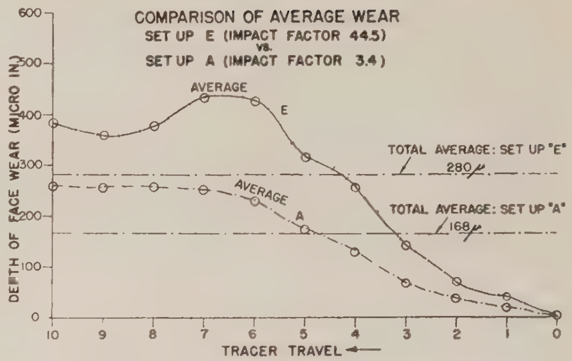

Fig. 14 Comparison of Average Wear; Setup E Versus Setup A

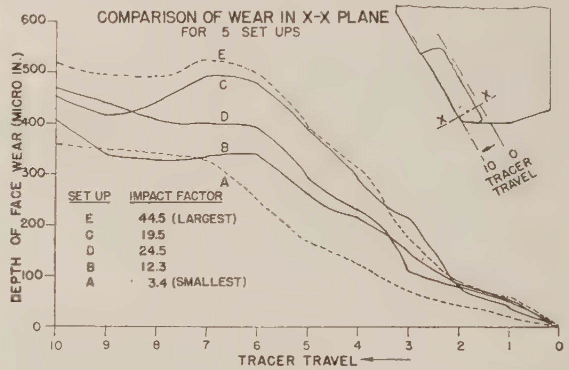

Fig. 15 Comparison of Wear in X-X Plane for Five Setups

marked X-X, Y-Y, and Z-Z, perpendicular to the cutting edge. The wear at each point was measured repeatedly.

It will be seen that the wear in the X-X plane was the greatest, with a maximum at tracer travel point 10 (that is, on the cutting edge). Tracer point 0 indicates the surface on the tool face not touched by the chip.

The dash-dotted line indicates the average of the wear in the three planes X-X, Y-Y, and Z-Z.

Setup A is the case where the impact factor is the smallest of the five setups tested.

Fig. 13 refers to the wear in the case of the largest impact factor (setup E), again measured in three planes perpendicular to the cutting edge. The distance of the cutter axis from the plane of engagement was $^1/_2$ in., the angle ϵ was $7^1/_2$ deg.

The averaged value of the three curves is again indicated by a curve marked "average."

Setup E and setup A are compared in Fig. 14, where the average curves of these two setups only are plotted. It will be seen that the wear in the case of the larger impact (setup E) was always greater than the wear of the smallest impact (setup A). Totaling the wear indicated by each one of the average curves results in a figure called "total average." This figure represents the over-all wear for each setup and is the result of about 200 values.

In the case of setup A, the total average was 168 microinches but as much as 280 microinches in the case of setup E. This appreciable difference of nearly 70 per cent is caused by the slight difference in the relative position of cutter axis to workpiece, and its resultant change in location and magnitude of impact.

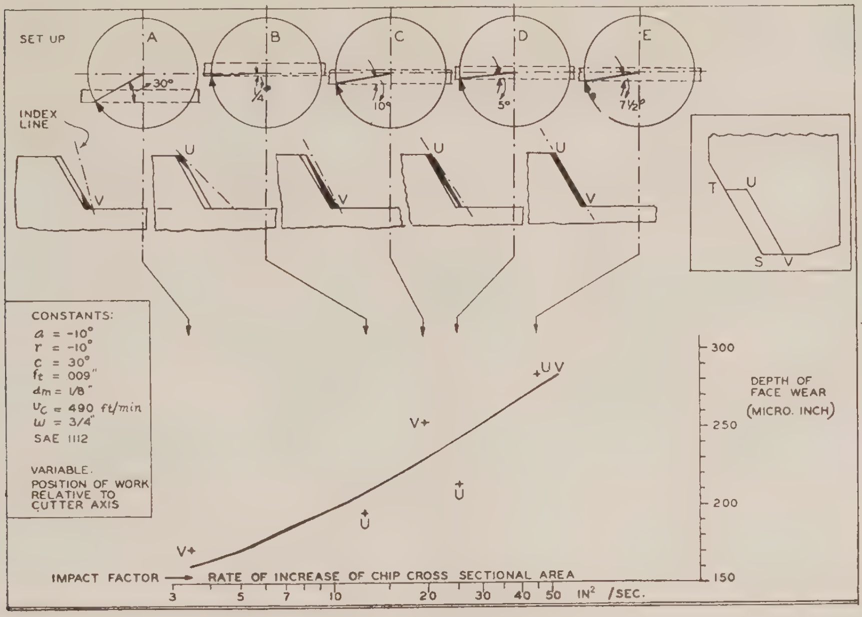

Fig. 16 Summary of Wear Tests

Diagram, Fig. 15, has been prepared in order to compare the wear for all five setups. Wear values in the X-X plane have been selected as an example, but the same trend holds also for the other planes.

It will be seen that the wear curves follow each other in approximately the same order as the impact factors.

Reading from the bottom up, the smallest wear (curve A) occurred in the case of the smallest impact; the second curve (curve B), referring to a larger impact factor, indicates also greater wear, and the greatest wear is found in the case of the largest impact factor.

Only curves C and D are reversed, because D has a smaller wear but a higher impact factor than curve C.

An explanation for this reversal is offered in Fig. 16 which is a summary of the wear tests. The impact factor is plotted logarithmically on the x-axis; the depth of the face wear on the y-axis, which is arithmetical.

Each of the five points is the result of approximately 200 values and represents the total average of the wear for the respective setup, indicated diagrammatically at the top. A definite trend is indicated by the curve, namely, the finding that tool-face wear increases with increasing impact factor, that is, with the rate of increase of chip cross-sectional area. It will furthermore be noticed that the points indicating the wear in case of U-contact are below the trend curve, while those for V-contact are above the curve.

It may well be the case that, within limits, a large impact applied at point U causes less wear than a small impact at point V. This may explain the reversal of the C and D curves in Fig. 15 where the D curve represents the case of a large impact applied at a favorable point of the tool (U-contact), while the C curve refers to a small impact applied at the less favorable point V. This would also indicate that equal impacts will cause less wear when applied at U than at V.

In so far as our tests indicate up to now, it is concluded that a small impact at point U is the most desirable condition, but a large impact at this same point (U) is worse than a small impact at V.

It appears that both the location and the magnitude of impact should be taken into consideration for determining favorable tool-life conditions. Their combined effect is a major factor in tool wear.

There are naturally other factors affecting tool wear; if these other factors cannot be kept constant when varying the location and magnitude of impact, they may change the trend indicated by the curve. The curve may run more horizontally or rise more rapidly. This will be the subject of further research.

Conclusions

With the aid of the graphical method, the following conclusions can readily be drawn from exploring contact conditions of various combinations of axial rake, radial rake, cutter diameter, distance of cutter from work, and for various shapes of the cutting edge:

1 For face mills and end mills, usually located on the work-side of the plane of engagement:

(*a*) The most frequent type is V-contact, that is, at a point on the face edge, remote from the sharp point of the tool by a distance approximately equal to the feed per tooth.

(*b*) U-contact can occur only when the axial rake is negative; the radial rake, however, may be either positive or negative, but must be smaller than the angle of engagement. This latter condition ($r < \epsilon$) is usually satisfied with face mills and end mills, except when the cutter axis is nearer to the plane of engagement than about 20 per cent of the cutter diameter.

(*c*) The larger the corner angle, the less likely is U-contact.

(*d*) Chamfering of a cutting edge renders it more difficult to obtain U-contact.

(*e*) Changing the corner angle c does not always affect initial contact. There is no effect if the axial rake is positive. There may be, however, an effect if the axial rake is negative. (If c is small, initial contact will be at U, if c is large, initial contact will be at V.)

2 For arbor-mounted cutters, such as straddle mills, side mills (and occasionally also for face mills, when only a portion of the width of the workpiece is machined):

(*a*) The most frequent type is *T*-contact, that is, contact at the top point of the cutting edge.

(*b*) The undesirable type of *S*-contact, at the weakest spot of the tool, can be eliminated by grinding a negative axial rake to the tooth.

(*c*) A negative radial rake alone does not necessarily eliminate the undesirable type of *S*-contact.

(*d*) Chamfering of a straight cutting edge having *T*-contact will not change this type of contact and is therefore ineffective as far as contact conditions are concerned.

(*e*) Chamfering of a straight cutting edge, however, having *S*-contact, will eliminate such contact by shifting the location of the contact point either to S_a (along the face edge) or to S_b (out of the plane of the machined surface), depending on the size of the chamfer angle.

(*f*) Changing the corner angle affects contact conditions of arbor-mounted cutters differently from those of face mills and end mills. In the case of arbor-mounted cutters, a change in the corner angle does not affect initial contact, when the axial rake is negative. However, if the axial rake is positive, it may be either *T*-contact or *S*-contact, depending on the relationship of index angle and corner angle.

3 *For all types of milling cutters: Tool angles on milling cutters such as face mills, end mills, straddle mills, side mills alone do not determine any type of initial contact. It is always necessary to consider also the angle of engagement.*

An existing cutter with given rake and corner angles may have different types of initial contact, depending on the position of the workpiece relative to the cutter axis, and on the cutter diameter. Tool life may therefore vary with the setup of cutter and work.

4 Exit conditions:

(*a*) The point of initial contact is not necessarily identical with the point that leaves the work first.

(*b*) The wider the workpiece, the less likely is the identity of the point of initial contact with the point that leaves the work first.

(*c*) Most frequently, the top point *T* of the cutting edge emerges first (*T*-exit).

(*d*) When the top point of the cutting edge contacts the work first (*T*-contact) it also leaves first (*T*-exit).

(*e*) In the case of a positive axial rake: *V*-contact may be followed by either *S*-exit or *T*-exit; *S*-contact may be followed by *T*-exit, depending on the width of the work and the combination of the other tool angles.

(*f*) In the case of a negative axial rake: *V*-contact may be followed by either *U*-exit or *T*-exit; *U*-contact may be followed by *T*-exit, depending on the width of the work and the combination of the other tool angles.

5 Tool wear:

(*a*) The combined effect of location and magnitude of impact is a major factor in the wear of sintered-carbide tools.

(*b*) A small impact at *U* seems to be the most desirable condition, but a large impact at this point is worse than a small impact at *V*.

(*c*) The most desirable condition can be obtained by careful co-ordination of axial rake, radial rake, corner angle, chamfer angle, and angle of engagement.

Acknowledgment

The author wishes to express his appreciation to Mr. Hans Ernst, research director, and to Dr. M. E. Merchant, physicist, for their helpful advice. The able assistance of Mr. Norman Zlatin, research engineer, and Mr. Robert Adams, who conducted the tool-wear tests, is also acknowledged. Mr. Emil Suhr, laboratory assistant, and Miss Jane Alexander assisted in the preparation of the models.

(Owing to travel emergency conditions existing when this paper was presented, discussion will be accepted until May 10, 1946)

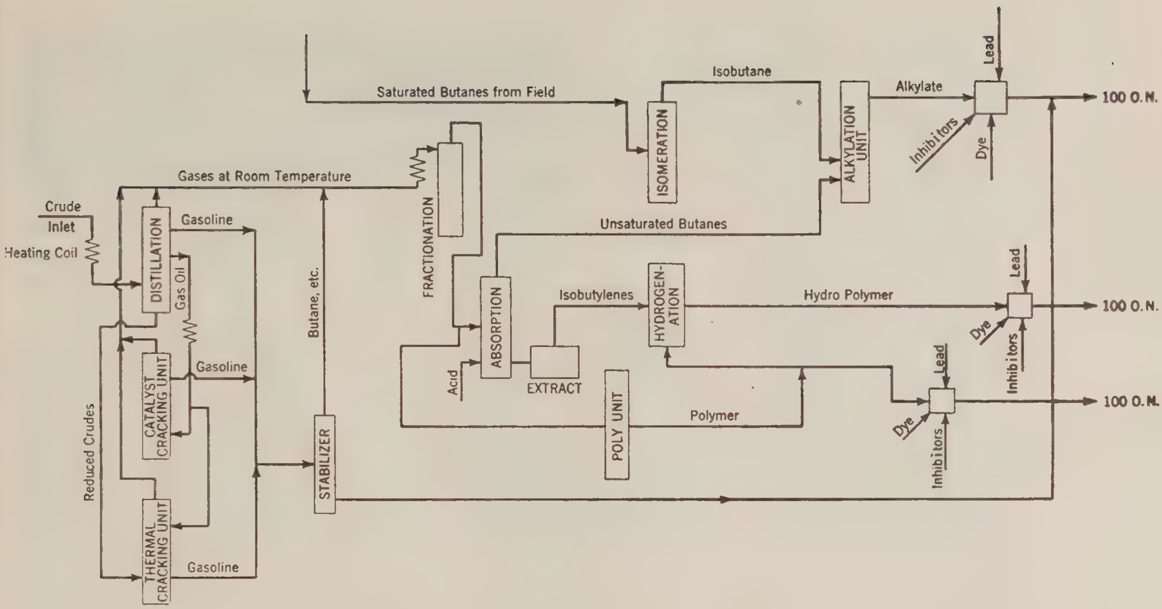

Fig. 1 100-Octane Gasoline Manufacture

Resistance of Nickel-Containing Alloys to Corrosives Encountered in the Petroleum Refineries

By B. B. MORTON,[1] NEW YORK, N. Y.

Production of bulk gasoline in a modern petroleum refinery is accompanied by corrosion during topping and cracking from sulphur and from weak hydrochloric acid which is formed from salts in the crude. Organic acids such as naphthenics are also often present and are quite corrosive. Solutions of refinery corrosion problems are considered in this paper.

The modern petroleum refinery under the stress of producing war essentials, such as high-octane gasoline, rubber, etc., has become a most complex organization.

Fig. 1, which is a rather simplified flow sheet of the processes employed in making 100-octane gasoline, hints at the complexities involved. A view of the towers, tanks, lines, and equipment involved would be more impressive but possibly less instructive.

As a homely comparison a refinery may be likened to a kitchen in which many cooks are turning out a large volume of good soup (standard gasoline). Other cooks, specialists, are busy making a sauce to be added in small parts to the soup to make it superlatively good. This sauce is the additives, made by polymerization, alkylation, hydrogenation, etc. These additives bring up the octane number of the bulk gasoline produced. The final step is the addition of lead compound, the supersauce.

The production of the bulk gasoline is accompanied by corrosion, during topping and cracking, from sulphur and from weak hydrochloric acid which is formed from salts in the crude. Organic acids, as naphthenics, also are often present and are quite corrosive. These acids are apparently becoming more of a corrosive factor during distillation as a result of the crudes used at the present time.

The corrosion problems associated with the formation of the additives are much more pronounced and are more varied than those associated with topping and cracking. This can be understood by considering some of the reagents involved in the manufacture of the additives:

Acids: Hydrochloric, sulphuric, hydrofluoric, phosphoric, etc.
Bases: Sodium hydroxide, potassium hydroxide, ammonia, etc.
Salts: Aluminum chloride, boron chloride, etc.

Corrosion in Refineries

The author has found it convenient to consider refinery corrosion as possessing two different identities, the dividing line being

[1] Development Engineer, Development and Research Division, The International Nickel Company, Inc. Mem. A.S.M.E.

Contributed by the Petroleum Committee of the Process Industries Division and presented at the Annual Meeting, New York, N. Y., Nov. 26–29, 1945, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

the temperature level at which water is no longer present; an arbitrary figure of 500 F has been taken. Above this temperature "dry" corrosion is considered to take place due to the action of sulphur and also some organic acids; below this temperature "wet" or electrolytic corrosion is assumed to take place.

The nature of electrolytic corrosion has been described in detail in the literature. It is pointed out that a metal tends to go into solution at an anode while hydrogen or another metal plates out at the cathode. It is generally recognized that the areas of the electrodes, the presence of depolarizing agents, and also the relation of the electrodes in a galvanic series, all affect the rates of corrosion. The gradual changes in composition of the film at the face of the electrodes can greatly affect the rate, direction, and nature of the corrosion.

It has been widely pointed out, though not well heeded, that the current passing is the important factor in corrosion by electrolysis rather than the potential between electrodes.

The electrolytic conception of corrosion has provided a working insight into much corrosion. It has also furnished an ingenious but often erroneous explanation of some corrosion. It has awakened a dread of the presence of dissimilar metals, sometimes unwarranted.

A galvanic series of some metals in salt water is provided in Table 1 (1).[2] This series will prove of interest in combating refinery corrosion[3] in condensers, run-down lines, separators, etc. It has been found that galvanic corrosion is greatly suppressed in the absence of oxygen, and this should be considered in evaluating galvanic corrosion in refineries. As light on this subject, Fig. 2 is provided. It will be noted that the nickel plate on the steel sucker rod has failed to produce as serious undercutting as might be expected from the coupling of these two metals. The rod was exposed to the corrosive brine of an Arkansas well. The metal removed is the result of contact with the tubing. The absence of oxygen is assumed to account for the absence of marked galvanic corrosion.

That highly vigorous attack can be produced under conditions favorable to galvanic attack is shown in Table 2. The data of this table were derived by coupling metals with a carbon-containing material which is used to line vessels against acid attack or to form packing or equipment in vessels. The necessity of insulating to prevent forming a couple of metal with this carbon-containing material can be readily seen. The difficulties of insulating effectively will be great in many cases.

[b] Normally fairly resistant to these conditions.

It must not be assumed that galvanic corrosion is an unmitigated evil. This form of corrosion can be usefully employed and is widely used though often without recognition of the fact. Galvanizing is a nice example of the use of galvanic effects. The iron is protected by the sacrifice of zinc. In general, to use galvanic protection a metal "less noble" than the one to be protected must be coupled with the metal whose life it is desired to prolong. No parsimoniousness can be tolerated in the use of the less noble metal. It must be considered definitely expendable and must be present in suitable mass and area to invite and to sustain attack over the desired period.

The destruction of the less noble metal need not be complete. Some Monel ($^2/_3$ nickel, $^1/_3$ copper) bolts from a condenser, Fig. 3, provide a good example of protection without destruction of the less noble metal. The cast iron in contact with the bolts built up a graphitic layer which protected itself while offering protection to the Monel. The vast area of the cast-iron pipes also tended to offset the attack directed to the pipe by the bolts. The use of greater area of the less noble metal is a common means of

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

utilizing galvanic corrosion to protect a part, as a weld or a rivet head, without unduly injuring the less noble material.

General Solution to Refinery Corrosion

A general solution to the two distinct types of corrosion occurring in a petroleum refinery appears as follows:

(a) *Elevated Temperature (Above 500 F)*. Chromium is the metallic element most useful to resist the action of sulphur. The necessary concentration of chromium in the metal appears to depend upon the temperatures used and the concentration of the sulphur compounds; also the nature of these compounds. Metals showing resistance to sulphur which are in wide use are listed in descending order as follows: 18 per cent chromium, 8 per cent nickel; 11 to 14 per cent chrome steels; 4 to 6 per cent chrome steels.

The variety of mechanical properties of these alloys as well as their corrosion resistance dictate the particular choice.

Where naphthenic acids are a source of corrosion at temperatures above 500 F, the following alloys are employed:

Inconel[4] (approximately 80 per cent Ni, 13 per cent Cr)
Type 316 (approximately 18 per cent Cr, 14 per cent Ni, 2–3 per cent Moly)

In some investigations reported, (2) it has been pointed out that 18-8 is more vigorously attacked by naphthenic acid under conditions of elevated temperature than is carbon steel. Both metals were vigorously attacked. Alloy 18-14-3, however, appears quite resistant. Inconel appears to be highly resistant, possibly since nickel itself is, and the 13 per cent chromium present gives protection against sulphur attack which might take place on nickel above 500 F.

Type 316 stainless steel 18-14-3 is finding increasingly wider uses in refineries as they turn toward the manufacture of chemicals from petroleum products. Its resistance to many organic acids is outstanding. It is considered less subject to "weld decay" than is regular 18-8.

The practical application of material to resist corrosion at elevated temperature consists in using tubing of 4–6 per cent chrome or of 18 per cent chromium, 8 per cent nickel alloy, lining equipment with 18-8 or 11 to 15 per cent chromium stainless. Where strip or other welding is used, 18-8, or better, 25 per cent chrome, 20 per cent nickel rod is used.

In some equipment as in certain bubble towers, a wide temperature gradient exists along the axis, say, from 700 to 370 F. In this case a stainless steel is indicated for the temperature region above 500 F, and Monel for the cooler top region Fig. 4. Some very large towers have 18-8 lining, trays, and caps in the high-temperature region and Monel lining, caps, and trays in the top.

Some exchangers exposed to attack from naphthenic acid at temperatures of 700 to 850 F are tubed and equipped with Inconel (approximately 80 per cent nickel 13 per cent chrome).

(b) *Low-Temperature Corrosion (Below 500 F)*. Corrosion occurring within the temperature region below 500 F is considered to be electrolytic in character. It is assumed that liquid water is present to form an electrolyte. The solution to the corrosion of this type is more difficult than in the case of corrosion at elevated temperature, owing to the complex nature of the attacking agents. No single element is effective against corrosion at low temperature as is chromium at elevated temperature against sulphur.

The most satisfactory means for studying corrosion of any type appears to be to install specimens of metals under operating conditions and to observe results. This is particularly true for electrolytic corrosion. Insulating between samples is necessary for this temperature region where water can exist, and this complicates testing. The test spool, Fig. 5 (3), has been developed and improved over a period of years by the author's company. Thousands of specimens have been exposed in various industries, and an impressive mass of data have been accumulated.

From a study of the data it appears that no general rule can be applied to the selection of a material for use in a refinery in order to combat electrolytic corrosion. The selection is best done by studying the exposed samples. Such a study is helpful in picking the most economical material, as the samples will indicate the relative life and the tendency toward pitting. Often the short life of refinery equipment, due to becoming obsolete, dic-

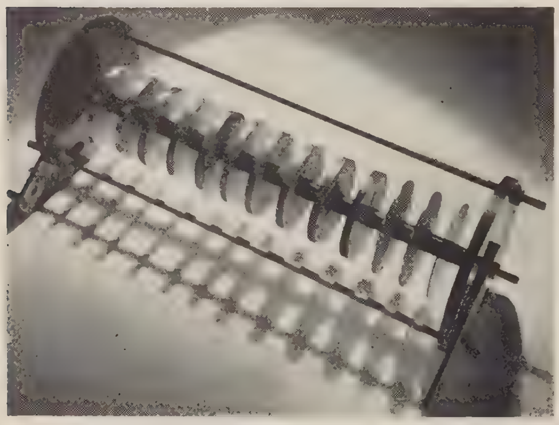

Fig. 5 Spool-Type Specimen Holder Used in Testing Corrosion of Metals

tates a less expensive material than would be selected if indefinite life is desired.

The use of nonferrous alloys to combat electrolytic corrosion is widespread, as will be evident in the consideration of material used in parts of refinery equipment exposed to corrosives.

Condensing Equipment

Condensing equipment suffers much from electrolytic corrosion. As the tendency is increased to improve the efficiency of this equipment the need for better and more corrosion-resistant materials is felt, that is, as the submerged coil of cast-iron pipe is abandoned for shell-and-tube or submerged-tube segments, the need for better material is noted.

Condenser shells are formed either of Monel-clad steel or are protected locally by liners of this alloy, Fig. 6. Where Admiralty tubing is suffering dezincification, the trend before the war was to use 70-30 copper-nickel tubes. Other nickel-containing tubing to thwart dezincification is hinted at as postwar materials.

The 70-30 copper-nickel tube offers greater resistance to impingement attack than does Admiralty tubing.

Isomerization Equipment

The introduction of HCL gas as an atmosphere in an isomerization operation has greatly intensified refinery corrosion problems.

Hastelloy B, an alloy of approximately 60 per cent nickel, 32 per cent molybdenum, is apparently one of the most resistant of commercial alloys to the corrosive conditions evoked by the use of the HCL atmosphere in the isomerization operation. Some data, Table 3, obtained by exposure of samples in an operating unit serve to place Hastelloy B in comparison with some other materials. The position of nickel is also indicated. It has been

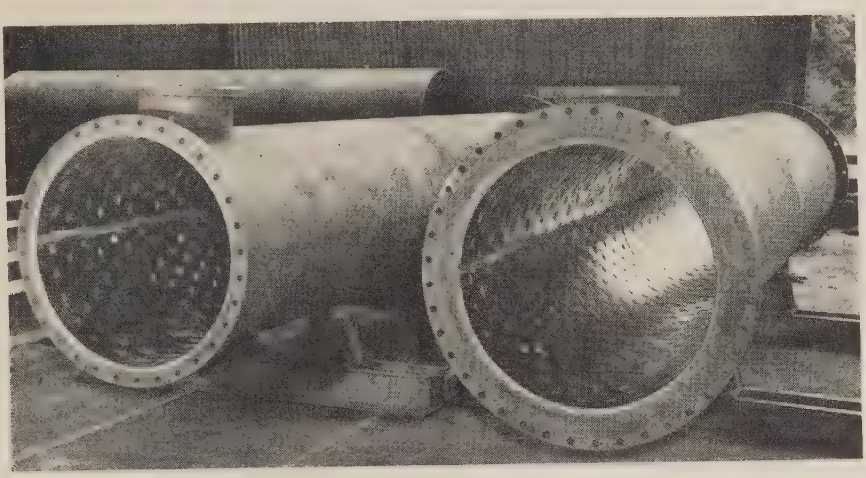

Fig. 6 Monel-Clad Heat-Exchanger Shells

noted in service that nickel is somewhat erratic in its resistance. The cause is not known for the variation noted.

The study of materials for use in isomerization units is proceeding apace. The widespread use of nickel would indicate that certain refinery units understand and can control its rate of corrosion. The success may depend on the efficiency of the dehydrating equipment. High efficiency of these drying units will permit use of the cheaper materials of construction.

Alkylation Units

Alkylation is carried out with the use of hydrofluoric and sulphuric acids as catalysts.

Monel has emerged as possibly the most useful of the commercial materials for parts of units using HF acid for the catalyst. It is now used as liners for vessels; as rings and packing; as valves and fittings, etc. There may be a tendency to use Monel lining with carbon packing. The corrosion engineer so inclined to this use is referred to Table 2 and is warned.

"S"-Monel, a high-silicon alloy (4 per cent Si) (see Table 5) has such excellent resistance to seizing and galling that its use as the plug and other parts of valves was considered for use in HF alkylation units. The vigorousness with which hydrofluoric acid attacks silica caused some concern that the silicon of S-Monel might be attacked. Laboratory results indicate that S-Monel is not attacked with especial vigor by HF, and use is made of this alloy as a plug material.

A welding rod to permit an overlay of S-Monel has been developed by the author's company. Since the rod must of necessity have a silicon content greater than that of S-Monel to compensate losses during the overlaying, the rod was tested in HF acid with results noted in Table 4. The rate of attack on the rod material itself is tolerable, and since the overlay will have the composition of S-Monel, which is apparently adequately resistant, the rod will probably fill a need for a corrosion- and a galling-resistant surface for valve parts.

Sulphuric acid presents many corrosion problems in refineries, especially when it is used as the catalyst in an alkylation unit or as a solvent. This is due to variations in concentrations and temperature. Table 5 lists some materials used in handling sulphuric acid in petroleum refineries.

When the problem involves concentrating acid, Hastelloy D has proved useful and it is used for the elements to introduce heat into the acid.

Pump and valve parts are made from the alloys listed in Table 5, and from similar alloys.

The behavior of sulphuric acid is so influenced by the presence or absence of oxidizing reagents, by the presence of chlorine or other halogens, also by the presence of salts that can form hydrochloric acid, that general recommendations rarely can be made.

[a] Including cobalt.
[b] Only as castings.
NOTE: Specific use can be determined by making tests or by seeking suggestions from suppliers.

The action of the presence of copper from copper-alloy fittings in the destruction of otherwise resistant alloys has been reported (2).

The most resistant metallic materials to a wide variety of concentrations of sulphuric acid and to temperature variations and impurities in the acids to come to the author's attention are the high-silicon cast irons, such as "Duriron" and "Corrosiron." The brittleness of these materials somewhat limits their usefulness but when considered in design they are used for many pieces of equipment.

Caustic Regenerators

Caustic is used both to neutralize acid and as a solvent for organic compounds. As an example of the latter consider mercaptan scrubbing and recovery.

Monel appears to be one of the most useful materials with which to line caustic regenerators, and for caps and trays. The tubes of the reboiler are often of Monel which appears quite satisfactory. The service of the tubes is severe since boiling and high attending velocity often injure protective films. An alloy of 70-30 copper nickel appears unsatisfactory for this service of tubes in reboilers in units recovering mercaptans from caustic. The vigorous attack of sulphur upon the copper-rich alloy and subsequent injury of film may account for the failures of 70-30 so far reported.

Before undertaking to line an existing tower that has been in a caustic regenerating unit with Monel, it is well to consider that sulphur on the steel wall may cause embrittlement of plug or other welds. The sulphur and adhering caustic must be entirely removed. Discussion of the proposed lining with the Technical Service group of the author's company might be advisable since observations to date could be presented.

Ni-Resist cast iron, a nickel or nickel-copper cast iron which is austenitic in structure, i.e., nonmagnetic, is useful for pumps and valve parts of equipment handling caustic.

Nickel-clad steel appears to be the favorite material of construction in units employing caustic and an organic compound to act as a solvent for mercaptans.

Solvents

Many solvents find application in petroleum refineries. In fact the use of selective solvents has revolutionized the art of refining.

Many of the solvents are corrosive toward steel. Others not originally corrosive become so after use and contamination.

For such solvents as phenol, furfural, and chlorinated compounds, Monel or 18-8 stainless will be found quite satisfactory. The 18-8 is the proper material to use at temperatures above 500 F. Monel is considered more satisfactory for use with chlorinated solvents at the temperature at which these solvents are used.

Solvents are often used at subzero temperatures of —50 F, —75 F, and —150 F. At these low temperatures corrosion ceases to be a problem but the impact value of many nonheat-treated steels suffers deterioration. Normalized nickel-containing steels retain a large part of the room-temperature impact value at low temperatures when properly made for this service. Nickel steels of $2^1/_2$ per cent are used at temperatures down to —75 F. Nickel steels of $3^1/_2$ per cent, properly deoxidized and aluminum-treated, should provide suitable material for vessels to operate at —150 F. The carbon of the steel should be low, preferably below 0.10 per cent. For uses at lower temperatures one should consider the austenitic stainless steels or Monel.

In the foregoing, plates and large parts capable only of being normalized are considered. Nearly all alloy steels that can be fully hardened by quenching and drawing will give good impact value at very low temperatures.

Hydrogen Attack

Hydrogenation is an important tool in petroleum refineries. Under conditions of temperature and high partial pressure of hydrogen, attack takes place upon steel and other materials in that there is a tendency toward decarburization and mechanical disintegration.

Sulphur attack also is a factor in much of the hydrogenation of petroleum.

The alloy, 18 per cent chrome, 8 per cent nickel, is highly resistant to hydrogen attack. It suffers some temporary loss in mechanical properties due to mechanical presence of hydrogen in the metal. The hydrogen can be removed by heating, and the properties restored.

For other steels the presence of carbide-forming elements as chromium, tungsten, molybdenum, and others are required to prevent decarburization. In general, the more complex the carbide the more resistant is the metal to decarburization under hydrogenation conditions. Unless 12 per cent or more of chromium is present sulphur attack must be expected.

Creep of Neoprene in Shear Under Static Conditions

By W. N. Keen,[1] Wilmington, Del.

This paper presents some of the mechanical properties, particularly the creep characteristics, of neoprene and natural-rubber vulcanizates. Included along with the creep data are the mechanical properties obtained in both compression and shear on the vulcanizates used in this study.

In an earlier paper Yerzley (1)[2] showed how changing the base composition by the use of different types of softeners and reinforcing fillers influenced the physical properties, particularly the creep characteristics, of neoprene vulcanizates.

This paper shows how the creep in shear of neoprene vulcanizates in the hardness range of 40 to 60 durometer (Shore Type A) is influenced by the following:

1 Degree of vulcanization.
2 Preconditioning in shear at elevated temperatures.
3 Changes in composition.

The long-time static creep-tests discussed herein show that as the degree or state of vulcanization of neoprene compositions is increased, the rate of creep and the set of these vulcanizates are decreased without appreciably altering other important mechanical properties.

Preconditioning at elevated temperatures reduces both the rate and the magnitude of creep to a greater extent for the neoprene vulcanizates than for the natural-rubber vulcanizate tested.

The greatest improvement in creep characteristics has resulted from changes in the composition of the vulcanizates.

Both the composition and the degree of vulcanization must be studied in order to obtain the most desirable combination of properties for a given application. Such a study should be broad enough to cover independent evaluation of the important mechanical properties involved.

Method of Testing Samples

The tests described in this paper were conducted at a controlled temperature of 82 F ± 2 F under a load of 17.75 psi. The sandwich or specimen designed for evaluating vulcanizates in shear on the Yerzley oscillograph (2) was used in this work. Fig. 1 shows the static-creep test stand with specimens under test. The rectangular rubber members of the specimen are each 0.5 × 0.5 × 0.882 in. The schematic sketch, Fig. 2, gives the details of the loading bar showing its knife-edge construction and the connecting linkage between the test specimen and the loading bar. The linkage is readily adjustable so that the bar may be leveled as creep takes place in the specimen. Creep in inches was measured by a dial gage (0.001) equipped with a special jig.

In order to present the data for the several compositions on a comparable basis, they are expressed in terms of relative creep, as defined by Yerzley (1). Relative creep may be expressed mathematically as follows:

$$\text{Relative creep} = \frac{\text{Total deformation} - \text{initial deformation}^*}{\text{Initial deformation}^*}$$

In other words, the relative creep at 5 min is zero in all cases.

S-7D	RN-530	15/287	..	..	..	..	...	...	...	...	...
S-8	SC-614	40/307	59	10	32	75	...	...	795	160	...
S-9	SC-612	65/307	59	10	18	58	...	...	770	160	...
S-10	SC-614	45/307	59	4	9	77	237	710	870	200	1070

The actual creep in inches is included in order to give the design engineer some idea of the magnitude of the dimensional changes resulting from creep.

As the state or degree of vulcanization of neoprene is increased (S-1 versus S-2), the rate of creep and the set of the vulcanizates decrease. The decrease in the rate of creep with increased state of vulcanization is shown graphically in Fig. 3, where per cent relative creep is plotted against time on log-log paper. The change in rate of creep or slope values B are given in Table 1. It will be noted in Fig. 3 that the magnitude of relative creep is also reduced for this composition as the degree of vulcanization is increased. The numerical values for creep at the end of 3 years and 9 months are given in Table 1.

Table 1 also gives the compression and shear set values determined under constant load and constant deflection. The shear set values were determined in accordance with A.S.T.M. D-395-40T with respect to time and temperature. These values indicate the actual shear strain remaining in the specimen after 30 min recovery at room temperature. As would be expected, there is little difference in the physical properties between S-2 and S-3 since the time and temperature relationship is such that the degree of vulcanization for them is about equal. From the manufacturer's point of view the shorter time of vulcanization at a higher temperature would be more desirable.

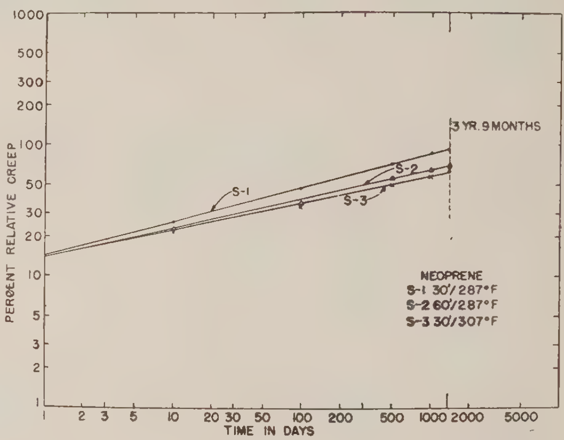

Fig. 3 Influence of Degree of Vulcanization on Static Creep in Shear of Vulcanizates of Same Neoprene Composition

Preconditioning to Reduce Creep

Another way to reduce the amount of creep of some vulcanizates is by preconditioning. Preconditioning of the neoprene (S-3D) and the natural-rubber (S-7D) specimens consisted of straining them 30 per cent in shear and heating in this condition for 24 hr at 158 F. After the heating period, the specimens were removed from the jig and permitted to rest for one week at 82 F before being mounted on the static-creep test stand. Fig. 4 shows how this preconditioning in shear reduces the rate of creep for a limited time for both neoprene and natural-rubber vulcanizates. These curves indicate that neoprene is more receptive to preconditioning as a means of reducing creep than is natural rubber. Deviations from a straight-line function similar to those exhibited by curves S-3D, S-7, and S-7D have been reported by other investigators (3).

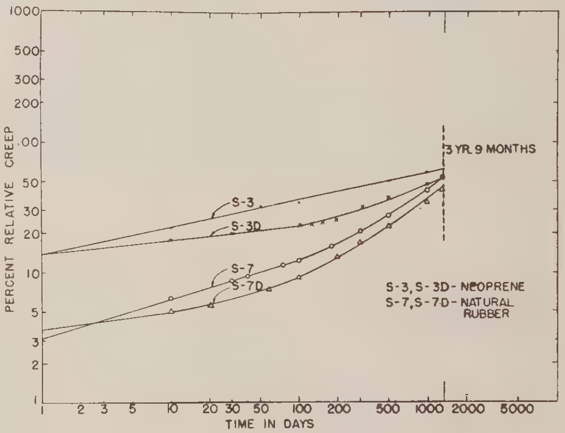

Fig. 4 Influence of Preconditioning, in Shear, on Creep in Shear of Neoprene Vulcanizate, Compared to Natural-Rubber Vulcanizate

Effect of Changing Composition

Fig. 5 presents some idea of how the relative creep may be varied by changing the composition. If this group of curves is considered from the standpoint of slope or rate of change of relative creep, they are all superior to the natural-rubber control except specimens S-4 and S-10. Specimens S-6, S-8, and S-9, would undoubtedly be of greatest interest to the design engineer because of their low rate of creep, as indicated by their slopes of less than 0.20. It will be noted, however, that while all of the curves except S-4 and S-10 have a lower slope than the natural rubber (S-7); all of them except S-10 have a higher per cent relative creep after 1 day. This higher initial creep can readily be taken care of by the engineer in his design of a spring or mounting.

In view of the fact that the relative creep - time curves are linear when plotted on logarithmic co-ordinates, they may be expressed by the equation

$$\text{Relative creep} = At^B$$

where A = Y intercept at 1 day
B = slope of curve
t = time in days

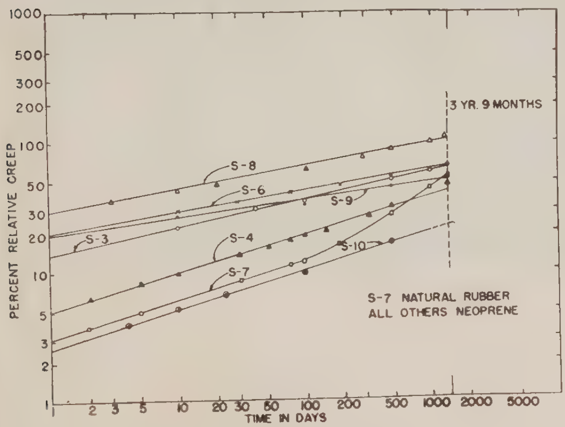

FIG. 5 INFLUENCE OF COMPOSITION ON CREEP IN SHEAR OF NEOPRENE VULCANIZATES

Table 1 gives the values for A and B for all of the curves except S-7D which has a variable slope.

As has been shown, the A.S.T.M. set, and the creep characteristics of neoprene are improved as the state of vulcanization is increased. Likewise some of the other mechanical properties in both compression and shear are increased as the state of vulcanization progresses (see Table 1). The compression characteristics were determined on cylinders 0.75 in. diam and 0.5 in. high, molded from the same composition used in making the shear specimens.

In view of the popular belief that high resilience is indicative of low creep, it is interesting to note that neoprene specimens S-6, S-8, and S-9, which have the lowest rate of creep of the compounds investigated, also have the lowest resilience. This is further evidence to confirm Yerzley's (1) statement that there is no simple correlation between creep rate and resilience.

Change in Properties With Age and Temperature

Since engineers are always interested in knowing how age affects the material with which they are working, the following data were obtained. The static creep test in shear after 3 years was terminated on specimens of S-1, S-4, S-7, and S-10, and the set in shear remaining 24 hr after removing the load was recorded. The change in the mechanical properties of these four specimens and in the specimens of the same four vulcanizates which had been stored at 82 F in an unstressed condition for 3 years were obtained by means of the Yerzley oscillograph. Data given in Table 2 show that natural aging for 3 years has caused a slight stiffening of the neoprene vulcanizates which is reflected by the increase in resilience, frequency, and moduli. There is little difference between samples aged in a stressed condition and those aged in an unstressed condition.

Knowledge of how the mechanical characteristics of a vulcanizate are affected by changes in temperature is for most applications essential to the design engineer. Riesing (4) has shown the effect of temperature on some of the physical properties of neoprene vulcanizates. He presented data showing the functional stability of neoprene at different temperatures by installing neoprene motor mountings, muffler support, and spring-shackle bushings in a car and conducting tests at ambient temperatures of —40 F and +140 F.

Both Forman (5) and Liska (6) have reported that some neoprene vulcanizates show delayed stiffening on long exposure to moderately low temperatures (32 F). This stiffening is the result of crystallization of the elastomer. From a practical consideration crystallization is not as serious as it sounds because the vulcanizate returns to its original state when the ambient temperature is increased or when there is mechanical work done on the vulcanizate. Recent technological advancements in the

processing of neoprene have led to a practical way of preventing crystallization (7).

Although static-creep tests give valuable information, an obvious disadvantage is the fact that they are time-consuming, and technical advancement often results in a composition becoming obsolete before the testing is completed. This emphasizes the desirability for a more rapid method of testing the creep characteristics of elastomeric materials. Considerable experimentation was carried out in the du Pont rubber laboratory during the past year for the purpose of developing a satisfactory dynamic-creep test. Apparatus has been built and is in operation.

Acknowledgment

The author takes pleasure in acknowledging the important contributions of N. L. Catton and A. M. Neal of the Rubber Chemicals Division of the du Pont Company to the progress of this work. He is also indebted to M. A. Gass, who made most of the measurements.

Fig. 1 "Plaspreg" Block Serves for Laminating Purposes

Physical Properties of Resin-Impregnated Plaster

By JOHN DELMONTE,[1] LOS ANGELES, CALIF.

While development work on impregnated plaster bodies has been in progress for many years, it was not until 1945 that the process was finally commercialized with low-viscosity furane resins, and extensive applications undertaken in the tooling field, and in general improvements of plaster-of-Paris patterns and forms. The impregnation of plaster of Paris with liquid thermosetting resins and the subsequent conversion of the product with heat, result in the formation of a material which has been called "Plaspreg." In this paper the methods of producing this material, its physical properties, and applications are discussed.

THE impregnation of plaster of Paris with liquid thermosetting resins and the subsequent conversion of the product with heat results in the formation of an entirely new material of construction. The resinified plaster body still retains the crystalline structural network formed on the hydration of $2CaSO_4.H_2O$, although considerably augmented through infusion with synthetic resins. In appearance and feel the impregnated plaster body resembles a cast plastic material more than it does the ordinary plaster-of-Paris bodies, though the improvements which are possible extend much further than the appearance, as all properties are greatly enhanced.

While development work on impregnated plaster bodies has been in progress for many years, it was not until 1945 that the process finally became commercialized with low-viscosity furane resins, and extensive applications undertaken in the tooling field and in general improvements of plaster-of-Paris patterns and forms. While the range of usefulness of resin-impregnated plaster (Plaspreg) forms will be analyzed more completely later in this paper, it will suffice for the moment to point out that among the applications are master models built of plaster of Paris (weighing several hundred pounds) which have been rendered much harder and more permanent through proper impregnation of furane resin; dies for hydropress operation in forming sheet metal; Keller pattern and duplicating dies; core boxes for the foundry; forms for laminating polyester resins; contoured shapes for shaping acrylic plastics; and general improvement in properties of dozens of plaster-of-Paris patterns of industrial and decorative value.

Method of Application

The application of low-viscosity furane resins to the hardening

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

of plaster-of-Paris bodies is a relatively simple procedure. Plaster of Paris or "hydrocal" forms are prepared in exactly their usual manner, i.e., added to water in certain optimum proportions and then stirred and poured. Depending upon the grade of plaster, the forms set in approximately 15 to 20 min, reproducing with the utmost fidelity the finest details of the mold. The sections can be splash castings $^1/_4$ in. thick or sections measuring several feet in thickness. The hydration process is an exothermic reaction and some heat is developed although temperatures seldom exceed 50 C. After the plaster has firmly set, it may be removed from the mold. There is a considerable amount of free water present which should be evaporated for best results. This can be accomplished by forced drying or leaving in the open for several days. Up to this point the process is standard practice in so far as the plaster industry is concerned. The next step is the application of low-viscosity furane resin which is applied by dipping, brushing, or spraying. The rate of resin diffusion is very rapid, and after thorough impregnation parts are generally cured at temperatures of 140 to 160 F. The final impregnated body is the entirely new structural material which has proved so useful.

The application of organic plastics to plaster-of-Paris bodies is not entirely a new idea, as coatings have been sprayed on the material for many years, largely to seal its surface or to apply some decorative finish. The writer first began experimenting with the impregnation of plaster some 5 years ago and has successfully applied many types of thermosetting urea, melamine, phenolic, and polyester resins and thermoplastic resins. Some of the background leading to the development of furane-resin-impregnated plaster was described in a recent paper before the S.P.I. (1).[2]

The final procedure selected for preparing Plaspreg involved a low-viscosity furane resin whose viscosity could be readily adjusted to meet various application conditions, not by methods of diluting with solvents such as water, alcohol, or acetone, but through proper polymerization conditions. Thus a complete liquid resin capable of conversion to an infusible, insoluble body was developed exclusively for plaster-of-Paris treatment.

A typical application of furane-resin impregnation to plaster-of-Paris bodies is shown in Fig. 1 illustrating a die for laminating purposes. A polyester resin has been laminated about the impregnated form and cured at 250 F. The technique of plaster impregnation was suggested by the author in 1943 (2). Further work upon hydrocal was cited in a more recent publication (3). A further example of furane-resin impregnation is shown in Fig. 2. The many fine details made possible by this impregnation and curing process are emphasized.

Fig. 2 Complicated Design Details, Maintained in Resin-Impregnated Plaster

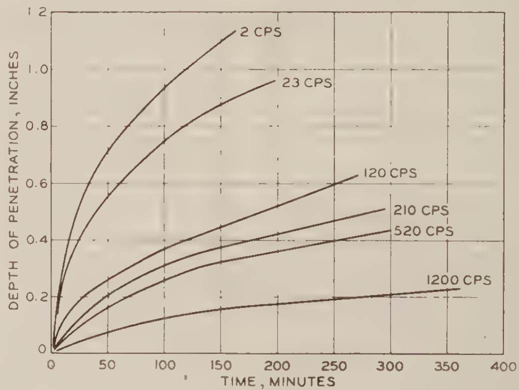

Fig. 3 Amount of Penetration Versus Time for Different Viscosities of the Same Furane Resin

Variables Which Influence Rate and Ease of Impregnation

Throughout all of the work which has been accomplished in the impregnation of plaster of Paris, it has become apparent that best results are obtained through infusion with low-viscosity resins into dry plaster-of-Paris bodies. There are several variables which will influence the rate and ease of impregnation. These are as follows: (*a*) Inherent resin viscosity in the absence of solvent; (*b*) relative porosity of the plaster structure, determined largely by the initial solids-to-water ratio; (*c*) temperature of the plaster-of-Paris body; (*d*) presence of impurities upon the surface. Inasmuch as the correct development of the physical properties of resin-impregnated plaster depends upon these variables, they will be discussed briefly.

(*a*) *Resin Viscosity.* The resin viscosity has a definite influence upon the rate of penetration into the plaster. The higher the viscosity, the higher is the molecular weight and the slower the rate of penetration. The mobility of the resin and its ability to wet surfaces are functions of resin viscosity and, due to the capillary nature of the diffusion process into plaster bodies, resin viscosity is most important. This fact is graphically illustrated in Fig. 3 where the amount of penetration is plotted against time for different viscosities of the same furane resin. The much slower penetration rate of the higher-viscosity resins should be noted. Variations in viscosity were achieved by polymerizing the resin to various degrees, otherwise the material is chemically the same. Another interesting observation which can be made is that the rate of penetration approaches a constant value after a period of time.

While the test method adopted precluded measurements of penetrations much beyond $1^1/_4$ in., it will be noted that complete cessation of penetration did not occur. A relatively simple technique was devised in which the plaster of Paris was poured into a

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

glass vial and then given an opportunity of thorough drying at low temperatures. Because of the slight expansion in setting, a tight fit was insured against the side of the glass vial. The penetration could be observed at the side of the glass vial and measurements made at frequent intervals. These checked completely with any observation upon samples cut open after different intervals of immersion in the resin.

From the data accumulated it was possible to express the rate of penetration by the following equation:

$$r = r_0\left(1 - e^{\frac{-kt}{u}}\right)$$

where

- r is rate of penetration at any time
- r_0 is final steady-state penetration rate
- k constant, depending upon physical factors, such as porosity
- t time
- u viscosity

Thinning the resin with low-viscosity solvents does not produce increased rates of penetration of anything except the solvent, primarily because the plaster-of-Paris body will act as a filtering medium and separate the higher molecular-weight components from their carrier. This means that a thick resin, such as a phenolic casting resin, may presumably be thinned to a low enough viscosity for good penetration. However, during application only the solvent will penetrate, with the high-viscosity phenolic resin remaining near the surface. Other variable factors such as method of application of the resin impregnant, will influence the penetration of the resin. Brushing on the resin and keeping it in motion will aid penetration.

(*b*) *Porosity of Plaster.* The porosity of the plaster has a definite bearing on the amount of resin which can be absorbed. It is seldom possible to produce a workable mix of plaster and water with less than 60 lb of water per 100 lb of plaster. Of the water used, however, only 18.5 lb are required to set the plaster chemically and the balance of 42.5 lb represents free water. This water is evaporated or forced out by oven-drying, leaving voids to be filled by the resin impregnant. While the author has employed a number of water-soluble resins for diffusion into plaster, and in this manner obtained a good penetration followed by subsequent hardening, the total amount of resin pickup is obviously less than when a 100 per cent resin impregnant is employed for application to a plaster in which the free water has been removed.

In Fig. 4 the relationship between the water and plaster ratio and the maximum theoretical pickup is illustrated (calculated on the basis of a 1.18 specific-gravity resin). The resin pickup is based on the total removal of free water after the cast has been made. In addition, the decrease in compressive strength of the plaster is illustrated, indicating that when large amounts of water are employed, the percentage of voids is greater and the effect upon the strength more pronounced. The values for compressive strength of the non-resin-treated plaster are obtained upon dry plaster which is appreciably stronger than wet plaster. At the same time, the compressive strength of resinified plaster is also illustrated. The reinforcing effect of the furane-resin impregnant is quite apparent, as even low-density lightweight plasters are considerably improved. The same improvement is also noted if, during the process of drying or during use, some of the water of crystallization is removed. Resin impregnation overcomes weakness or loss of strength in plaster.

To demonstrate the increased rates of resin impregnation for more porous plasters, a group of test specimens was prepared from 100/60 (solid-to-water ratio) to a rate of 100/100. When these had been thoroughly dried of free water, resin-impregnation tests

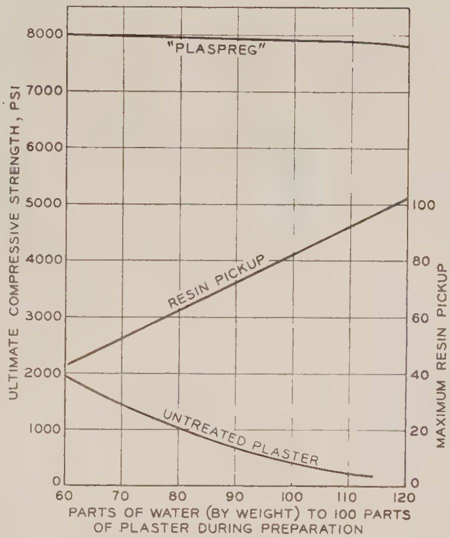

Fig. 4 Relationship Between Water and Plaster Ratio and Maximum Theoretical Pickup of Furane Resin

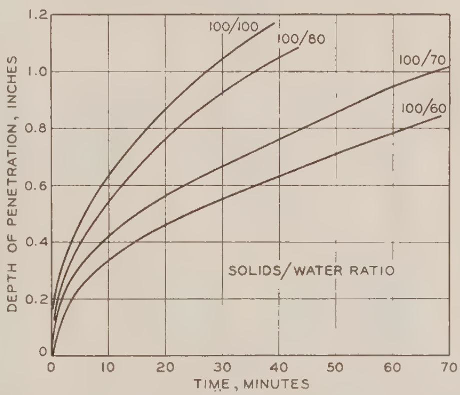

Fig. 5 Effect of Porosity of Plaster on Penetration

were conducted and depth of penetration versus time observed. Averages of several test results are reported in Fig. 5 for a furane resin of initial viscosity of 2 to 3 centipoises. Viscosity measurements were conducted at 25 C, with a "Zahn" viscosimeter cup purchased from the General Electric Company. The increased rates of penetration for more porous plasters are readily indicated upon this curve sheet.

The porosity may also be checked by the water absorbed and in some processes, such as pottery manufacture, this is an important procedure. Aside from this application, low water absorption is an asset. In resinified plaster, where voids are substantially filled with furane resin, water absorption is very low; less than 2 per cent A.S.T.M. water absorption in 24 hr when properly prepared. Herein lies the utility of furane-resin-impregnated plaster tools and articles from a weathering standpoint; they are substantially more satisfactory than untreated plasters. Within a few minutes' immersion, most plasters of the 100/plaster/60 H_2O composition will have a water absorption of 25 per cent. Parts will deteriorate rapidly, while nonporous resinified plaster is infinitely more satisfactory.

(*c*) *Temperature of Plaster.* While not of major consequence

the temperature of the plaster at time of impregnation will influence the rate of penetration of the resin. By raising the temperature of the plaster it is possible at the time of resin application to obtain quicker penetration. From a practical point of view, as forms are removed from the drying oven they can be immediately treated with the resin impregnant without waiting for them to cool. In Fig. 6 is compared the rate of penetration of a 1 to 2-centipoise-viscosity furane resin at room temperature of 75–80 F, 135–140 F, and 180–185 F, respectively. The faster

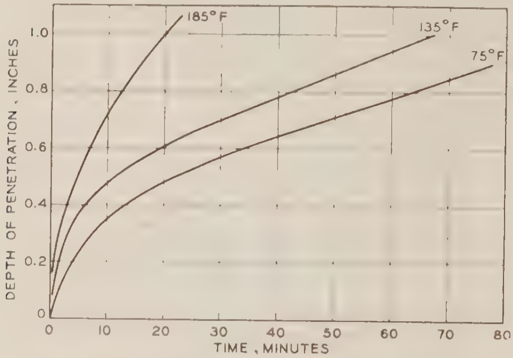

Fig. 6 Effect of Temperature on Penetration Into 100/60 Plaster

rate at 185 F is immediately observed. After a period of time the higher temperature has a retarding action inasmuch as the resin impregnant begins to cure or polymerize, resulting in a decrease in the rate. The plaster used in this experiment and others, unless otherwise indicated, is 100 solids to 60 parts of water.

(*d*) *Impurities on Surface.* There are several types of surface impurities which may influence the rate of penetration of the resin into the plaster. This becomes of practical importance when, for example, treating large surfaces and uniform appearance is necessary. One of the more common surface imperfections may arise from too liberal use of a parting agent in preparing plaster-of-Paris molds and patterns. Stearic acid is largely used for this purpose, as well as various soaps. These materials, if present, would restrict penetration of resin into the surface. However, if removed by light sanding or finishing operations upon the plaster surface, uniform pickup of resin is assured. In applying furane resin to develop resinified plasters, these surface irregularities can be readily observed, and a few spots where an excess amount of lubricant is present may be easily detected. A light touch with very fine sandpaper eliminates this problem.

Another type of surface imperfection finds origin in the mixing of the plaster. This imperfection is known to the plaster trade as a "hard spot." It occurs, generally, on large smooth surfaces, particularly near sharp corners or edges where rapid drying occurs. The hard spots are due simply to portions of plaster not too thoroughly mixed with the balance of the batch. If this is the case, such that a higher solids-to-water ratio is present, the plaster will tend to be harder, and porosity a little less. Once again, however, light sanding over this region will make the pickup of resin more uniform.

Amount of Resin Required

While best physical properties are obtained upon fully impregnated forms, it is also feasible to consider surface penetrations of $^1/_4$ to $^1/_2$ in. without necessarily going through several inches of plaster. For many contour blocks and tools this procedure has been followed for reasons of economy, and a good hard surface obtained without full treatment of the plaster. The amount applied may be controlled to some extent by the number of times the surface is gone over with a brush that has been saturated with liquid furane resin. Absorption of resin into the surface may be likened to the absorption of ink into a piece of blotting paper. Penetration takes place instantaneously upon the initial application, though at a slower rate after 10 or 15 min.

While vacuum and pressure vessels have been employed to obtain even faster and more thorough penetrations, the entire procedure is conducted at atmospheric pressure and temperature. When thin, low-viscosity resins are employed, the amount of build-up on the surface is negligible. However, when high-viscosity impregnating resins are employed, there is some build-up on the surface which must be wiped off before the part is cured. For greatest accuracy of dimensions this is quite important. Likewise, obscuring of surface details is avoided, and the plaster-of-Paris part is unaffected in detail though materially improved in substance.

For quick estimates of the amount of resin required to impregnate completely a plaster-of-Paris body, the article is weighed and approximately 40 per cent of its weight is prepared in impregnating resin. The actual amount required depends, however, on how thorough a penetration is desired, how well the plaster has been dried, and the other variable factors previously described.

Curing Impregnated Plaster

After the plaster has been properly impregnated, it is cured to develop optimum physical properties, which are consistently a 300 to 400 per cent improvement over the straight plaster-of-Paris structure. The curing procedure does not invite any special complications, simply requiring placing the form in an oven and slowly raising the temperature to about 145–150 F. The rate at which temperature is raised or the rate at which it is lowered must be conducted, of course, with concern for thermal expansion and shrinkage characteristics, in order to avoid the development of internal stresses at any position such as may mark the meeting of a thick or thin section of material.

While a very slight initial shrinkage may be observed, of the order of 0.05 per cent, the aftershrinkage of resinified plaster is negligible, and dimensions are held with utmost accuracy. This is a fortunate circumstance when considering the problems brought on by cast liquid resins, and the excessive shrinkages they have incurred, even with a judicious selection of fillers. Even after prolonged heating at 185 to 190 F, the dimensions are unchanged in resinified plaster.

At the same time these tests were made, the thermal-expansion coefficient was determined at 0.000022. This value approximates the expansion coefficient of aluminum alloys. This property has been utilized to advantage in providing for localized reinforcement of resinified plasters at positions of high stress concentration. The insertion of aluminum-alloy strips or corners, folded from sheet metal, gives the end product greater toughness where it is most needed. At first, this reinforcement may be viewed as an obvious procedure. However, the fact remains that cast plastics tooling has not been reinforced with metal strips because the plastics are too unstable and their aftershrinkage characteristics would create conditions for internal stresses and ultimate cracks in the casting. The complete absence of aftershrinkage in resinified plaster and the coincidence of identical thermal-expansion coefficients make a sound combination with aluminum alloy.

In Fig. 7 are curves showing the attainment of cure conditions at different temperatures. There are two stages to the cure: One in which the impregnating resin takes a set and turns to a dark color and the other in which the strength is progressively increased. The criterion proving most useful for this work is the

value of compressive strength, measured upon 1-in. cubes at frequent intervals during cure time. Impact-strength measurements run parallel to these. This set of results is also quite significant and explains in part why resinified plasters are much harder and more chip-resistant than unimpregnated materials. Of course, the values of impact strength indicated will not prevent the part from breaking, although there are various design principles which can be followed to give improved results. These design

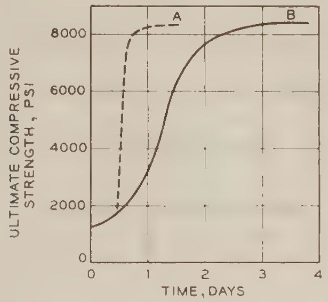

Fig. 7 Attainment of Cure Conditions at Different Temperatures

(*A*—Initial cure at 135 F; followed by 180–190 F. *B*—Cure at 130–140 F. Resin XP, impregnated plaster.)

principles place emphasis upon generously rounded corners and ample sections of materials to withstand load conditions. Impregnated plaster is not flexible, as the modulus of elasticity is quite high and hence when loaded, as in the application to a hydropress forming operation, the base should be perfectly flat and preferably mounted upon a true surface without any "bowing" before load is applied.

Additions of various fillers to the plaster composition to achieve even higher impact strength, will be discussed later in this paper. Comparative physical properties with various methods of reinforcement will also be outlined.

Temperature Stability

One of the most important gains registered in furane-resin-impregnated plasters over unimpregnated plaster is improvement

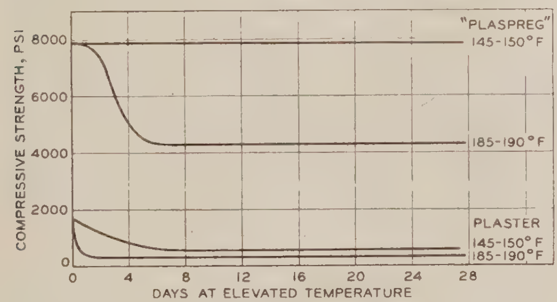

Fig. 8 Effect of Continuous High Temperature on "Plaspreg"

in temperature stability. This has already been indicated in part by pointing out that the material has a negligible aftershrinkage. The study, however, goes deeper than that and in two respects resinified plaster is far superior to ordinary plaster:

1 Maximum continuous operating temperature which it will withstand without suffering any permanent change in physical properties is in the neighborhood of 180 F. This value is appreciably more than straight plaster, the temperature limit of which is about 120 F, because above this it loses water of crystallization and strength. Likewise, the liquid casting resins have temperature limits of about 140 F or thereabouts, because at higher degrees they shrink too excessively.

2 The maximum temperature at which resin-impregnated plaster can operate continuously and still be stronger than the initial plaster, is about 250 F. Above 180 F the strength may fall off slowly to a certain level and then stop, although it will be stronger than the original plaster of Paris. This has been quite important to foundry work where plaster forms and core boxes have not been considered because of the rapidity with which they lose strength when raised in temperature.

The permanency of the physical properties of resin-impregnated plaster is indicated by the retention of its strength over a long period of time. Impregnated bodies prepared a few years ago test as strong as when they were first cured. To accelerate the aging of resinified plaster, a constant-temperature oven at 185–190 F is employed and compressive strength is observed after various intervals of time. Typical results are shown in Fig. 8. For purposes of comparison, straight plaster has also been tested. The loss in strength of plaster is due to loss of strength on removal of water of crystallization at high temperature. Retention of strength after exposure to high temperatures is indicative not only of the permanency of the materials, but also of operating temperature limits. As is the experience with most thermosetting plastics, short exposures to high temperatures in excess of continuously operating temperature limits will not be damaging.

Limiting factors in the temperature resistance of resinified plaster are (*a*) the loss of water of crystallization, and (*b*) the temperature limits of the furane-resin polymer, which lie about 250–300 F. Further improvements in temperature stability can be realized by substituting an inert filler such as powdered silica for part of the plaster of Paris. This can be accomplished without weakening the total cured structure.

Chemical Resistance

The chemical resistance of furane-resin-impregnated plaster is much more satisfactory than is that of untreated plaster. Water-absorption tests at room temperature are shown graphically over a long period of time in Fig. 9. Not only is water absorption greatly reduced because of the presence of furane resins to fill the voids, but furane-resin solids (100 per cent) show an A.S.T.M. water absorption of less than 0.05 per cent in 24 hr. In Fig. 9 sanded surfaces are compared with polished surfaces. For maximum weather protection, resinified-plaster toolings are polished or rubbed by hand with a wax suitable for finishing purposes. This will enable parts to be stored in the open, whereas in the past plaster has fallen apart or was seriously weakened by such exposures.

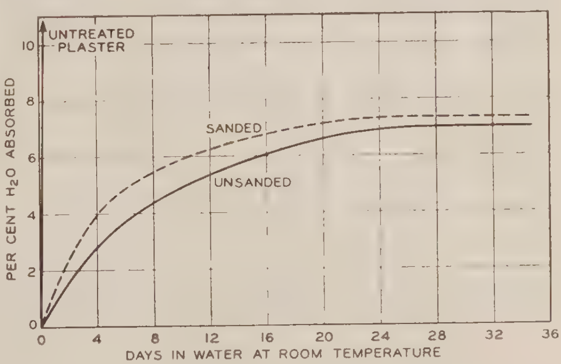

Fig. 9 Water Absorption of Furane-Resin-Impregnated Plaster

Strong acids and alkalies affect resinified plaster only slightly, whereas they cause untreated plaster to decompose. As evidence of their good chemical resistance, various resinified plaster parts have been electroplated after first applying a thin high-polymer film, followed by stannous chloride and then a silvering solution.

For general chemical and temperature resistance, the parts shown in Fig. 1 illustrate the utility of resinified plasters as tooling for low-pressure laminating. The service life of plaster parts is increased quite appreciably owing to the much higher strength. In addition, forms are rendered quite impervious to various polyester resins which must be cured at temperatures as high as 300 F. In the illustration shown, XRS-16631 served as the laminating resin for glass cloth which was cured under vacuum pressure. A vinyl-resin lacquer provides a good release agent for the parts in question.

In another important laminating problem for complicated ducts for aircraft, a removable core of plaster was necessary for each operation, requiring breakage to take the piece out. The plaster cores did not possess sufficient strength to stand up under the laminating operation, although the problem was solved by subsequent treatment with furane resins. By impregnation they acquired sufficient strength to withstand the pressure of the laminating operation. A number of air ducts for fighter airplanes was produced in this manner.

Physical Properties of Resinified Plasters

The discussion so far has centered upon furane-resin-impregnated plaster of Paris. Results are even more noteworthy when various fibrous reinforcements are included in the plaster. Long fibers such as hemp or sisal fiber have been known to strengthen plaster patterns and tooling. They likewise add considerably to the strength of the resin-impregnated plasters. Glass flock, in particular, is effective in forming a strong and tough body which can take much mechanical abuse, and its introduction into plaster before impregnation is an important step.

In Table 1 some of the physical properties of furane-resin-impregnated plaster are noted.

TABLE 1 PHYSICAL PROPERTIES OF RESINIFIED PLASTERS

Material Property:	Unimpregnated plaster	Resinified plaster no filler
Specific gravity	1.15 (dry)	1.65
Compressive strength, psi	1500-1800	7500–8000
Flexural strength, psi	400–500	2500–3500
Impact strength, Charpy unnotched, ft-lb per in	0.15–0.25	0.8–1
Water absorption, per cent in 24 hr.	35	2

All of the physical tests followed the applicable A.S.T.M. standards with the exception of compressive-strength tests which employed 1-in. cubes instead of $^{1}/_{2}$-in. cubes. The unimpregnated plaster and resinified plaster contained 100 parts of solids and 60 of water at the time of preparation. Materials were dried at room temperature for 3 or 4 days and then overnight at 140 F, to remove all traces of free water. They were impregnated with low-viscosity resins and cured about 48 hours at 150 F.

In conclusion, it appears desirable to sum up some of the advantages and disadvantages of resinified plaster. It represents the application of a new thermosetting resin, the 100 per cent furane resin, into the plastics picture and the development of a new and important outlet for plastics in the ceramics industry. A new, low-cost tooling material with negligible shrinkage has made its appearance.

The advantages of resinified plaster are as follows:

Low Cost. Resinified plaster is prepared from a low-cost base material, plaster of Paris, which costs about 1 cent per lb. When fully impregnated, the cost of the treated plaster is appreciably less than that of a thermosetting cast-phenolic resin.

Ease of Fabrication. From the standpoint of ease of fabrication and workability, plaster has few equals. In the resin-impregnation process, plaster of Paris or hydrocal tools, forms, or patterns are prepared in their usual manner and set at room temperature. A very stable structure is prepared with simple tools. Upon resinifying and hardening, this form is rendered permanent.

Physical, Chemical, and Thermal Properties. These properties have been vastly improved over the straight plaster, placing fully resin-impregnated plaster in the same class as liquid-cast resins, with the important advantage of zero aftershrinkage.

Applications. No form is too small or section too big to be handled by this process. Resin penetrations up to several inches have been accomplished at room temperature and atmospheric pressure. Wherever plaster is used resin impregnation may be applied to convert these articles to permanent, stronger materials of construction.

The disadvantages of resinified plaster are as follows:

Drying. For best results the plaster forms should be thoroughly dried out. This necessitates an additional step in preparing plaster and lengthens the time lapse before the tool can be used.

Breaking. While all properties are improved some 300–400 per cent, furane-resin-impregnated forms can still be broken, and one should not expect the treatment to convert plaster into a rubberlike, unbreakable material.

The Control of Fouling Organisms in Fresh- and Salt-Water Circuits

By JOHN G. DOBSON,[1] SHORT HILLS, N. J.

The difficulties encountered by industrial water users due to fouling organisms are discussed. To control such fouling, a knowledge of the organism's life cycle and reactions to stimulus is necessary. Typical mollusks, Bryozoa, sponges, barnacles, and tunicates are considered. Their control can be effected by heat, change of salinity, change of oxygen content, increased velocity, acids, antifouling paints, screening and poisoning with a number of different poisons. It is concluded that chlorination is the most effective and economical of these methods justifying itself in most plants by improved heat transfer alone. Factors to be considered in designing water systems that may foul are also outlined.

INTRODUCTION

Examples of Problems

THE growth of marine macroorganisms, both plant and animal, has been a continuing source of difficulty to power stations, oil refineries, and other users of industrial water. Although much has been written concerning accumulation of microorganisms of the capsulated and slime-forming types on heat-exchanger surfaces with attendant reduction of heat-transfer efficiency (1, 2, 3),[2] little has been published on the growth and control of the macroorganism in closed water circuits. This paper deals with those fouling organisms visible to the naked eye which cause industrial difficulties.

One of the more important, although perhaps the least obvious of the difficulties resulting from fouling by the larger aquatic organisms, is the reduction in the carrying capacity of a pipe line by reduction of the Hazen and Williams coefficient and also by actual reduction of the pipe-line diameter. In addition to some fresh-water grasses and mats of fresh-water algae in the sunlit portions of the water conduits, the most common organisms responsible for this blocking of fresh water lines are the Bryozoa, notably *Pectinatella magnifica*, and the sponges. In salt-water or brackish-water lines, the various hydroids and Bryozoa, as well as Mollusca and Tunicates, are responsible for such reduction.

Sponges, both of the calcareous and of the siliceous or fiber types have been responsible for occasional fouling of pipe lines. In one southwestern city the Hazen and Williams coefficient has dropped from 145 to 94.5 on a 60-in. iron pipe line due to sponge accumulations. Occasionally large cast-iron pipe lines have become almost completely blocked with various Mollusca, notably *Mytilus edulis* and *Pecten latiauratus* in salt-water circuits and various *Dreisseniidae* in fresh-water circuits. As much as 266 tons of shells have been removed yearly from the circulating tunnels of one New England power station. Another station has an accumulation of dead shells 3 ft to 6 ft deep in a tunnel with a 6 × 11-ft cross section and 400 ft long. Figs. 1 to 4 inclusive, illustrate conditions in a tunnel on October 1, 1945. The tunnel walls and floors had been made broom clean by scraping 4 months before. Where salt water is used in fire service, these same organisms have not only reduced carrying capacity of the line, but shells loosened by sudden rush of water due to fire demands have blocked valves, hydrants or other irregularities, and have completely shut off water supplies with disastrous results.

Similar difficulties have been encountered where salt water is used for displacement of gasoline or fuel oil from underground storage.

Sea-going vessels in harbor waters of temperate climate and most tropical waters have had fire and flushing lines clog with marine growths.

Growths, particularly of shelled organisms, continue to enlarge until their exposed area becomes so great that they are torn from their moorings on the pipe line and are swept into screens, tube sheets, or pumps. In one Gulf Coast refinery, Bryozoa so blocked the tube sheet of divided water-box condensers that the pressure from circulating-water pumps burst through the dividing wall and forced whole sections of the refinery "off stream."

When the lines or tunnels serving shell-and-tube or surface condensers become fouled with these organisms, additional difficulties are encountered. After the organisms break off or die, the shells float up with the circulating water. Many seaboard stations and some stations using river and lake water have had to shut down entire turbogenerator units two or three times a day to permit removal of shells that are blanketing the tube sheets. Some shells in these cases are sure to enter the tubes and cause high impingement velocities with attendant erosion and reduction in tube life (4).

The presence of macroorganisms, as well as that of microorganisms on the surface of metals, cause differential cells and attendant corrosion (5), particularly of steel materials. Attacks on nonmetallic structural materials also occur (6).

Mechanics of Fouling

The exact mechanics of fouling have been studied to only a limited extent. Most of the work has been done on smooth metal or glass plates simulating conditions on a ship's bottom. The first organisms to attach to a newly immersed plate are the unicellular capsulated bacteria, Fig. 5. Whether these organisms attach first merely because of their rapidity of growth, or whether they form a necessary footing for other larger organisms is not clear.

Some "conditioning" of a surface has been thought necessary before fouling begins, even in the case of natural rock (7). This "conditioning" apparently consists of a roughening of the surface and possibly the elimination of the material being leached from the surface.

After that period of "conditioning," first one and later other organisms may become predominant (8). Eventually stable conditions result (9).

History of Control

Early recorded experimental work (10) covering control of

fouling organisms in closed water circuits was begun when the consulting-engineering firm of Kennedy and Donkin was commissioned early in 1919, by the Electricity Committee of the Edinburgh Town Council to make recommendations regarding the control of marine growths in the circulating tunnel of the Portobello Generation Station, which was then in process of design.

The investigators studied various control methods which had been previously attempted. One private firm at the Leith Docks had attempted to control mussels by annual flushings with high concentrations of sulphuric acid. This control was partly successful but severe corrosion resulted. Others had attempted annual or semiannual cleanings of inlet pipes by use of tight-fitting balls and other cleaning implements being dragged through tunnels; but several pipe lines were severely damaged. At Portsmouth an electrically insulated pipe line had been freed to some extent of mussels by using electrical discharges between the pipe and a central electrode.

Screening to prevent the entrance of small organisms, the use of various antifouling paints, and the use of various mechanical

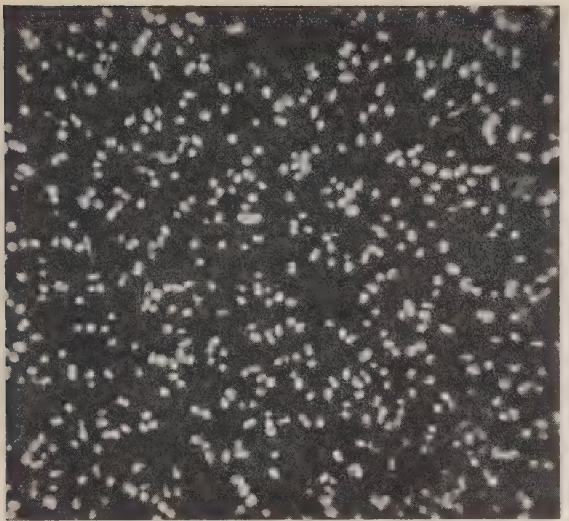

FIG. 5 SMALL GRAM NEGATIVE ENCAPSULATED COCCOBACILLI TYPICAL OF SLIMING MICROORGANISMS IN SALT WATER; ×930

cleaning methods, were considered and rejected as impractical. Chemical means were then attempted.

It was found that sulphuric acid in concentrations of 1 part in 10,000 was unsuccessful; that the larger mussels, after immersion in fresh water even for as long as 120 hr, were unaffected.

Experiments were then tried with heated water. Mussels were removed from sea water at 69 F and placed in salt-water tanks which were gradually heated. Selective killing occurred above 100 F during immersion periods of 25 to 50 min. All mussels failed to revive when returned to normal sea water, after immersion at 106 F for 22 to 63 min.

Based on these experiments, it was recommended in 1921 that the Westbank Station of Portobello be built so as to permit the reversal of flow in the condenser cooling waters, and that that reversal be carried forward at about 4-week intervals. It was also recommended that during this reversal period, the circulating water flow be throttled so as to increase the water temperature on the exit of the condenser to at least 110 F.

Various other attempts were made in the succeeding decade to obtain satisfactory chemical methods of control. These were summarized by the British Electrical and Allied Industries Research Association (11) in 1929. Apparently based on abstracts, the author reported successful control of marine growths by use of chlorine. The major paper upon which the author relied (12) had merely suggested that since chlorination would kill slime-forming and other microorganisms, and since these organisms were the food for mussels, chlorination might control *Mytilus edulis*. No experimental work had been done and since we now know that *Mytilus edulis* does not require living organisms for food, the hypothesis was unsatisfactory.

A German professor (13) has been widely quoted as reporting successful control of the fresh-water mussel *Dreisseniidae polymorpha* in the flumes of a powerhouse on the Glambacksee near Berlin. His report in 1921 indicated that the larvae of this organism died in the laboratory under chlorine dosage but apparently no unchlorinated control was used. No plant-scale work had been carried out. Some confirming laboratory work was done in Germany in 1929 (14). Similar discussions of the use of chlorine were later published (15, 16).

The first work in this field in the United States was started under the direction of W. J. O'Connell. In 1924 experimental work on intermittent treatment of condenser cooling water for the control of slime-forming microorganisms in cooling-water systems had begun in co-operation with Commonwealth Edison Company of Chicago, and the first plant-scale experiments of such intermittent treatment were tried at the Kearny Power Station of the Public Service Electric and Gas Company of New Jersey. The extension of this work to the control of marine growths was started in 1929, at the Northport Station of Long Island Lighting Company with the co-operation of L. H. Curley. The work there and at Corpus Christi indicated that it was possible, by intermittent chlorination, to eliminate completely the growths of the grasses and higher algae, and to reduce effectively the growth of bivalve forms. However, at that time eliminations of the order of 99 per cent were not attempted.

TYPICAL ORGANISMS

The life history, method of reproduction, food, responses to various unfavorable environments, and living habits of fouling organisms must be thoroughly understood before any intelligent plan can be suggested for their control. It is impossible to cover the wealth of material that is available about all the fouling organisms, but representative types can be discussed. However, before commercial installations are started, details regarding the organisms responsible for the particular fouling should be known.

Luckily for the engineer interested in controlling such growths, very few of the approximately 822,000 invertebrate animals which have so far been described by the biologists, cause fouling difficulties.

THE MOLLUSCA

Of the fouling organisms, the members of the phylum *Mollusca*, which includes the snails and other single-shelled *Gastropoda;* and the clams, oysters, mussels, and other bivalve or two-shelled *Lamellibranchiata* are the most troublesome. *Mytilus edulis*, or the edible or black mussel, is probably the most common fouling mollusk throughout the world. This organism has been responsible for most of the fouling difficulties in the British Isles and along the North Atlantic coast of the United States. The closely related *Mytilus californianus* has been responsible for

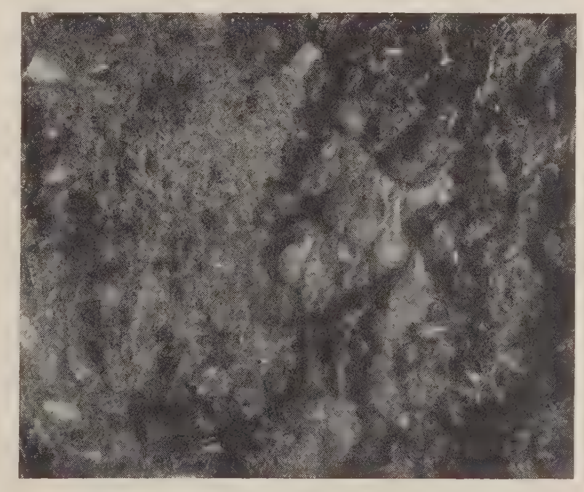

FIG. 6 HYDROIDS GROWING IN LOW-VELOCITY AREA OF A TUNNEL (Young mussels appear at right; dead mussel shells in upper left-hand corner.)

much of the fouling difficulties which have occurred along the western coast of the United States.

The black mussel (17) is familiar to all who have frequented any rocky coast of the northeastern United States. The shell is wedge-shaped, pointed in front and round behind; black or dark brown outside with indistinct circumferential growth rings around the shell. The interior of the shell is pearly with violet margins. Shells vary in length to a maximum of about 4 in. Its life history is typical of many other of the fouling invertebrates (18). Other *Mytilus* have nearly identical life cycles. The sexes are separate, but one individual may be male one year and female the next. The eggs and sperm from near-by individuals are discharged almost simultaneously and the eggs are fertilized in the open water. The sperm has only limited range of locomotion (19). An average female discharges from 5,000,000 to 12,000,000 eggs although a female $3^1/_2$ in. long may release as many as 25,000,000 eggs. Cell division begins immediately after fertilization and is completed within 20 min. The first cilia begin developing at the end of 4 hr (based on 68 F sea-water temperature), and at the end of 5 hr the embryo is completely free-swimming.

Development continues and at the end of 24 hr the organism is a very active swimmer; and by the end of 40 hr the complete digestive tract and the glands for forming the shell are becoming evident. At the end of 44 hr the organism has attached to some stable hard material such as rock, concrete, glass, rubber, or similar solid support, and has begun to develop the first single shell. At the end of 69 hr the elementary single shell or prodissoconch has completely enclosed the fleshy portions. The organism is still capable of rapid swimming and is able to crawl on solid surfaces, vertical walls, and the tops of horizontal tunnels. Some time later the true bivalve shell or dissoconch develops. Contrary to popular belief, the organism, which is now attached by long clear threads, known as byssus threads, (20) is still capable of motion, and if conditions of poor feeding, inadequate oxygen supply, or mechanical or chemical irritation develop, the organism will break the byssus threads from their point of attachment and crawl by a "foot" which projects out of the shell near the hinge. Such "walking" is similar to the locomotion of the familiar terrestrial snail. The mussel can also move by secreting new byssus threads and breaking off older ones.

The greatest growth rate occurs when the organism is completely submerged at all times, although under natural conditions predatory fauna may reduce the number of organisms below the low-water line (21).

Under normal conditions the adult *Mytilus edulis* will leave the shell open about 15 to 20 deg, the cilia on the mantle will vibrate rapidly and water containing food will be forced through the digestive tract. This flow of water amounts to about 10–20 gal per day in a specimen 2 in. long (22, 23) and seems to be constant, provided the organism is not irritated. This water circulation is called "drinking." The rate of digestion, on the other hand, seems to vary with metabolism demands. The shell remains open about three quarters of the total time in a temperature range of 31 to 77 F (24) without any variation with temperature.

As the water is circulated through the digestive tract any suspended solid matter adheres to the mucus surfaces. Digestive juices then digest such material as is usable for food, and this is assimilated. The balance is excreted as fecal pellets. By this process, mussels are capable of clearing cloudy and turbid water.

The exact nature of the food requirements is still little known. It was originally believed that living microorganisms mostly diatoms and algae, Fig. 7, were required, and they undoubtedly make up a large part of the natural food (25, 26). Robinson (12) based his theory of killing of mussels on this postulate. However, more recent work has indicated that while organic matter is necessary as food, decaying animal and vegetable material is as efficient as living organisms (27, 28, 29). It is known that domestic-sewage pollution, provided continuous anaerobic conditions are not set up, encourages growth.

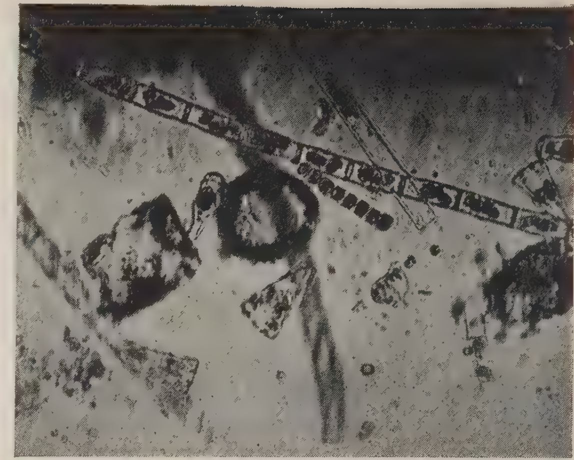

Fig. 7 Algae and Diatoms Which Form Basic Natural Food of Mussels; ×460

Each species has its own preference as to conditions of light. The author has repeatedly placed *Mytilus edulis* and *Modiolus modiolus* in equal quantities in adjoining and connected cells, one light and the other dark. Marked migration of *Mytilus edulis* toward the dark and *Modiolus* toward the light is always noticed. *Mytilus* grows three times as fast in total darkness as in sunlight (30), although a weak light may be still more favorable. Optimum growth occurs at 50 to 68 F, and is seriously inhibited by heating for even a few minutes a day (31).

If any unfavorable conditions develop or anything disturbs the organism, the shell will close within a fraction of a second and only after an extended period will the mussel open the shell slightly and "drink" very cautiously. This ability to close its shell tightly makes all adult *Lamellibranchiata* very difficult to control. All mussels have a cushion pad which forces the shell open as soon as the adductor muscle is out or relaxed. Therefore a gaping shell can be considered as a sign of damage to the organism.

Pecten (scallops) (32) are not usually responsible for fouling, but *Pectens latiauratus*, which attaches with byssus thread reduced an 18-in-diam cast-iron line serving a South Carolina power plant to 6 in. in about 12 months.

The various fresh-water mussels have a life history similar to *Mytilus edulis*. However, important differences exist. Instead of releasing single-celled eggs, the adult female permits the eggs to be fertilized while still within the mantle, and free-swimming "glochidia" about 0.014 in. diam are released (33). A parasitic period on host fish is necessary before metamorphosis into shelled forms can take place. *Dreisseniidae* is limited in range to fresh or brackish water of less than 1 per cent salt content (34).

Dreisseniidae is similar in appearance to *Mytilus edulis* but lacks the pearly shell interior. The organism is common in Germany, having been responsible for actually shutting down a power station on the Glambacksee with a 12-in-thick growth on tunnel walls (13). The American oyster (*Ostrea virginica*) is a common Mollusca responsible for severe fouling of power inlets on our South Atlantic and Gulf coasts, where it is easily recognized by its rough shell and white interior. Its life history, together with that of its European cousin (*Ostrea edulis*) has been carefully

studied because of its importance in the culture of oysters for food. Its life history is similar to the edible mussel (35). However, its spats are apparently considerably more delicate. The period of pelagic or larvae life varies from 13 to 17 days (36), depending upon temperature. The spat prefers a dark place to settle, and metamorphosis can be delayed by failure to find a suitable resting place (37). Spawning can be stimulated out of season by raising the water temperatures from 82 to 86 F (38). It can be induced by the presence of eggs or sperm in the water, not only of its own specie but those of other mollusks, or by various chemicals (39). The season of normal spawning varies with location, being from April to June in some eastern United States waters and from July to August in others (40). In Denmark it occurs from late May to mid July, while in Holland spawning occurs in September.

The daily rate of growth varies with age of the organism and water temperature, but does not vary with the actual size of the organism (41).

The Sponges

The sponges (*Porifera*) are the simplest of the fouling macro-organisms. A "sponge," as normally seen with the naked eye, is a colony of individuals with the large number of "pores" on the outer surface. Through these pores, water containing food material is circulated by flagella, and as it passes through the cloacal cavity, exposed cells absorb food material and transmit it to near-by cells. No truly "specialized" organs exist.

Reproduction is by three separate and distinct methods, i.e., by budding, by the formation of gemmules, and by sexual methods.

Budding takes place within the organisms and results in a single "sponge" increasing in size or even dividing, but does not permit the formation of new groups at a distance from the previous place of attachment.

The formation of gemmules is similar to a formation of "spores" in microorganisms. A living cell migrates to the center of the colony and is covered with a capsule secreted by the adjoining cells. When unfavorable conditions of temperature (in fresh water lakes) or dryness (in tropical lakes) occur, these dormant forms resist those unfavorable conditions and upon the return of conditions conducive to development, burst the capsule and begin development of a new sponge.

Sexual reproduction is in the main responsible for the development of new colonies. "Some sponges are hermaphroditic, others are unisexual. No special sexual organs are present, the ova and sperm developing from ... the inner cells .... The ... egg develops into a ciliated two-layered larva which swims actively about in the water, which finally attaches itself and, after metamorphosis, develops into the adult animal" (42).

It is during the larva stage that the sponge is most vulnerable to attack by poisons. They are relatively sensitive to changes in pH (43).

The Bryozoa

The Bryozoa, or Polyzoa as they are called in England, are minute colonial animals that are often confused with seaweed and sponges both by the layman and the early naturalists. There are about 3000 marine species and 35 fresh-water species. Upon first examination, they may appear as red or white encrusting patches, as groups of dead sticklike organisms, brown or purple in color, projecting from a rock or as branched sticks with plumed ends (*Plumatella*). The familiar jelly balls in fresh-water lakes (*Pectinatella*) are also Bryozoa.

Each colony or "zoarium" increases in size by budding. Sexual reproduction also takes place; the eggs and sperm being released into an inner cavity and developing to a larva stage there. The larva are released either through special openings or by the death and disintegration of the parent. Other specie (notably the fresh water *Plylactoloemata*) are capable of forming "statoblasts" to resist unfavorable conditions similar to those developed by sponges.

Statoblasts of *Pectinatella magnifica* can endure much drying but not absolute desiccation. They are not harmed by brief exposure to temperatures as low as 31 F and as high as 130 F; while the adult form or "polypids" survive only in a range of 50 to 104 F (44). The statoblasts of fresh-water Bryozoa usually germinate at 62 to 66 F. These statoblasts not only provide a means of surviving unfavorable conditions, but also provide a ready form for transportation by wind and birds.

Grave (45) has reported on the development of *Bugula flabellata*, one of the common Bryozoa on the New England coast. The breeding season at Woods Hole, Mass., extends from June 10 to November 15. The young are expelled from the colony as swimming embryos. After a free-swimming period of 4 to 6 hr, the larva attaches, profound metamorphosis takes place involving the loss of some larva organs, and the colony begins development. At the end of a week the colony has increased by budding to 8 or 10 individuals, at the end of 2 weeks to 100 individuals, and by the end of a month the colony is half grown and has reached sexual maturity. Colonies $1^1/_2$ to $1^3/_4$ in. diam are able to hibernate successfully and resume growth in early May. Even more rapid growth occurs in South Atlantic and Gulf Coast waters where the time from first infection to serious difficulty in industrial water circuits may be only a matter of weeks. Colonies of *Bugula neritina* grow as long as 4 in. at Beaufort, N. C. (46). Many fresh-water Bryozoa flourish in dark as well as light, and cause serious fouling in water mains (47).

The Barnacles

The barnacles are probably the best known of the fouling organisms, since they have been responsible for most of the serious fouling of ships' bottoms. Because of their hard shell with several parts and because they seemed to "drink" like the mollusks, they were so classified by the early zoologist. J. V. Thompson in 1830 was the first to show definitely that they were Crustacea, closely related to the crayfish, lobster, and soft-shelled crab. Darwin (48) in 1850, made an extensive study of the group (49).

Moore (50) on the Isle of Man and Grave at Woods Hole, Mass. (51), among others, have made extensive studies of the barnacles. They are mostly hermaphroditic but in a few cases are unisexual. Some species have a male form which is very tiny and lives parasitically within the shell of the female.

The eggs (52) are held within the mantle cavity and the larvae are released as free-swimming forms after hatching. The "nauplei" changes form slightly with each moult into forms known as "meta-nauplei," and then metamorphoses into an entirely different type of organism known as the cypris larvae or the "cyprid." This later stage lasts from 7 days for *B. amphitri* to two weeks for *B. balanoides*. During this stage the cyprid swims with a sudden backward motion of the appendages. The barnacles then settle down on a suitable place of attachment and begin to undergo a second metamorphosis and form a shell. Actually the organisms will make several attempts to find a suitable place to attach and if the one selected is not satisfactory the barnacles will break away even after they have become partially attached. After finally reaching a suitable place, some small motion in an area of about $^1/_2$ in. is still possible (53).

"In immature barnacles tissue growth continues throughout the year but is most rapid in the spring and autumn. In mature barnacles there is a sharp drop in growth rate during the summer

and a slight one during winter associated with the development of the larva." In exposed places, below mean-tide level, the *Chthamalus* reach sexual maturity in the first year and die in their third year. In less exposed places, the organisms reach sexual maturity in their second year and die in their fifth year (54).

The spat will choose its resting place partly on the basis of light intensity, apparently making a choice of optimum light, shying away from too bright and too dark places. The organism apparently can only distinguish light from dark areas. Light has also some control on growth (55, 56), and the adult organisms will close their shells when a shadow passes over them (57).

Barnacles also react to changes in potassium (58), alcohol (59), carbon dioxide (60), calcium (61), salt-water dilution (62), strong electrolytes, urea, glucose, and glycerol (63).

The Tunicates

The highest organisms responsible for fouling in industrial plants are the tunicates. They represent a "subphylum" of the phylum *Chordata* to which also belong the vertebrates including fish, mammals, and man. They derive the name from their thick, hard, cellulose coating and are one of the few animals capable of synthesizing cellulose.

Of these, one of the most common is *Molgula manhattensis*. It consists of a brown sac with two distinct openings at the end of noticeable tubes. While the individual organisms are only about 1 in. in diameter, they form large colonies which break off in mats from tunnel walls and often blanket tube sheets. It is also not uncommon, for example in the Kill Van Kull off Staten Island, for these mats to be broken off by wave action and block inlet screens and sometimes even bar racks. Related specimens with nearly clear tunics have been clogging powerhouse screens in Stamford, Conn., harbor. They are commonly called "squirt balls" because of the habit of ejecting water from their body cavity sometime after they have been lifted from water.

The life history of the *Molgula manhattensis* has been carefully studied by Berrell (64). Eggs of about 0.006 in. diam are released in the water and fertilized there. The time taken from fertilization to hatching varies with temperature, being approximately 120 hr at 46 F, and 40 hr at 62 F. The hatched egg yields a "polliwog" which is free-swimming with an active tail. The tunicates have a heart, elementary circulatory system, digestive tract, liver, a nerve cord, and a gangula which is an early form of the brain. After a period of 160 to 450 hr, which period depends on CO_2 content of water, salinity, pH, and temperature, the "polliwog" attaches to rock, inlet tunnel or tube sheet, or other structure, with three sticky tentacles and begins a retrogressive metamorphosis. Powers of locomotion are lost, the existing digestive tract disappears, and a new one begins to form on the remaining portion of the animal.

Even this high animal can reproduce by "budding" and thus form extended colonies. In order to attain maximum efficiency in control of tunicates, control methods must be timed to attack the organism during the early active larvae stage or during early metamorphosis, before the larvae alimentary canal, through which both food and oxygen are absorbed, is eliminated from use.

Al arge number of standard zoological texts, as well as specialized books and articles, give further details on the life history of the fouling and related organisms. Pratt (42) is a good representative general text for identification of invertebrates; while Ward and Whipple (65) give more detailed treatment covering the fresh-water organism.

A good recent review of the reactions of invertebrates to stimuli has been published by Warden, Jenkins, and Warner (66).

CONTROL METHODS

Numerous methods have been suggested for preventing the settling of larva forms and the killing of adult forms of fouling organisms. Among them are the following:

1 Heating the water.
2 Increasing or decreasing salinity of the water.
3 Creating anaerobic conditions in the water.
4 Increasing water velocity in tunnels.
5 Poisoning with acids.
6 Antifouling paints.
7 Screening the tunnel entrance.
8 Poisoning with miscellaneous poisons.
9 Poisoning with chlorine.

Any theory of killing or method of control is only as valuable as it can be proved in actual practice at plant scale. Heat, increased velocity, surface treatment, acid, and chlorine are the only methods that have been put into practice on a large scale.

In selecting a particular method of operation, it is well to bear in mind the factors to be considered. While there will be differences of opinion as to the relative importance of these various factors, most designers will wish to consider them all.

1 The method should not materially increase the operating cost of the plant. Too often in evaluating the various methods involved, designers are likely to decide against one particular method, because of a direct cost of operation and decide upon another that disproportionately increases pumpage costs or lowers the general efficiency of the plant.

2 The method should have lowest possible first cost consistent with low operating cost. Particular care should be taken in evaluating cost of special equipment for control of marine growths compared with increased cost of general plant equipment to make possible other methods of control.

3 The method should assure that no organism can grow to a size that will be detrimental to plant equipment, and a method should be available for recovering control of the growth if, for any reason, the treatment method must be interrupted.

4 The method should permit operation of the plant at full capacity without interruption.

Control by Heat

The earliest method of control used on plant scale was heating circulating water. One power station throttled the circulating-water flow until the desired heat balance was obtained. The amount of heating required is dependent upon the normal average temperature and normal range of temperatures of the water in which the organism has grown.

Without reporting initial temperature of the water from which the organisms were removed, Henderson (67) found that by raising water temperature gradually and removing specimens to cooler water for recovery, the lethal temperatures for various mollusks were *Leda tenuisulcata*, 88.7 F; *Cardium boreulis*, Conrad, 88.9 F; *Modiolaria discors*, Beck, 89.4; *Saxicava rugosa*, Lamaich, 91.0 F; *Crenella glandula*, Atoms, 91.0 F; *Cardium pinnulatum*, Conrad, 91.8 F; *Astarte undata*, Gould, 92.4 F; *Pandora trilineata*, Say, 92.4 F; *Modiolaria nigra*, Loven, 94.2 F; *Yoldia sapotilla*, Simpson, 94.7 F; *Zirpoea crispate*, Gray, 92.4 F; *Mactra solidissoma*, Chemnitz, 98.6 F; *Mya arenaria*, Linne, 105 F; *Mytilus edulis*, Linne, 105.4 F; *Nacoma fusca*, Atoms, 108.2 F; *Venus mercenaria*, Linne, 113.3 F; and *Ostrea virginica*, Lister, 119.3 F.

It is interesting to note that *Tubularia* in water above 68 or 70 F, remains dormant, although it is able to recover when held for 3 days at 65 F (46, 68). In Scotland successful control of

Mytilus edulis on plant scale has been obtained by heating the circulating water to 120 F.

The cost of operating such a system can be extremely high. Assuming that a power station with initial steam conditions of 400 psi and 500 F, and capacity of 25,000 kw is fully loaded, and assuming that the circulating-water temperature must be raised from 65 to 120 F, the fuel cost alone due to the corresponding loss in vacuum for a 2-hr period will amount to approximately 40 tons or, computed at $2 a ton, $80. The load capacity of the plant is, of course, at the same time reduced.

In addition, increasing the temperature of the condenser may cause leaking ferrules and other leaks due to uneven expansion of tubes and tube sheets. Any operator who has experienced a failure of condenser water supply will appreciate this problem.

The cost of the initial installation of such a heating system for a steam power plant will also be higher than other methods of marine-growth control. This can be readily appreciated when it is realized that the entire circulating-water system, and particularly the pumps must be designed for reverse flow. For plants not having waste heat available, the cost of such heating would be prohibitive.

Control by Changes of Salinity

Fresh water has been used as a means of eliminating marine growth from fouled surfaces since ancient times. Early mariners ran their vessels up fresh-water streams to loosen the ship's fouling load.

Most marine organisms are adversely affected by reductions of salinity, but the absolute value that will support life varies with the species, the salinity of environment from which they are removed (69), and the rate at which the change in salinity occurs. Because of the number of variables, it is difficult to correlate various experimental results. Sudden reductions to 30 per cent of normal salinity have been found to be fatal to *Mytilus* (70). *Ostrea virginana* will not fatten below 20 per cent salinity (71). The critical salinity for maintaining life and for growth varies from individual to individual within a given specie (72).

Most fresh-water invertebrates die in salt concentrations above 5 grams per liter NaCl (73) but *Physa heterostropha* have been known to live actively in 25 per cent sea water if the concentration is slowly increased to that figure (74). Contrary to the average tendency, the oyster drill grows to a larger size in brackish water than in salt water (75). Increase or decrease of salinity from that of normal sea water acts as an anesthetic, causes loss of sense of balance in the motile organisms and paralysis of the motor systems (76, 77).

Practical applications of this method for control of growths in industrial-plant water circuits are difficult, unless brackish streams varying in salinity with rainfall are readily available. Unfortunately even for plants with such streams available the problem is not fully solved for all the fouling organisms are not as sensitive as those just mentioned, and some will thrive under conditions of widely varying salinity.

Plants on such brackish streams are faced with another problem which is acute along the St. Johns and Hillsboro Rivers in Florida. Spring rains almost invariably change these streams from brackish to fresh water. The mussels and barnacles which have set in the circulating-water tunnels are killed, and the shells and debris of the dead organisms float up and clog pipe lines and blanket tube sheets. No operator having tube sheets badly clogged with shells will say that natural variation of salinity is a cure for his marine-growth problems!

Control by Creating Anaerobic Conditions in Water

The reduction of oxygen content of the water below certain critical levels will eliminate many organisms. The exact value of dissolved oxygen which will support life varies with species. All fish and most of the invertebrates require free dissolved oxygen. At least one of the contributing causes of death of oysters in water heavily polluted with paper-mill waste has been the reduction of oxygen content (78, 79).

However, no practical means are available to remove oxygen from industrial-water circuits. The gross pollution which has been so common in some of our tidal streams has effectively done this in certain areas; but the disagreeable odors and prevention of recreational use of the streams are too high a price to pay for elimination of fouling organisms (80, 81). As pollution of streams is reduced with improved waste treatment, these anaerobic conditions will be eliminated. This trend will probably be greatly accelerated in the near future, both by governmental pressure to eliminate such public health hazards and by the realization by industry that many valuable products may be recovered by proper treatment of their industrial wastes. Even in streams having completely anaerobic conditions certain mollusks are still able to survive. *Mya arenaria* (82), *Saxidomus gigantea* (83), and various others (84) have been shown to be capable of acting as facultative anaerobes. By this is meant that they are capable of obtaining energy by the breakdown of organic matter without use of oxygen.

It has not yet been conclusively demonstrated whether the Mollusca can continuously live under these circumstances, or whether they must be subjected at regular intervals or at stated times in their metamorphosis to aerobic conditions.

Sewage pollution will also encourage certain seaweed growth such as sea lettuce (*Ulva latissima*) (85), which also often blocks screens and tube sheets.

Control by Increasing Velocity

Where high velocities in the line can be obtained without unduly increasing the cost of pumping, such increased velocities may be used for the control of aquatic growths. The author has observed that *surface* velocities in excess of 1 fps minimize the set of mussel and barnacle larvae on smooth metal surfaces. However, very much higher *average* velocities must be attained to arrive at surface velocities of 1 fps on rough surfaces; such as, cast-iron pipe and concrete tunnel walls. *Mytilus*, which have already formed bivalve shells have been successfully removed by increasing the water velocity in cast-iron pipes to $13^1/_2$ fps for a period of 1 hr each week. However, such a means of eliminating marine growths is practical only where catch basins or strainers can be economically installed to eliminate the debris before it reaches critical equipment; such as condensers and pumps. The idea of high-velocity flushing is definitely practical for application in small plants. However, in large installations, particularly where large circulating- and cooling-water flows are required, the cost of pumps to attain these velocities, and the cost of power to operate them at the higher friction losses make the method economically impractical.

Control With Acids

The shifting of pH of the water was one of the earliest methods of control of fouling organisms attempted. Plant-scale experiments were carried out with partial success as early as 1915. Extensive studies of the effect of lowered pH on various mollusks were later carried out by Prytherch (86, 87) who was searching for an easier method of opening oysters to expedite commercial shucking. The natural pH of sea water and its buffer capacity varies slightly from place to place in the open sea (88) and varies considerably where industrial pollution is present. Fig. 8 is a typical curve of a buffer capacity of sea water, as measured by glass-electrode titration of samples taken in the open sea off the New Jersey coast.

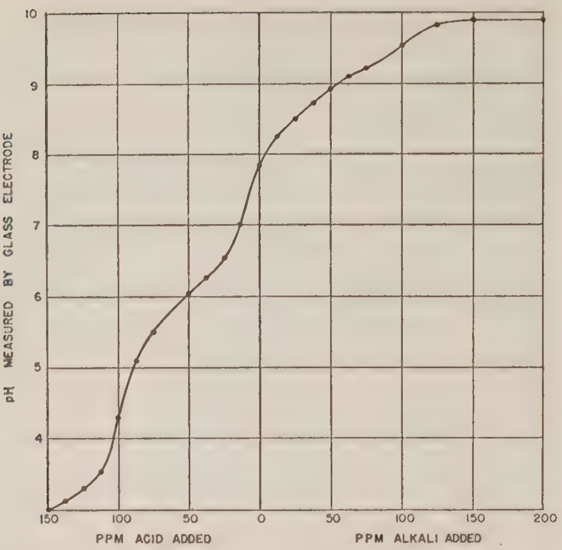

Fig. 8 Buffer Capacity of Sea Water Measured as pH by Glass Electrode With Sulphuric Acid and Sodium Hydroxide
(The curves remain flat at pH 9.9 until all calcium carbonate has been precipitated.)

It has been found that maintenance of pH between 2 and 5 depending upon the organism, and for periods varying from 1 to 3 hours will anesthetize the average *Lamellibranchia* and cause the shell to open sufficiently wide to permit insertion of a knife. Considerably longer periods are required actually to kill the organism. Corrosion, at these pH values, particularly of brass condenser tubes, is serious. As will be noted from the curve, 150 ppm acid is required to obtain a pH of 3. Translated to plant scale on a 25,000-kw electric generation station, it would require 5625 lb of 60-deg Bé sulphuric acid for a 3-hr period. Computed at current prices of $1.25 per cwt, that would amount to $70 per day of treatment. Corresponding increase in cost would, of course, occur in larger plants. Lower concentrations are useless. Ritchie (10) found that 10 ppm of sulphuric acid in water had no effect on mussels after submergence for 240 hr.

Control With Antifouling Paints and Surfaces

A large amount of carefully detailed experimental work and large-scale tests have been carried out by the United States and British navies and by various laboratories and paint manufacturers in an attempt to discover antifouling paints and surfaces for ships' bottoms. Literally thousands of patents have been issued covering various surface treatments to prevent the accumulation of fouling organisms. Paints containing as wide a variety of materials as mercurials, arsenicals, silicates, lead, copper, zinc, strychnine, cyanides, phenols, creosote, resins, asphalt, hair, guano, asafetida, and cow dung have been suggested (89). A smooth surface, while it will discourage fouling, will not prevent it, for even a smooth plate-glass panel will foul. Some authors (90) have suggested that paints can be compounded so as to slough off at high rates and take the load of fouling organisms with it. However, the required rates are high enough to make the method impractical.

Copper and copper-bearing paints have been found to be the most efficient antifouling materials, and recent exhaustive tests (91) have indicated that the antifouling properties of copper-bearing paints are directly related to the leaching rate of the metallic copper. Means of making laboratory determinations of leaching rates which correlate with fouling determinations have been devised (91).

Antifouling paints, which necessarily leach out material and become porous, should never be used to prevent corrosion. Protective primers of known corrosion-preventative ability should always be used under antifouling finishes.

All antifouling finishes eventually lose their efficiency; most of them after a single season. In long cast-iron pipe lines and on cement tunnel surfaces, the surfaces are too rough to make the use of paint economical. This is particularly true in plants where dewatering once a season for the renewal of the painted surface would be extremely expensive, as well as creating a hardship due to the required plant shutdown. On ships' bottoms and other metal surfaces which must be painted at regular intervals to prevent corrosion, it is the best method of preventing fouling yet devised.

Control by Screening

Water inlets of all power stations and other large users of industrial water are screened. However, to have a screen fine enough to catch the larvae forms of the fouling organisms, which are less than $^1/_{100}$ in. at early stages of development, is totally impractical. Any screen which would catch such organisms would quickly clog with microbiological accumulations, and unless made of corrosion-resistant material, would soon become permanently blocked with corrosion products.

Poisoning With Active Poisons

Various active poisons have been suggested as controls for marine growths. Cyanide has been suggested but has been rejected because of extreme danger to human life.

Some plants have used coal oil, gas-oil drip, kerosene, creosote, and similar oily products for control. Sections of the circulating-water tunnels between high and low tide become coated with these materials and become unsatisfactory places of attachment for fouling organisms. Some control is thereby obtained but no control is effected below the low-water line. Any method using a poison which is not dissipated, or consumed by mixing with other sea water, is dangerous in that it is likely to kill near-by oyster and clam beds and to cause public-health hazards at near-by beaches. Release of such poisons could well become the subject for damage suits and injunctive relief by the owners of proprietary oyster beds near the industrial plant using such poisons. Also, in almost all cases the cost of these poisons at the required dosage are prohibitive.

Other chemicals are useful in the control of particular organisms. For instance, quicklime spread over oyster beds at the rate of 400 lb per acre will kill starfish without affecting the oysters. This material burns the soft flesh of the starfish and causes lesions that fail to heal (92).

A patent (93) has been issued covering the use of cyanide in conjunction with chlorine for freeing a ship's bottom of fouling organisms.

Control by Chlorination

Chlorine is the most economical and widely used means of controlling fouling organisms in both salt- and fresh-water circulating systems. It has proved successful in many plants throughout the world. A few plants have experimented with chlorine and have failed to achieve control. These failures have occurred because of lack of appreciation of the need of proper residuals (i.e., active chlorine left in the water), proper treatment periods, proper variations of treatment with breeding periods, and proper control and distribution of chlorine in the circulating water.

Early experiments using chlorine have already been detailed.

Power stations scattered along the Atlantic coast from Massachusetts around the tip of Florida and as far along the Gulf coast as Corpus Christi have chlorinated successfully. The organisms thus controlled have covered a wide range of species.

Cursory details of English experience (94) and the installation at the United States Naval Air Station at Quonset Point, R. I. (95), have already been published.

It has been reported that successful control of *Mytilus edulis* has also been obtained with chlorine at the Corporation Power Station at Belfast and Dublin, Ireland, and Brighton and Southampton, England.

Early attempts using chlorine were based on continuous chlorination. Later short intermittent treatments were found unsuccessful. We have now found that properly spaced intermittent-treatment schedules are more economical than continuous treatment and are completely satisfactory. It will be remembered that all fouling organisms have a spat or larvae stage during their sexual reproduction and that infections in new areas can begin only by the ingress of such larvae. Therefore if the larvae can be killed at regular intervals, before they have completed metamorphosis, no new fouling will occur. In this the design engineer is fortunate, for most organisms during metamorphosis have a higher metabolism than at any other time in their lives and therefore are more vulnerable to poisoning.

It is obvious that if chlorination is carried out periodically so as to kill all the larvae in the tunnel, and is then repeated before any new larvae that enter the tunnel after treatment stops have had time for complete metamorphosis, complete control will be established. Such a statement is, however, an oversimplification of the problem. It is always possible, and will occasionally occur, that some larvae will arrive in the tunnel in an advanced stage of development and will complete metamorphosis almost immediately. When it is realized that a normal fouled shore line may contain a thousand million barnacles per mile and that these will release a million million larvae, or that a single *Mytilus edulis* may release as high as 25,000,000 eggs, it will be realized that only a very small percentage of the larvae need escape to cause serious difficulty.

A distinction should be drawn between complete prevention of fouling and substantial reduction or control of fouling. In all cases where fouling must be completely prevented, continuous chlorination during the fouling season must be used. However, where control only is required, intermittent chlorination may be used more economically.

In those cases where intermittent preventative treatment is to be used the lines should be purged by continuous treatment for short periods at regular intervals. Glass flanges should be inserted in pipe lines or test blocks should be inserted into tunnels and observations made at weekly intervals. As soon as the residual fouling that is not being prevented by the intermittent treatment, reaches the point where the organisms threaten to cause plant operating difficulty, then a corrective treatment should be instituted. This treatment will consist of chlorination at higher residuals and for longer periods than the preventative treatment. The reason for this longer period is obvious, since all of the *Lamellibranchia* are capable of closing and remaining closed for long periods. Chlorination periods must be extended until the organisms are forced to open their shells to obtain food or oxygen.

Observations by the author on experimental troughs set up at the inlet slip of the power station of the New York, New Haven, and Hartford Railroad at Cos Cob, Conn., through the courtesy of Mr. Sidney Withington, Mr. E. F. French, and Mr. John Coolidge, will illustrate the method of killing adult organisms. A large group of shelled *Mytilus edulis* of varying size was removed from the piers near the site of the experiment and placed in untreated wooden troughs with fresh sea water continuously circulated through the troughs. Time was allowed for the organisms to become acclimatized and no treatment was begun until all specimens were fully attached by byssus threads. Chlorination was then begun in different troughs at levels sufficient to yield 2.5, 5, and 10 ppm chlorine residuals.

Fig. 9 illustrates the rate of detachment and rate of killing of these adult organisms. It will be noted that the mussels break their byssus threads and attempt to migrate to more favorable environments before chlorination actually kills them. Killing, in this case, is defined as reaching a state such that when the organism is removed to clear fresh sea water it does not recover and in a few hours or days it has opened its shell and actual decomposition has begun.

Most larvae, as contrasted with adult forms of fouling organisms, are killed by chlorine residuals of 0.5 ppm applied continuously. This has been confirmed by experiments at various places along the Atlantic Coast from Massachusetts to Florida. However, on one plant scale operation in Virginia 0.5 to 0.6 ppm chlorine residuals maintained continuously failed to control mussels and barnacles.

In another case, an electric plant in New England chlorinated

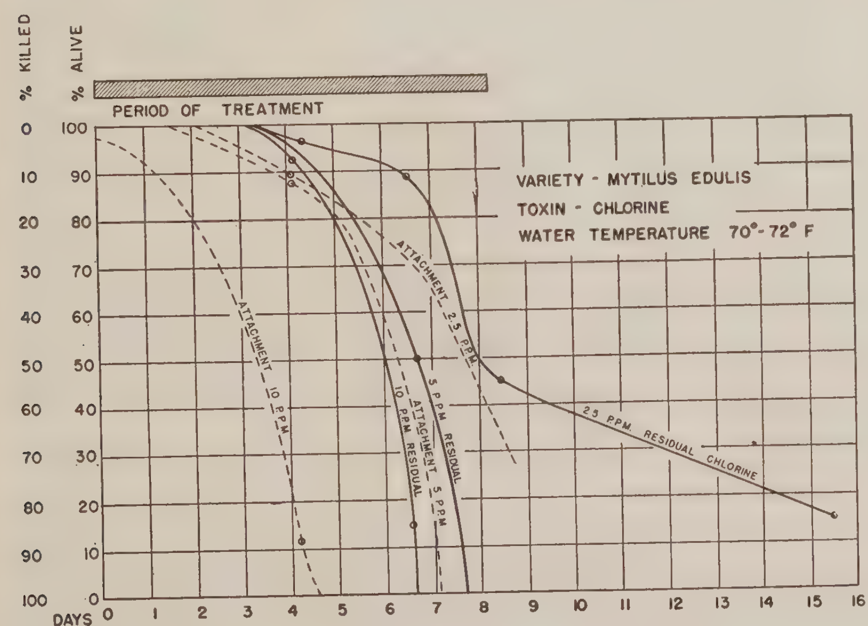

FIG. 9 TIME REQUIRED TO FORCE MUSSELS TO DETACH AND TO KILL MUSSELS IN VARIOUS CONCENTRATIONS OF CHLORINE

during one season at 0.5 ppm chlorine residuals on schedules of 20 min each, six times per day, and obtained complete slime control on condenser tubes, but showed no noticeable reduction in their annual accumulation of 600 cu ft of mussel and barnacle shells. The following season the same plant chlorinated at residuals of 0.7 ppm on a schedule of two 1-hr periods per day. The accumulation that year was 25 cu ft. Further reduction could have been effected.

In June, 1944, the plant of the Montaup Electric Company in Somerset, Mass., removed 20 tons of growth from its tunnels. This was considered a normal annual accumulation. Chlorination was started in January, 1945, and examination in June, 1945, showed less than $^1/_2$ ton of fouling-organism accumulation. Observation indicated that most of this had accumulated prior to the beginning of treatment. Because of physical variations among different plants with regard to water-circulating tunnels and the piping arrangements, as well as predominating fouling organisms, these experimental results and previous plant experiences should be used as a basis of design in other plants only with extreme caution.

Care should also be taken in instituting plant scale operations. For instance, in the beginning of treatment of a circulating-water system that has been in use for some time, a large quantity of organisms, usually sufficient to block tube sheets, and often sufficient to cause serious damage to circulating-water pumps, will be released if curative treatment is immediately applied. To prevent this, chlorine residuals should be held at low levels and chlorination should be short at the beginning, gradually lengthening as less and less fouling organisms remain in the tunnel.

In the preventative treatment, extreme care must be taken that the regularity of intermittent schedule be uninterrupted. The author inspected one tunnel that had been under treatment. Because of failure to obtain chlorine in the required time, the plant had been without treatment for 4 days. No continuous curative treatment was attempted to fill in the deficit. Three months later a full $1^1/_2$ in. thickness of *Pecten* of nearly uniform size had developed. During the 2 years following when no interruption in treatment occurred, no fouling was found.

The chlorination of salt water carried in steel lines has certain distinct difficulties. If continuous treatment is used, the slime film which ordinarily would inhibit salt-water attack on the line is completely removed and corrosion is aggravated. Cases have been observed in which $^1/_4$-in-thick scales have developed on steel lines within a few months. However, if corrosion-resistant alloy or cast-iron lines are used so that the natural aggressive action of salt water is minimized, chlorination will prevent bacteriological corrosion (96, 97, 98) and thus materially increase metal life. Where the water is naturally aggressive and the use of steel lines is indicated, intermittent chlorination, which will permit the reformation of protective slime films during idle periods, will minimize salt-water corrosion and yet maintain macroorganism control and also heat-transfer efficiency. Where the water is not naturally aggressive, such as is normally the case in fresh-water lines, continuous chlorination at properly controlled residuals will reduce rather than increase corrosion rates.

The means of applying chlorine to large circulating-water flows should be carefully considered. Chlorine is only slightly soluble in fresh water and is still less soluble in salt water. For this reason special apparatus for obtaining completely dissolved chlorine in water solution must be provided. In order to obtain marine-growth control in large tunnels and pipe lines, the chlorine solution must be evenly distributed through the circulating-water flow. Unless wide experience is available as to the type of flow that will be found in screen wells and suction chambers, it is likely that a point of application and means of diffusion will be selected which will completely free one area of serious growth and permit uncontrolled growth in other areas. It also should be remembered that while chlorine in the low concentrations required for the killing of these organisms is not corrosive to normal materials of construction, it is highly corrosive in higher concentration and particularly if released as a gas. Therefore, if adequate mixing and dilution are not provided local areas of high concentration may severely corrode pump bells, impellers, and casings.

The chlorination of circulating water will have no adverse effect on oyster or clam beds lying off shore nor on near-by bathing beaches. This can be readily appreciated when it is realized that the "chlorine demand" of normal sea water is such that the mixing of chlorinated water with an equal volume of sea water will eliminate or materially reduce the residual chlorine so as to be no longer toxic to oyster beds. The residuals carried approximate those used in swimming pools, and therefore if pH is maintained as it will be by the natural buffer capacity of sea water, beneficial rather than harmful effects would occur from swimming directly in the discharge water.

Throughout this discussion the term "chlorine residual" has been used to indicate a free chlorine residual or active HOCl as contrasted to a bound or chloramine residual, where the chlorine is bound by reaction with ammonia or amino compounds. Recent work (99, 100, 101) has indicated the wide difference between the killing power of chlorine and chloramine residuals. Chloramine residuals have distinct use for specific purposes since they are more stable in the presence of organic matter. They are therefore highly useful for the sterilization of swimming-pool water, and stock and pulp systems in paper mills. However, where ammonia content is not high, and this is true in most applications where marine fouling by macroorganisms is a problem, the use of free chlorine is recommended. Unfortunately, even if no ammonia is added, chloramine residuals often still occur because of the high ammonia and amino-nitrogen content of water which has been subjected to organic pollution. In those cases a question arises as to whether it is more economical to use "Break Point" chlorination and remove the ammonia, or to take the longer killing periods and higher required residuals of the chloramine. The determination as to whether a particular water with a particular chlorine dosage and contact period is yielding a chlorine or chloramine residual can easily be determined by the Laux-Nickel test (102, 103) or by titration with arsenite (104).

Chlorination should be carried out only at the higher residuals necessary to kill macroorganisms in their larvae form during those periods when the larvae are in the water. Naturally, most industries will desire to chlorinate at lower residuals during the remainder of the year to prevent formation of microorganic slime and thereby maintain heat-transfer efficiency (105).

The cost of marine fouling control with chlorine can usually be economically justified. A 25,000-kw station will usually be able to achieve control for about $3.50 per day during the fouling season. More than this amount will be saved due to improved vacuum as well as reduction in cleaning cost and outage resulting from marine fouling.

The time of year during which fouling will occur and rate of fouling will be dependent upon the fouling organism responsible for the difficulty, upon the water temperature, and upon the particular season. Seasonal variations are in turn dependent upon whether a large or small group of adult organisms succeeded in establishing themselves in the near-by waters during the previous reproductive periods, and whether these organisms survive to the next breeding time. Conditions of tide, particularly as it affects water temperature, will also influence fouling periods and rates. These factors are too numerous and varied to permit accurate forecasting. To obtain this type of informa-

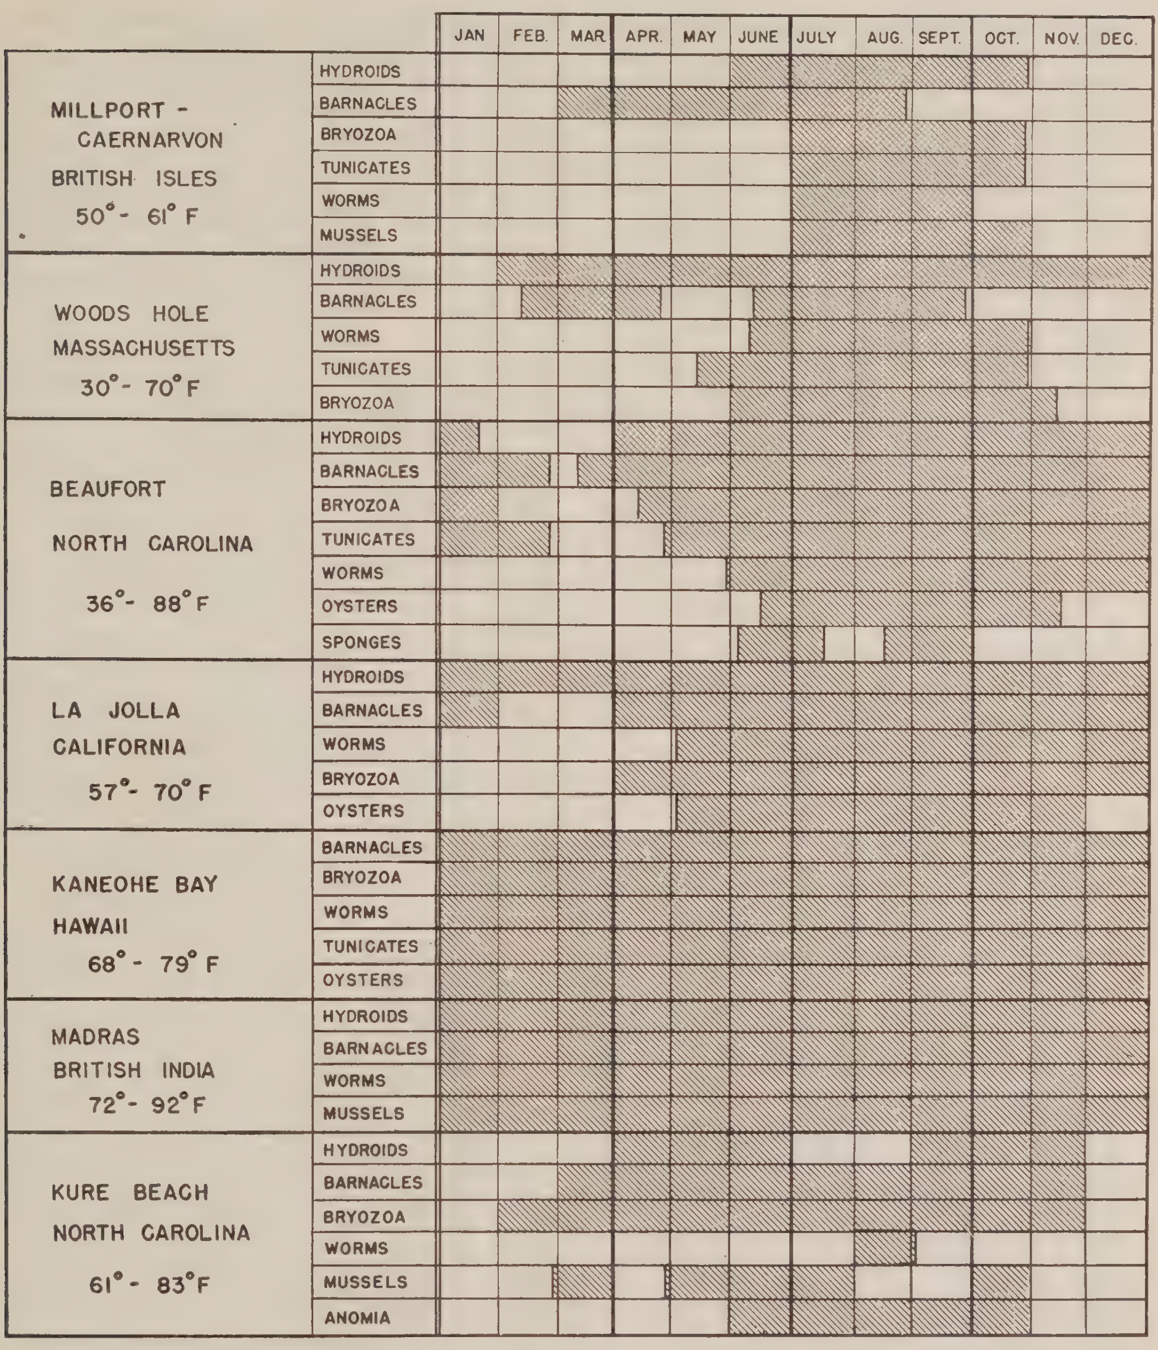

Fig. 10 Fouling Periods in Various Harbors

tion, the William F. Clapp Laboratories of Duxbury, Mass., and the Woods Hole Oceanographic Institution of Woods' Hole, Mass., have maintained for a number of years test blocks and panels at a large group of stations on the Atlantic and Gulf Coasts and elsewhere. These specimens are returned to the laboratories at regular intervals and examined to determine both settling rates and growth rates for the particular station and time. From these examinations much valuable information has been amassed.

The technique of setting such panels in order to obtain reproducible results over a long period is beyond the scope of this paper. Color and material of the panel depth and angle of submergence, type of support, and location of the tested area with respect to contaminating influxes and tidal rips are a few of

the factors to be considered. While results obtained from such test blocks cannot be used to forecast particular conditions at a station unless those tests are taken from the circulating flow of that particular station, some of the published results may be of interest (46). Fig. 10 indicates the fouling periods at widely scattered points.

In shipping or storing specimens for later examination, they may best be preserved by draining surplus water from them and placing in sealed bottles containing 98 per cent alcohol.

Designing for Fouling Conditions

In the design of new plants using fresh or tidal water likely to foul, two questions must be answered: (*a*) What will be the extent and nature of the fouling organism? (*b*) What design steps must be taken to overcome them?

Often forecasts of fouling conditions have been made, based on studies of test panels or of fouling on logs, piers, rocks, and structures near the site of a proposed plant, or on studies of fouling conditions at an adjoining plant.

Such forecasting is extremely dangerous and should never be relied upon. Industrial water supplies taken from large bodies of water usually afford ideal conditions for invertebrate growth in their screen chambers, pump-suction wells, supply pipes, and flumes.

The sessile organisms naturally dependent upon water motion to carry their food to them will thrive and grow at rates unprecedented on the previous shore line. This is naturally due to water velocities usually in the range of $^1/_{10}$ to 2 fps. Differentials of growth rates as high as 3 to 1 have, for instance, been recorded for barnacles in wave-swept waters as compared with barnacles living in comparatively still tidal water. Still faster rates of growth have been noted in industrial tunnels. Where the water taken by the industrial plant is used for cooling an additional factor which cannot be forecast is introduced. The enormous heat output in cooling water from a large power station or refinery is often sufficient to shift the over-all temperature of the body of water as much as 15 deg F. This shift in water temperature may be enough to encourage year-round growth and reproduction of an organism that has previously been dormant a large part of the year, or may permit overwintering and luxurious growth of some organism which has been previously subject to seasonal extermination.

A good example of this occurred in the Southwest during the war. A new plant was to be erected on tidal water and take its cooling-water flow from a brackish stream only a few hundred feet from the inlet of an existing oil refinery. Design engineers, basing their judgment upon the fact that the existing plant had experienced no difficulty, and upon a belief, based upon rather limited experience, that no organism could thrive in varying salt-content water, provided no protection from fouling. Luxuriant Bryozoa growth shut down the plant before a single year of operation had been completed.

For another example, there are two power stations in Rhode Island whose cooling-water inlets are a city block apart. Negligible differences exist between the plants in so far as salinity, water temperature, sewage pollution, and other normal factors are concerned. The plant upstream from the sea has had severe fouling with *Mytilus edulis;* the one nearer the sea has had none. The difference probably exists in variations in river bottoms. Some plants have experienced severe fouling recently after a period of comparative freedom, probably due to changes in industrial and domestic pollution in their water source.

It should be realized that even though conditions are known to be unfavorable to the fouling organisms that exist near the proposed plant site, these same conditions of salinity, temperature, and pollution may encourage luxurious growth of some other organism, not now native, when changed water flow and temperature due to the new operations occur.

It is only sound engineering to design as though fouling will occur. Satisfactory design will require that all portions of the system be accessible for inspection and manual cleaning; and preferably be capable of being readily dewatered; but such manual cleaning should be considered only as an emergency measure. From the standpoint of efficiency, of continuity of operation, and of cost of cleaning, control methods as previously discussed are more satisfactory than manual cleaning. Designing with such control methods in mind from the very inception of plans will often substantially reduce corrective construction and operating costs.

Discussion

S. P. Ewing.[3] This paper is an excellent condensation of the extensive and scattered information on fouling organisms as related to circulatory salt-water systems, and the Bibliography will be helpful to those who wish to learn more about this interesting subject. The paper is another example of the economic and engineering value of pure science. Certainly the engineer cannot expect to deal effectively with the fouling problem unless he uses the knowledge of the marine biologist.

There is little that the writer can add to the subject of the paper. But it might be worth while to mention a few other instances where the engineer must deal with fouling organisms, and show how in each case the problem is an economic or engineering problem where the marine biologist could contribute to the solution.

The salt-water piping system on ships is similar to the shore cooling system. The fouling problem is in some respects more important because the piping is designed for relatively high velocities, the pipes are relatively small so that comparatively little fouling may greatly reduce the capacity. On combat ships, failure of the piping at a critical time might result in loss of the ship. Hence it is not sufficient to be able to remove the fouling at intervals. The piping and also the hull must be kept free of fouling at all times because nearly perfect performance at all times is essential. It is impossible to design and operate the ship's piping so that the water velocity exceeds the minimum required to prevent fouling. Nor is it possible to close completely parts of the system at regular intervals, and thus kill small attached organisms by suffocation. The use of chlorine or other poisonous chemicals is objectionable on combat ships because of space limitations and the added hazard of these materials in case of battle damage.

The possibilities thus seem to be limited to the use of (1) copper alloys which will prevent fouling, (2) antifouling paints on the interior of the pipes, and (3) chlorine generated electrolytically from sea water. One might think that with a large power plant available, it would be a simple matter to produce enough chlorine from the electrolytic decomposition of sea water to prevent fouling in salt-water pipes. The work that has been done by the Bureau of Ships and the experience on ships indicates that the best solution is to use copper-nickel pipes, which corrode enough to prevent fouling for at least 1 year and then use antifouling paint or abrade the interior of the pipe so as to restore its antifouling characteristics. With steel pipes, the best solution is the use of antifouling paint.

Another well-known instance where marine organisms interfere with the activities of man is the damage to wooden structures caused by marine borers. Here the best defense is to treat the wood so that these organisms are discouraged from boring in it, or to cover it with a material which the borers cannot penetrate. The method used since ancient times to prevent attack on wooden

[3] Bureau of Ships, Navy Department.

Note: The opinions expressed in this discussion are not to be construed as those of the Navy Department or the Naval Service at large.

vessels has been to cover the underwater hull with sheet copper. This method was used extensively on early steel and iron vessels. An elaborate and expensive system of wooden sheathing was used between the copper and steel to control the galvanic couple and thus prevent rapid corrosion of the steel.

There are numerous types of structures where fouling in itself is not particularly objectionable. For example, fouling on a wooden pier does not interfere with the proper functioning of the pier, so long as the organisms do not penetrate the wood and weaken it. Fouling on steel piers, lock gates, buoys, submarine nets, and submerged pipe lines is not particularly objectionable so long as the organisms do not penetrate the organic protective coating and cause corrosion of the steel. On lock gates, buoys, and submarine nets, the added weight may affect buoyancy because the shells are heavier than the water. However, the effect on buoyancy is only about $^1/_4$ of the total weight in air of the fouling growth.

It is well known that when certain barnacles grow on relatively soft bituminous materials and some paints, the shell of the barnacle gradually penetrates the organic material so that after the barnacle reaches its full growth its shell is in intimate contact with the steel over nearly the entire area of its base. Serious corrosion of the metal often occurs in this area, especially if the electrical conditions are favorable for corrosion. This situation has occurred on lock gates and submerged pipe lines. Other unidentified marine organisms are reported to attack asphalt coatings in a somewhat similar manner.

There are several possible ways to prevent damage to the coated metal. An antifouling paint might be applied over the bituminous coating, but this will be effective for only a limited time, since most antifouling paints lose their effectiveness in less than one year. Tests may show that a sufficiently hard coating will prevent penetration. This is certainly the case with barnacles. A sufficient amount of hard mineral filler in the bitumen may be an effective means for discouraging other types of boring or digging animals. If the attack of the marine organisms on the coating is rather slow, and only a few holes are made in a relatively long period, the use of cathodic protection to prevent corrosion at the holes in the coating may be the most economical solution. Each case will have to be studied in order to arrive at the most effective and economical solution; and the solution will probably require identification of the culprit, and a knowledge of its life history.

L. W. Hutchins.[4] This paper fills a gap in the literature of fouling problems. The engineer is presented with an introduction to some of the complex biology involved in the fouling of water circuits, and, indeed, of any fouling. On the other hand, the biologist is offered an excellent review of the practical problems from the engineer's standpoint. The number of new observations recorded and the extensive review of the practical literature, which generally does not come to the attention of biologists, are particularly worthy of praise.

The author has pointed out very well the extent to which the solution of engineering problems must depend on competent biological knowledge. His remarks on the inadequacies of fouling control by screening, on the possible variations of control by heat, and in particular, the variable dosages of chlorine which must be adjusted both to the types of organisms present and the stages of their life histories are good cases in point.

It happens not infrequently that biologists are not able to give the best possible consulting advice about fouling problems simply from ignorance of the practical aspects of the situation. This situation can be alleviated by papers such as this which present both sides of the picture.

[4] Woods Hole Oceanographic Institution, Woods Hole, Mass.

Cases have come to the writer's attention in which plants and designers have refused to allow dissemination of the factual information about the fouling problems they have encountered, in the rather naïve belief that the occurrence of fouling in their setup was a reflection on the abilities of the operator or designer. That view is quite incorrect.

The only sound procedure, as the author points out, is to design with the expectation—a practical certainty—that fouling will occur, and to make suitable provisions accordingly for inspections, cleanouts, and, if desired, attempted control. The failure of any intended control system, moreover, does not necessarily reflect on the engineer, but as often as not, on the inadequacies of the biological knowledge concerning his problem.

Improvement in this general subject can be obtained only by a thorough understanding of both points of view so that the biologist can know the lines which his investigations should follow, and the engineer can have a true picture of the information available for application in designing and operating control measures

The need for more exact biological knowledge has become increasingly clear along two lines. In so far as the economical use of control measures must involve their quantitative relation to the incidence of fouling, it is obviously desirable to know as fully as possible the fouling expectancy and the effects of factors modifying it. The particular fouling population which will develop in a highly localized site appears to depend on the natural populations to which that site is accessible. In harbors and other such locations generally of interest to industry this question of accessibility appears to be highly complicated. The set of local currents may profoundly alter the probable accessibility as judged by simple geography. Pollution, which may be either somewhat beneficial or detrimental to the growth of individual species, depending upon its nature and extent, is another factor believed to be of very great importance in such areas. Far too little is known, however, about the effects of individual contaminants to permit predicting localized harbor fouling conditions with any assurance. There is a need for further facts about all such factors modifying the incidence of fouling.

The second line along which further exploration is indicated is that of the knowledge of toxicity and factors which may be utilized in control of fouling. The investigations of possible toxics other than chlorine and heavy metals can hardly be said to have been prosecuted with any vigor. Knowledge is inadequate even as to possibilities, particularly in the line of organic toxics. Similarly, with reference to chlorination, it would seem worth while to investigate much more thoroughly than has been done the problem of control by intermittent treatment. Even with the intermittent applications now in use, the cost appears sufficiently high so that possible savings would more than justify considerable research aimed at the reduction in chlorine usage. This is a problem in which the biologist must go first, studying the effects of various concentrations and of various time dosages on a wide variety of organisms and attempting thereby to develop generalizations which can be put into practice by the engineer.

The writer feels that the greatest importance of the paper is as an aid to the further profitable co-operation between professional biologists and engineers.

F. L. LaQue.[5] On the basis of some of our investigations in related fields, the writer is able to confirm some of the author's conclusions:

1 We have found that when sufficient chlorine is used to prevent the development of slime films, as well as fouling organisms,

[5] In Charge Corrosion Engineering Section, Development and Research Division, The International Nickel Company, Inc., New York, N. Y.

corrosion of steel pipe lines by sea water moving at high velocity is increased, presumably through the loss of the protective effect of slime films and accumulations of macroorganisms. At the same time, there has been some evidence that small amounts of chlorine in sea water retard rather than accelerate corrosion of some nonferrous alloys, such as Admiralty brass and 70:30 cupro-nickel, perhaps through some reinforcement of protective films. Likewise, the prevention of fouling and perhaps, also, a slight increase in the oxidizing capacity of sea water due to the presence of a small amount of chlorine, have been found to exert a beneficial effect on the performance of stainless steels.

2 Our observations generally confirm those of the author with respect to the influence of water velocity on the fouling of smooth surfaces. We have found that macroorganisms are not likely to become attached at steady flow rates much above about 3 fps, but once attached during periods of lower velocity flow, they may be able to retain a foothold and grow in contact with water moving at much higher velocities, e.g., 10 fps.

3 Examinations of many specimens of steel covered with fouling organisms after exposure to sea water have failed to indicate any significant effect of the organisms in accelerating corrosion through differential cell action as suggested by the author. However, with highly alloyed steels, such as stainless steels and other passive alloys, local attack believed to be due to differential cell action under fouling organisms is common.

Since the possible effects of chlorination on corrosion of equipment are of natural concern to those contemplating the use of chlorine to prevent fouling, it is hoped that more extensive investigations of this phase of the subject, and particularly with respect to intermittent chlorination, will be made and that the results will be made available.

S. T. Powell.[6] The author has given an excellent history of methods undertaken for the control of biological microorganisms responsible for fouling condensers and similar equipment. In addition to this valuable record, he has presented a very clear and concise discussion of the specific types of organisms which have been responsible for such difficulties and has submitted a constructive review of miscellaneous corrective treatments and their application. The paper also includes one of the most complete bibliographies which has been published, and this material alone is an invaluable contribution to this subject.

That portion of the paper dealing with "control by chlorination" is a concise statement of the value and limitation of this type of treatment and should correct many misconceptions as to the application of chlorination.

In general, the paper is a worth-while contribution to the literature and represents an authoritative reference work with a high degree of reliability.

Lester Randall.[7] The writer in support of the facts given in the paper is able to provide some results obtained at the power station of The Connecticut Power Company, Stamford, Conn.

The Stamford station has grown from the early days of the industry so that when an additional unit of 25,000 kw capacity was installed in 1940–1941, a complete new intake system for this unit was necessary. The circulating pumps are propeller type, located in the screen house on the waterfront. The intake tunnels are two 36-in. cast-iron pipe lines from the pumps to the condenser, one line to each side of the divided water box. The combined length of the two lines is 262 ft.

Circulating pumps for the old portion of the plant are of the submerged slow-speed centrifugal type, located in another screen house also on the water front. The intake tunnel for the old plant is also 36-in. cast-iron pipe but laid out as a loop, like a hairpin, with the two ends connected through valves to a header located near the pumps. Take-offs to the condensers are on one leg of the hairpin so that in effect there is a cooling-water header supplying the old condensers, this header being fed from both ends. Division valves make it possible to inspect sections of this line while other sections are still operating. The whole length of this loop, including leads to condensers, is 680 ft, but only 570 ft are in active use, the remaining section being connected to units not regularly operated, and because of a closed division valve very little water circulates through it.

The new unit was put in service during October, 1941. Intermittent chlorine treatment was started in January, 1942, for this unit and in April for the old part of the station. Prior to this time no method of controlling intake fouling had been used. Heavy growths occurred in the pipes and had to be scraped out at least twice a year. The fouling included all sorts of marine animals but mussels predominated.

The new plant has operated as a base-load unit, being shut down over a week end every 6 to 8 weeks for inspections and maintenance. The old plant seldom operates over a week end and when shut down no chlorine is fed, although a small amount of water is kept circulating through the lines.

Circulating water is taken from the harbor, an arm of Long Island Sound. Normal water velocities during the summer in the several pipes are 5 fps for the new plant; 6 fps for a 325-ft section of the old intake piping; and 7.5 fps for another 240 ft.

Until July 20, 1942, the program for chlorination was three 20-min periods per 24 hr, at which time the treatment was increased to four 20-min periods. The following year, 1943, the program was changed to two periods of 60 min each 24 hr. This was started May 12, 1943, and has been in effect most of the time since.

Residuals have been carried at 0.5 ppm, except during July, August, and September, when it has been kept slightly higher, from 0.55 to 0.65 and occasionally, for short periods, to 0.7 ppm. Samples for residual determination are taken from the condenser outlet in the new plant and condenser inlet in the old plant.

Results have been gratifying. Considering the old plant only, the 1942 program of three and four 20-min chlorinating periods per 24 hr reduced the total amount of material to be removed manually by 50 per cent. The two 60-min periods per 24 hr has reduced it by more than 95 per cent when compared with conditions before chlorine treatment.

Results for the new plant are even more interesting. From October, 1941, to August 12, 1945, nearly 4 years, a total of 10.5 cu ft of material, all mussels, has been removed from the 262 ft of 36-in. pipe and 8-in. suction lines to the cooling-water booster pumps. One half of this total was taken out the first year, 1942, when using the 20-min chlorinating period. Probably an important reason for the small amount this first year was the smooth condition of the pipe surfaces, which had been given a shop coat of bitumastic paint.

Prior to chlorine treatment, it was regular operating practice during parts of the year to drain half a condenser at night and pick out the mussels and shells that were wedged in the ends of tubes. Sometimes it was necessary to do it during the noon hour. This operation has been completely eliminated. Rubber plugs are blown through all condenser tubes every 4 weeks to remove such shells as do lodge in the tubes and might cause failures.

The cost of chlorination for the combined plant is 15 tons of chlorine per year; generation for the same time is up to 300,000,000 kwhr.

Considerable time has been given to studying mussels. The beginning and duration of the spawning season and the rate of

[6] Chemical Engineer, Baltimore, Md. Mem. A.S.M.E.

[7] The Connecticut Power Company, Stamford, Conn.

growth are important considerations. Four years of observation has pretty well determined that with the present chlorine treatment, mussels will not begin to appear in the pipes until July 1. It has also been determined that if the pipes are cleaned after October 15, they will remain free of any growth except a scattering of barnacles, for the following 8 months. For removing such mussels as do get started two cleanings are made, the first about August 20, the second about October 20. Using this schedule, mussels that may get started are removed before they get large enough to crowd each other loose from the pipe surface and be carried along by the current.

These results apply to Stamford station. Other stations must determine the treatment best suited for their particular conditions. Some of the factors to consider are nature of tunnel surfaces; velocity of water; size of tunnels; continuity of service and chlorine treatment; nature of fouling organisms.

The author suggests installation of glass inspection plates or hanging test pieces in tunnels. The writer considers that method unreliable, especially for salt-water plants.

In the old plant, during the summer of 1945, a solid blanket of mussels covering 8 ft of 36-in. pipe became established in a section between a condenser take-off and a closed division valve. Also a good-sized patch started in the 24-in. connection at one side of one of the old condensers. Why these patches start in an otherwise clean pipe is difficult to explain. In the new plant, water for the turbine coolers (hydrogen and lubricating oil) is taken through 8-in. suction lines to two 750-gpm booster pumps, one on each main intake pipe. One pump is operated at a time for 1-week intervals. Each summer, mussels completely blanket the insides of these suction lines. Also, in the new plant mussels completely filled the crease in the reinforced rubber expansion joints just below the water boxes.

So far only intake pipes have been mentioned. The pump and screen wells do collect growths on the walls. This is due to a design that does not give good mixing of chlorine with the water in the wells. Chlorine feed pipes are placed just in front of the pump suction, between the pump and the screen, so the chlorine passes directly to the pump and into the pipes.

Chlorine has eliminated all non-shell-bearing animals, slimes, etc., and nearly all mussels from the circulating-water piping. However, barnacles do not seem to be affected, in fact it would seem they like the clean surfaces. In the old-plant intake lines they will nearly cover the surface by midsummer. They are hard to scrape off but because they are so securely fastened to the pipe walls and are so small, they are not a hazard in operation of the plant.

W. D. Bissell.[8] At the time the chlorination system was installed at Montaup Electric Company one of the condensers had been completely retubed the previous year and another condenser was completely retubed at the time the treatment was started.

The selection of sampling points for observation and control was carefully considered and these were located at the discharge elbow of the circulating pumps, each condenser discharge elbow, half the distance along the pump discharge tunnel where house service pumps are located, and also at the combined discharge of all condensers.

As the tunnel system was known to have considerable growth, extreme care was used when treatment was first started in February, 1945, in order to observe the sluffing-off of this growth. A thirty-minute cycle per day was used for about two weeks maintaining a residual of 0.3 ppm at the condenser outlet. The cycle was then changed to fifteen minutes of treatment three times daily and the residual was increased to 0.5 ppm, where it has been maintained since. No difficulty was experienced from accumulated growth dropping off during the initial cleaning period.

It was interesting to observe, during the difficulty which was experienced maintaining chlorine residual during the first month of treatment, that the discharges of the pumps would vary in chlorine residual from day to day. This variation leveled off later so that each pump discharge would indicate the same residual.

It is believed that this variation was due to the uneven deposits in the pump suction and the gradual cleaning of them resulted in the leveling off of residual at all pumps.

The greatest demand of chlorine was along the distance from the river intake screens to the pump discharges which was three or four times greater than through the condensers from the inlet to the outlet. Due to having sampling points at these important locations close observation could easily be obtained. The results were accurately logged which was of great assistance in maintaining machine control and residual control.

When the water temperature reached about 45 deg in the spring of the year the chlorine demand increased very rapidly until 50 deg was reached. From that time to 75 deg, chlorine demand was observed to be quite normal. During the period of warm water operation at temperatures of from 68 deg to 80 deg, an interesting changeable condition would occur in the foam on the surface of the condenser discharge water. This would be very dark brown for a few days at a time and would then change to a light yellow and the chlorine demand would change rapidly.

The control of chlorination was obtained by results as indicated on the condenser tubes, sheets, inlet and discharge water boxes, at regular frequent inspections. When chlorination was first started the growth of so-called moss and marine growth was about $^3/_8$ in. thick on the internal surfaces of the water boxes with some adhering to the tube sheets. After several weeks of treatment this could be easily removed by rubbing with the hand. In about three months this growth was completely removed and the surfaces could be coated with red lead.

Previous to chlorination the condensers were rather foul-smelling and it was extremely difficult for men to make repairs or to stay in them any length of time. Extended periods of working in a condenser would make a man ill. Since chlorination has been used the condensers have not been odorous to any extent, and are not objectionable for men to remain inside for extended periods to make any necessary repairs.

The purpose of using chlorination was to remove slime deposits on the heating surfaces chiefly. Mussels in the intake tunnel were of considerable nuisance and also would collect in various station salt-water lines and valves which caused considerable trouble in the past.

Chlorination has completely removed the slime and reduced the mussel growth so that it is negligible. The station water lines have been free from any growth or deposits and it has not been necessary to clean cooler surfaces, etc. Previous to chlorination such conditions as described in Figs. 2, 3, and 6 were usually found when the tunnel was dewatered.

The use of chlorination has been quite satisfactory in keeping the condensers and the condenser water system clean and we feel that good results have been obtained. However, some points have been raised such as the following:

1 In keeping condenser tubes free from slime and any organic growth by the use of chlorination, will this permit corrosive action caused from oxygen or any corrosive gases in the circulating water to attack the condenser tubes, which may shorten their life?

2 (a) Does the type of bacteria change at different seasons of the year? (b) Do they change at different temperatures? (c)

[8] Engineer, Somerset, Station Montaup Electric Company, Fall River, Mass.

Is it usual to have chlorine demands change rapidly from causes such as mentioned above?

3 In the process of first applying chlorination will chlorine demands change rapidly in initial cleaning periods?

4 Do river-bed deposits change gradually from year to year, thereby affecting the type of growth and gases in the water which may result in changes in the chlorine demand?

5 (*a*) Is it considered advisable to discontinue chlorination during the winter period when temperatures are at 33 deg or thereabouts? (*b*) Should the chlorine cycle be reduced in frequency? (*c*) Should the chlorination residual also be reduced?

6 If marine growth and fouling organisms vary from season to season at various temperatures, is not the best means of control obtained from observation of results which can actually be a guide for correct residuals, thereby obtaining positive control?

7 Since variable conditions of the tide are observed to have an effect on the chlorine residual, can this be explained?

Author's Closure

The author wishes to express his appreciation to the various discussors for their thoughtful and well-prepared contributions. The discussions papers by W. D. Bissell and L. E. Randall are interesting in that they present the viewpoint of the problems as seen by the operating man.

Mr. Bissell has pointed out a familiar observation that the chlorine demand, as indicated by the difference between chlorine dosage in the screen well and chlorine residual in the tailpipe, is made up of two parts: (1) The demand of the water itself during the time of contact permitted, and (2) the demand or absorption of chlorine by the surface accumulations on the tunnels and heat-exchanger tubes. Naturally, when large accumulations exist in a concrete tunnel, considerable chlorine will be absorbed by this organic matter until such time as it has been completely oxidized, and in most cases, has completely sloughed off. Mr. Bissell has raised certain specific questions which the writer will attempt to answer. The question as to whether the chlorination of condenser tubes and the resultant bright tube condition will permit the aggressive action of salt water, of dissolved gases, and of other corrosive fluids to increase the corrosion rate of these tubes over the corrosion rate existing in slime-covered tubes is a subject which will still bear considerable investigation. Mr. LaQue, in his discussion of this paper, seems to feel that such accelerated corrosion does not exist, and that, in fact, the elimination of the slime film and macroorganism fouling will retard the corrosion of nonferrous metals. Further research should be carried out in this field; but suffice to say, from a practical viewpoint, corrosion rates of installed tubes have never been demonstrated to have been increased by chlorination. A few cases are on record where the tube corrosion rate increased simultaneously with the use of chlorine for elimination of slime accumulations, but in all cases where the chlorine was abandoned for a period, the increased corrosion rate continued unabated.

The type of bacteria and other slime-forming organisms responsible for heat-exchanger sliming do not vary in terms of the season. However, the type of organism present at any time is dependent upon water temperature, upon food supply, and upon other factors such as oxygen content in the water. Since these factors, in turn, have seasonal variations, it is possible that specific flora will be more regularly found at certain seasons of the year. Certain microorganisms multiply very rapidly at specific temperatures, but are in practically static conditions in all but a very narrow range of temperature. Certain others are tolerant to much wider temperature conditions, and will thrive throughout the temperature range of normal circulating-water conditions. Mr. Bissell has outlined in his own discussion a very clear demonstration of the high chlorine demand of fouled surfaces during the initial clean-up period of a circulating water system. His experience is quite typical of the conditions in a normal circulating-water tunnel.

The variations of river bottom do not have a particular effect upon the growth of microorganisms in circulating water. In most cases these organisms exist free-floating in the water, and unless the river bottom is contributing changes of water conditions, such as oxygen depletion or hydrogen sulphide production, the condition of the river bottom will not seriously affect the growth of microorganisms on heat-exchanger surfaces. However, the macroorganisms, such as mussels, have only a limited field of locomotion between the point of fertilization of the egg and final point of attachment of the larva animal. For this reason, an invasion of mud over a rocky bottom, which quite frequently occurs in tidal water, may well eliminate the breeding grounds and ultimately the source of infection for macroorganisms for a given tunnel.

The question as to what changes of treatment should be made as water temperatures approach freezing is one that can be answered only after a study of the particular problem. It should be remembered, however, that temperature at which the organism is breeding is not the temperature of the water, but rather the surface temperature of heat-exchanger metal, and for this reason, even at 32 deg water temperature there may be lively growth of the microorganism. As a practical matter, chlorination should be continued at residuals sufficiently high, properly spaced, and of sufficient duration to kill the flora attached to the flume, condenser, or other surfaces.

The answer to Mr. Bissell's sixth question is again a matter of practical application of biological facts. If a station could afford to have continuous studies by an experienced biologist to determine when the spat form of each organism is present in the water, then residuals and dosage periods could easily be varied in accordance with season and water-temperature conditions, so as to yield maximum economies of chlorine use. But the average plant finds it much easier to feed chlorine at residuals sufficiently high to kill the spat form of the macroorganisms during the entire period when water temperature is sufficiently high, or seasonal advance is sufficiently completed to warrant a belief that some of the fouling organisms may be breeding.

Variations of chlorine demand with tidal conditions is quite common. The common condition of a polluted stream moving into a relatively clear estuary will yield high chlorine demands during periods of ebb-tide, due to the preponderance of river water and low chlorine demands while the tide is in flood due to the preponderance of sea water. In any particular harbor the question of what mixing will occur at various tides can become extremely complex.

Mr. Randall's report is an excerpt from the data which he has accumulated during the past six years. These experiments are the most carefully controlled and fully observed plant-scale demonstrations of the control of fouling organisms by chlorination known to the writer. I hope that Mr. Randall will publish his very carefully detailed data in the near future. His experiences have indicated some of the pitfalls which may well trap the unwary operator attempting chlorination for the elimination of fouling organisms. No plant which is circulating any salt water should permit that salt water to circulate for a period of more than twelve hours without treatment. Mr. Randall's difficulty with his dead-ends in the old station is typical of the problems which will occur if this precaution is not taken. In the placing of test panels or plate-glass windows in circulating-water tunnels, the place chosen for test must be representative of conditions throughout the entire station, and if any doubt exists as to whether the place chosen is representative, spot checks throughout the system should be made. The control of barnacles re-

quires slightly higher residuals than those required for the killing of other fouling organisms, and therefore unless barnacles are giving trouble it is uneconomical to chlorinate at these higher residuals.

In the cleaning up of fouled tunnels either when starting to control fouling in existing tunnel, or in the cleaning of a tunnel which has been under treatment and which has been permitted to foul to a limited extent by "preventative treatment" recommended in the original paper, there is always a question of the economy as to whether chlorination or manual cleaning should be used. In all cases where plant shutdown and dewatering is readily possible and access to the tunnel can be made without undue expense, it would seem advisable to choose manual cleaning. Under other circumstances chlorination might easily be the answer.

Dr. Ewing's discussion of problems related to the fouling of circulating-water systems has been very valuable in rounding out the view of the subject. The writer has had some contact with the design work involved in the production of chlorine cells for use on board fighting ships. Certainly considerably more improvement of those cells, and improvement of the antifouling materials for lining the ships' pipes is in order. Such development can best be carried on by the co-operation of all interested parties.

Dr. Hutchins' discussion of this problem from the viewpoint of the biologist will warrant careful study by the designing engineer. His warnings of the unpredictability of fouling in tidal waters should be a warning to all designers faced with this problem. His plea for effective co-operation between the professional biologist and the engineer will, I hope, encourage further publications by operating men and designers who have experienced difficulty in this field.

Mr. LaQue's authoritative discussion on corrosion is much appreciated. It is the writer's hope that further work along these lines will be undertaken within the near future.

All the discussors have been kind enough to point to the gravity of the problem of fouling organisms to circulating-water systems, and the writer trusts that these discussions will lead to a fuller appreciation of the problem and careful consideration by the designers in the planning of future circulating-water tunnels.

Discussion

In 1945, when there was a ban on national meetings, some papers originally scheduled for these meetings were presented before local groups. In the case of these papers the Committee on Publications suspended its rule, which requires simultaneous publication of paper and discussion, and accepted discussion based on the published paper.

Irreversibility in the Theoretical Regenerative Steam Cycle[1]

G. M. Dusinberre.[2] To future workers on this subject the writer recommends the analysis based on 1 lb throttle steam as used by the author. This seems more straightforward than to base on 1 lb through steam.

The author's Fig. 5 is a concise way of presenting the data on this cycle. But if a need really exists for data on the properties of this cycle, the writer feels that neither heat-rate tables nor the entropy-increase diagram is adequate, for two reasons: (1) Reheat cannot be handled except in a roundabout manner, as the author points out. (2) This ideal cycle is based on net work, that is, turbine work less feed-pump work. The practical use of the data would probably be in the study of high pressures where pump work is relatively large. Since there is no necessary relation between turbine and pump efficiencies, the application of any sort of efficiency factor to the ideal heat rate at least makes the fourth significant figure look a little foolish.

The writer concludes that the most useful form in which the data could be presented is (a) to use the divided cycle proposed by Markson,[3] and (b) to tabulate or plot the turbine work, pump work, and through steam, for 1 lb throttle steam: The corresponding heat items are readily obtained from the steam tables.

If the pump work is required, the author's integration is not directly useful as we need values of $(1-w)$ for $\int(1-w)v_f dp$. To get these, the writer has found that $\int \frac{T_f}{H-h_f}\, ds_f$ is more convenient than the function used by Selvey and Knowlton,[4] as the curvature is less.

When data are in graphical form, such as an indicator card, the logical method of integration is to use a planimeter, and not to pick off points for numerical integration. But when the data are in numerical form, as in the present case, it is equally more logical to use some method of numerical integration rather than to introduce the extra step of plotting a curve.

H. G. Elrod, Jr.[5] A completely accurate alternative to the author's Equation [6] can be obtained readily in the following manner.

Consider a regenerative cycle $ABCXZfA$ in the author's Fig. 1. When 1 lb of throttle steam is circulated in this cycle, $(1-w)(s_z-s_f)$ units of entropy are rejected by the system, and (s_c-s_a) entropy units are received. The net entropy increase of both the system and its surroundings is given by

$$\Delta S = (1-w)(s_z-s_f)-(s_c-s_a) \quad [1]$$

The variation of ΔS with exhaust conditions is found by differentiating Equation [1] of this discussion

$$d(\Delta S) = -(1-w)ds_f-(s_z-s_f)dw \quad [2]$$

Using the author's Equation [3] (corrected to include a minus sign), we obtain

$$d(\Delta S) = -(1-w)\left[1-\frac{T_f(s_z-s_f)}{H_z-h_f}\right]ds_f \quad [3]$$

Substituting the value of $(1-w)$ from Equation [1] into Equation [3] of this discussion, we find

$$\frac{d(\Delta S)}{s_c-s_a+\Delta S} = d\ln(s_c-s_a+\Delta S) = -\left[\frac{1}{s_z-s_f}-\frac{T_f}{H_z-h_f}\right]ds_f \quad [4]$$

The left-hand side of Equation [4] is directly integrable. The right-hand side may be evaluated in the manner illustrated by the author.

A comparison of Equation [4] with the author's Equation [6] shows that the author's approximation amounts to the assumption that $\ln(1+x)=x$. Using Equation [4], we obtain for the example cited by the author

$$\ln\left(1+\frac{\Delta S}{s_c-s_a}\right) = 0.0288 \quad [5]$$

or

$$\Delta S = 0.5425 \times 0.02922 = 0.01585 \quad [6]$$

The corresponding heat rate is 6000, which more closely agrees with the accurate value of 6001.2 computed by Shapiro.[6]

Ernest L. Robinson.[7] When the writer first became interested in this subject, there were great gains to be made in station performance. In 1923 he published curves for the efficiency of the extraction cycle which extended up to 1000 psi and 700 F, pressures and temperatures far beyond anything in use at that time.[8] The extraction cycle is now commonplace with steam conditions far above those. The gains looked forward to 20 years ago have been more than realized, and modern discussions are largely confined to the technique of calculation.

The writer has always believed that the best technique of calculation is to formulate the difference from some precisely known relationship and then to calculate that difference with care.

[6] Discussion by A. H. Shapiro, of "Theoretical Regenerative-Steam-Cycle Heat Rates," Trans. A.S.M.E., vol. 66, 1944, p. 508.

[7] Turbine Engineering Department, General Electric Company, Schenectady, N. Y. Mem. A.S.M.E.

[8] The Margins of Possible Improvement in the Central Station Steam Plant," by Ernest L. Robinson, Trans. A.S.M.E., vol. 45, 1923, p. 644.

Mr. Hansen has selected the Carnot cycle for his precisely known relationship and has proceeded to formulate the departure of the extraction cycle from perfect reversibility when superheated steam is bled.

This is an excellent method to pursue, as it enables attention to be focused on the magnitude of the departure itself, and thus the errors of calculation become errors of the second order of smallness.

The author takes advantage of this to introduce as an approximation the assumption that the weight flow throughout the cycle is in inverse proportion to the entropy difference between steam and feedwater. The close check with the Selvey and Knowlton tabular values justifies the assumption.

However, since the author uses graphic integration anyway, it does not seem to the writer as if it would complicate his calculation if the correct expression for weight flow were used. When the writer first set down this expression, he used w to represent the weight flow of extracted steam per pound to the condenser. Thus the weight flow in the turbine per pound to the condenser is

$$1 + w = e^{\left[\int_{h_G}^{h} \frac{dh}{H-h}\right]}$$

In evaluating the integral for high pressures it would be desirable, as Selvey and Knowlton pointed out, to allow for the feed-pump work.

Thus

$$1 + w = e^{\left[\int_{h_G}^{h} \frac{1-\frac{vdp}{Jdh}}{H-h}\, dh\right]}$$

The author uses w to represent the weight flow of extracted steam per pound to the throttle. Thus, using his notation, the weight flow in the turbine per pound at the throttle is

$$1 - w = \frac{1}{e^{\left[\int_{S}^{S_A} \frac{Tds}{H-h}\right]}}$$

In conclusion the writer would like once more to call attention to the advantage of weight-flow curves in extraction-cycle analysis. Especially with reference to a fixed exhaust pressure, such as 1 in. Hg, they may be drawn on the Mollier chart as characteristic lines per pound to the condenser for any stage efficiency. With the weight flow throughout the cycle known, performance is easily computed from cycle input and output. This technique is particularly useful for actual efficiencies other than 100 per cent.[9]

Ascher H. Shapiro.[10] The relation between Equations [2], [5], and [7] of this paper, and the first and second laws of thermodynamics is most obscure, due, it is felt, to the only too common practice of not clearly defining the system under consideration. What mass of material, for example, does the dS of Equation [2] refer to? Analysis indicates that it is the increase in entropy in an infinitesimal heater per unit of throttle flow. Referring to Fig. 1 of this discussion, we get for the increase in entropy flux of an infinitesimal open heater.

$$dS_{\text{heater}} = (1 - w + dw)s_f - s_x dw - (s_f - ds_f)(1 - w)$$

After simplification and combination with the "heat balance," Equation [3] of the author's paper, this becomes

$$dS_{\text{heater}} = [H_x - h_f - T_f(s_x - s_f)]\, \frac{dw}{T_f} \quad \text{[7]}$$

which is identical with Equation [2] of the text. Note that in deriving this equation it is unnecessary to allude to fictitious "lost-work" effects.

Thermodynamically, the chief criticism of the writer is that the

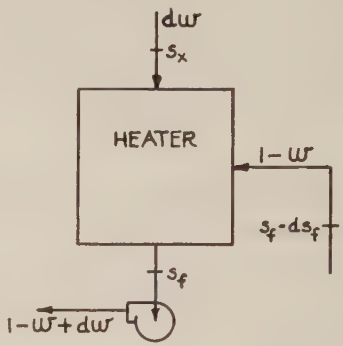

Fig. 1 Flow Diagram for Infinitesimal Heater

author identifies the value of $\Sigma dS_{\text{heater}}$ found from Equation [2] with the ΔS of Equation [7] of the paper. The writer sees no connection between this reasoning and the laws of thermodynamics.

The actual definition of the ΔS of Equation [7] of the paper resides in Equation [7] itself. For the heat rate of the cycle we may write

$$\text{Heat rate} = \frac{3412.75(H_C - h_A)}{H_C - h_A - (1 - w)_{\text{cond.}}\,(H_D - H_G)} \quad \text{[8]}$$

where the flow rate to the condenser (based on unit flow rate to the throttle) is found through integration of Equation [3] of the author's paper, to wit

$$(1 - w)_{\text{cond.}} = e^{-\int_{\text{cond}}^{\text{throttle}} \frac{T_f ds_f}{H_x - h_f}} \quad \text{[9]}$$

If Equations [8] and [9], herewith, are compared with Equation [7] of the author's paper, the exact definition of ΔS is found to be

$$\Delta S_{\text{exact}} = (s_C - s_A)\left[\frac{(s_C - s_G)/(s_C - s_A)}{e^{\int_{\text{cond}}^{\text{throttle}} T_f ds_f/(H_x - h_f)}} - 1\right] \quad \text{[10]}$$

Equation [6], giving the author's formula for ΔS, becomes, after a slight rearrangement

$$\Delta S_{\text{Hansen}} = (s_C - s_A)\left[\log_e \frac{s_C - s_G}{s_C - s_A} - \int_{\text{cond}}^{\text{throttle}} \frac{T_f ds_f}{H_x - h_f}\right] \quad \text{[11]}$$

A comparison of Equation [10] with Equation [11] of this discussion shows that the author's formula for ΔS is correct only when

$$\log_e \frac{s_C - s_G}{s_C - s_A} = \int_{\text{cond}}^{\text{throttle}} \frac{T_f ds_f}{H_x - h_f} \quad \text{[12]}$$

or, in other words, only when ΔS is identically zero.

Equation [12] is not a thermodynamic identity, and can at best be satisfied only approximately. It appears that for the cases given in the author's Table 2, the agreement is fairly good.

[9] "Notes on the Comparison of Steam Turbine Efficiencies," by Ernest L. Robinson, *General Electric Review*, vol. 29, 1926, pp. 503–510.

[10] Assistant Professor of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Mass. Jun. A.S.M.E.

Taking, for example, the steam conditions of Table 1, we get

$$\log_e \frac{s_C - s_G}{s_C - s_A} = 1.006; \quad \int_{\text{cond}}^{\text{throttle}} \frac{T_f ds_f}{H_x - h_f} = 0.977^*$$

Since the author's method apparently rests on the fortuitous fact that Equation [12] is approximately satisfied when steam is the working fluid, an important consideration concerns the maximum error which might be incurred through its use. For example, is one likely to encounter considerably greater errors than the largest error in Table 2, viz., 7 Btu per kwhr?

As regards the author's claim that his method requires less labor of computation than that of Selvey and Knowlton, attention is called to the writer's discussion of the Selvey and Knowlton paper. In that discussion it was shown that Selvey and Knowlton's procedure could be improved slightly as regards the thermodynamic analysis itself, and improved in considerable measure as regards computation technique. The method employed in that discussion was essentially equivalent to integrating Equation [9] of the present discussion with the aid of Simpson's rule and then substituting in Equation [8] of the present discussion to solve for the heat rate. With steam conditions of 3200 psia, 1200 F, 1 in. Hg, it was found that with only four calculations similar to those of Table 2 in the present paper, heat rates could be calculated with an accuracy of about 1 or 2 Btu per kwhr. With eight such calculations, the accuracy of the method is of the order of 0.1 or 0.2 Btu per kwhr.

H. Le H. Smith.[11] The author's three-dimensional consideration of temperature-entropy-quantity of steam is of special interest. Some of the general treatment raises questions of rigor, where fluid quantities are spoken of when fluid rates of flow are seemingly meant.

In dealing with adiabatic expansion and the resulting theoretical cycles, the treatment does not come to grips with reality. The author says, "Usually engineers are reluctant to utilize the concept of entropy except when it remains constant, ..." Can these things be?

The problem of the heat-cycle loss when superheated steam is bled for feedwater heating is an important problem, but surely its importance in a realistic sense is in application to real turbines, expanding nonadiabatically.

Toward the end of the paper explicit statements are made concerning the procedures by which the method could be modified to transfer it from the status of dealing with an unrealistic hypothetical turbine to that of dealing with a real turbine.

It would be an enlightening contribution if the author would make this transfer in a supplementary paper.

Author's Closure

The suggestion by Lieutenant Elrod eliminates the approximation to which objection is made in two of the discussions, without adding appreciably to the work involved. However, the error introduced by the approximation is negligible at any temperature likely to be employed in practice for some time to come, as may be shown by solving Equation [5] of the discussion for ΔS, letting A equal the area found graphically or otherwise.

$$\Delta S = (S_C - S_A)(e^A - 1) \ldots\ldots\ldots\ldots [13]$$

The exponential may then be expanded into an infinite series, by means of Maclaurin's theorem.

$$e^A = 1 + A + \frac{A^2}{2!} + \frac{A^3}{3!} + \ldots + \frac{A^n}{n!} \quad [14]$$

The approximation employed in the paper amounts to rejecting all terms beyond the second. If the value of A so found is of the order of 0.03, as in the example worked out in Table 1, the error introduced through letting $(e^A - 1)$ equal A, amounts to 0.00045, which would affect the heat rate by approximately 2 Btu per kwhr. If the value of A is 0.0014, as in the third line of Table 2, the error amounts to 0.000001, which would affect the heat rate by less than 0.01 Btu per kwhr. There is thus no justification for assuming that the discrepancies shown in Table 2 are due to this "approximation." The author has solved Equation [9], using Simpson's rule with eight intervals, and obtained a heat rate at 400 psia 700 F throttle conditions of 8228.3 Btu per kwhr. This indicates that a major part of the discrepancy referred to may be attributable to inaccuracy in the Selvey and Knowlton value of 8222.

Solution either of Equation [6] of the text or of Equation [13] just given is facilitated by the use of Simpson's rule. The following have been computed from data given in Table 1, by plotting the figures in column 10 and reading values at desired intervals.

No. of intervals	A	ΔS	Heat rate, Btu/kwhr
2	0.0284	0.0156	5999
3	0.0288	0.01585	6000.4
4	0.0288	0.01585	6000.4
8	0.0290	0.01595	6001.2

Three intervals[12] are sufficient to obtain an accuracy within one Btu per kwhr, compared with eight necessary if Equation [9] is used. At throttle temperatures below 1000 F, probably two intervals would prove ample. A still rougher approximation would be

$$A = \frac{S_A - S_G}{3}\left[\frac{1}{S_C - S_A} - \frac{T_A}{H_C - h_A}\right] \ldots\ldots [15]$$

The derivation in the paper is predicated on one pound of throttle steam. The time interval involved does not enter the discussion, hence it is unnecessary to employ terms indicating flow rate.

The manner in which reheat may be handled, merely by addition of the ΔS for each expansion, seems to the author exceedingly simple. Commander Dusinberre's observations regarding turbine and pump work are apt. However, it does not appear that theoretical pump work can be of much value, inasmuch as actual feed-pump work usually bears little relation to the theoretical.

It has been pointed out that much remains to be done before a rapid method of estimating real plant heat rates with high accuracy can be made available. The intention in the present paper has not been to indicate exactly how this may be done. It has rather been to clarify the concept of regeneration in the superheat region as an irreversible process, as implied by the title chosen, with the particular purpose of showing how quantitative results may be obtained.

One further step may be taken in the direction of actuality by making an analysis similar to Lieutenant Elrod's, but considering S_X to be variable, and letting feed-pump efficiency be m (assuming motor-driving the feed pump to have 100 per cent efficiency). This leads to the following

$$\Delta S = (S_C - S_A)(e^{(a + b + c)} - 1) \ldots\ldots\ldots [16]$$

* The value 0.977 is taken from the writer's discussion of the Selvey and Knowlton paper, author's reference (3).

[11] Supervisor, Power Department, B.M.T. Division, Board of Transportation, City of New York. Mem. A.S.M.E.

[12] Statement of Simpson's rule given in most handbooks applies only for an even number of intervals; with three intervals, y being the value in Table 1, column 10

$$\text{Area} = \frac{S_A - S_G}{8}(y_0 + 3y_1 + 3y_2 + y_3)$$

in which

$$a = -\int\left[\frac{1}{S_x - S_f} - \frac{T_f}{H_x - h_f}\right] dS_f \qquad [17]$$

$$b = \int \frac{dS_x}{S_x - S_f} \qquad [18]$$

$$c = -\frac{1-m}{m}\int \frac{v_f dp}{H_X - h_f} \qquad [19]$$

All integrals are of course between limits of throttle and condenser pressure. (Statement in paper that "ΔS value because of irreversibility in turbine expansion can be read from the expansion curve" is obviously incorrect, as such a value would not take into account the reduced quantity of steam reaching condenser.) Of the three components of the exponent, only *b* would be comparable in magnitude with the exponent to be evaluated if Equation [9] is employed, being of the order of half of the latter. Using Simpson's rule, not more, and probably fewer, than eight intervals would be required. If the steam flow is wanted, it can be found from the following

$$(1 - w) = \left[\frac{T_G(S_C - S_A)}{H_D - h_G}\right] e^{(a+b+c)} \qquad [20]$$

The inference may be drawn that other factors could be devised to be added to the exponent in Equations [16] and [20], to cover other departures from complete reversibility.

Development of the Lysholm-Smith Torque Converter[1]

Author's Closure

The author regrets that owing to wartime conditions, he has not been able to close the paper before.

Mr. Eksergian agrees with the author that the flow of a multistage reaction converter increases with reduced speed. The influence of this increased flow on the input torque is, however, not correctly interpreted by Mr. Eksergian. By using his theory, the input would increase on both sides on the optimum point, which is not substantiated by the test results. For the converter in question, the last turbine stage acts like a guide to the pump impeller giving a counterrotating vortex. The higher the secondary speed is, the less the circulation of this vortex will be, causing an increased unloading of the impeller. It has also been confirmed by tests made by the author that if a stationary guide is arranged before the pump impeller, the input torque will be substantially constant near the optimum point but, due to the increased flow decreases somewhat at stalling and racing. The dimensions of the various parts of the converter may be obtained from Fig. 1, which is drawn to a scale of 1:6.7.

Mr. Wislicenus comes to the conclusion that by using the equation given below Fig. 2, the actual pressure drop will be twice as great as derived from Equation [1]. This is not correct, as Equation [1] applies both to guide and rotating blades, thus making up for the missing factor of 2. The author regrets that this was not stated in his paper.

The author agrees that it is very difficult to separate losses in a hydraulic converter. The approximate method used when computing Table 1 was to estimate leakage, rotation, and mechanical losses according to usual formulas and try to balance the remaining losses in a reasonable way to correspond to the total losses obtained by the tests.

The carry-over losses are the losses in the open space between turbine and pump, or vice versa.

The author's Equation [2] was taken over from a similar equation used for calculating losses of the Ljungström double-rotation steam turbine. As shown in Fig. 4, this factor is by no means constant, but varies considerably over the range of inlet angles.

The rate of flow indicated in Fig. 2 is valid for constant input horsepower—that is to say, a constant value of $Q\Sigma\Delta h$. The values have been computed from test data for a great number of primary and secondary speeds by means of a Pitot tube fitted after the guide blade *C* in Fig. 1. This characteristic has to be accepted as correct on account of these tests, but it is also possible to confirm the test results by the cut-and-try method described below Fig. 2 in the paper.

Experimental Study of the Flow of Coal in Chutes at Riverside Generating Station[1]

R. F. Legget.[2] This lucid account of an exhaustive experimental study into a complex operating problem has proved of unusual interest to the writer since he was working on an allied problem at the University of Toronto, apparently simultaneously with the authors of the paper. His findings, which to some extent supplement those of the authors, will be presented at a future date.

The writer's investigation was concerned with the clogging of bituminous coal in the large reinforced-concrete bunkers of the new steam-generating plant of the Polymer Corporation at Sarnia, Ontario. A model of a bunker was used, one-twelfth full size, but made of wood and not of such a convenient material as pyralin. The grading of the coal used did not correspond with that shown in Fig. 1 of the present paper; however, the coal used for experiments was modified as the authors suggested.

In all the experiments conducted at Toronto, no "scale effect" was noted, and the writer is therefore puzzled by the authors' statement with regard to this matter, especially since it is difficult to see what should cause a difference between the behavior of coal in model and prototype. Possibly the authors will discuss this matter further in their closure.

The comment given on the use of "wetting agents" confirms the writer's experience; he cannot but think, however, that in some way these remarkable chemical products may one day assist in the solution of problems involving the movement of coal.

In view of the differing character of the units being studied, it is the authors' interesting discussion of the physical properties of the coal which provides the closest link between the two investigations. Although the approaches to the study of the properties of coal were somewhat different, the moisture content is paramount in both. Accordingly, it would be helpful if the authors would state how their moisture contents are expressed, i.e., as percentages of the dry or of the wet weights of coal.

Failure of Ductile Metals in Tension[1]

By G. SACHS[2] and J. D. LUBAHN,[3] CLEVELAND, OHIO

The extensive fabrication of aluminum-alloy sheet in the aircraft industries has revealed the lack of fundamental knowledge regarding the phenomena which explain the performance of metals under various stress and strain states. Previous investigations appear to have neglected entirely both the effects of the part geometry and the fact that the strength of the metal and limit of forming are frequently determined by a process of instability, or "necking," rather than by the process of fracturing. In this paper a theory of necking is developed in order to predict the forming limits for various stress or strain states based upon an analysis of the true stress-strain curve in pure tension. A criterion for necking is advanced, based upon the maximum-load (or pressure) conception of instability, and is applied to different geometrical shapes formed at room temperature. Future publications will present, in support of the criterion advanced, experimental analyses of the forming of different geometrical shapes under various loading conditions and stress and strain states.

Nomenclature

The following nomenclature is used in the paper:

A = cross-sectional area

e = ordinary principal strain = $\dfrac{L - L_0}{L_0}$

F = tensile load

F_{max}/A = stress at maximum load point

L = length of longitudinal element

p = internal pressure in tube, sphere, or circular bulge

R = radius of curvature to inside surface of thin-walled tube, sphere, or circular bulge

s = principal stress

h = thickness of element, or wall thickness of a tube or sphere

V = volume of element

w = width of element

ϵ = natural strain or logarithmic strain = $\ln(1 + e)$

0 = subscript denoting conditions before straining

1 = subscript denoting direction of principal stress or strain of greatest algebraic value

2 = subscript denoting direction of principal stress or strain of intermediate algebraic value

3 = subscript denoting direction of principal stress or strain of least algebraic value

Introduction

The general term "forming limit" may cover a variety of fundamentally different metal characteristics. It generally defines the maximum strain, or rather the magnitude and state of strain, which may be achieved with a certain type of equipment. This forming limit may be determined by the "cohesive" strength or "ductility" of the metal, which is often considered to be the only forming limit. However, a process may be limited by the strength of the equipment rather than by the ductility of the metal. In many commercial processes, particularly those of the compression type, the maximum strain is limited only in this manner.

Another rather peculiar type of forming limit results from a condition of loading which causes a local breakdown of the metal. A generally known and much discussed group of phenomena of this type is called "buckling." The buckling of a slender structural member limits its strength in a manner quite comparable to a brittle failure. Besides those phenomena of buckling discussed in textbooks on elasticity, there is also a variety of types of plastic buckling known which limit the forming under certain stress states, such as the wrinkling of deep-drawn cups and the folding of sunk or necked tubing.

The general characteristics of buckling may be defined as a load condition where an increase in strain occurs without an increase or with a decrease in load. Such an instability, therefore, should occur always when the load F goes through a maximum, or when the differential of the load becomes zero

$$F = \text{maximum} \qquad dF = 0$$

This condition determining the forming limit in buckling also applies to another group of instability phenomena, the best known representative of which is the local "necking" of a part strained in tension. When the load passes through a maximum, and the strain increases by a small amount at some location, this location becomes less strong in comparison with the remainder of the part. Then all further strain will occur here while it will discontinue at other locations, thus resulting in a "neck." The necking of a regular tensile-test specimen has attracted considerable interest, and numerous publications deal with stress-strain conditions conducive to necking (1–7).[4]

The condition of necking for pure tension can be written as follows:

$$dF = d(As) = 0$$

$$\frac{ds}{s} + \frac{dA}{A} = 0$$

where s is the true stress corresponding to a cross-sectional area A. This rather lucid formulation of the necking condition relates the instability to the fact that the rate of increase in tensile load by the increase of stress (due to strain-hardening) is no longer able to compensate for the decrease in tensile load be-

[1] This paper is one of a series of reports on the research program on hot-forming of aluminum alloys conducted at Case School of Applied Science under contract with the Office of Production Research and Development of the War Production Board. This research, which was supervised by the War Metallurgy Committee under the "restricted" project NRC-547, is the basis of this paper which has been released for publication by the OPRD.

[4] Numbers in parentheses refer to the Bibliography at the end of the paper.

cause of decreasing cross-sectional area. The necking condition in this form has been applied to processes other than uniaxial tension, such as a sheet subjected to biaxial tension (13), a rotating disk, and a tube subjected to internal pressure (8, 9, 11).

In order to develop an instability condition that is applicable to the wide variety of commercial conditions of loading and geometry, the original maximum-load conception must be extended. Already it can be concluded from previous analyses that the instability of a flat sheet and of a tube subjected to the same stress state occur at different strains. Therefore the conception is advanced in this paper that instability occurs, or "necking" begins, if, with increasing strain, one of the external loads passes through a maximum. So far only the tensile load has been considered ($dF = 0$). However, the primary source of stress in parts subjected to internal pressure is this pressure p and consequently instability should then occur when

$$p = \text{maximum} \qquad dp = 0$$

The purpose of this and subsequent papers will be as follows:

1 To develop the conception that under various load and geometrical conditions the forming limit for a homogeneous metal may be determined by instability, and to associate this "necking" with a maximum in either the tensile load or the internal pressure, as discussed previously.

2 To develop a theory of instability which may be applied to the stress-strain curve as experimentally derived for the load conditions and geometrical conditions actually present.

3 To extend this criterion of instability to predict the forming limit for any stress state and condition of geometry considered, using only the stress-strain curve in pure tension.

In the present analysis equations have been developed which apply to actual relations between the stresses and strains that exist during a particular type of test on a particular material. These relations, which are necessary in order to predict the necking strain, may be determined experimentally in a simple manner for certain conditions of geometry and loading, such as a tube subjected simultaneously to internal pressure and longitudinal tension. In this case the stresses and strains are calculated readily from the measured load, the pressure, and the dimensional changes, such as the changes in length and diameter of a tube. However, in other instances of geometry, such as a circular hydraulically formed bulge, a tedious experimental analysis and possibly also a theoretical analysis is necessary to establish the stress-strain relations that are required for the application of the derived necking condition.

Experimentation generally supplies the three principal stresses and the three principal strains for each point of the test, thus defining completely the stress and strain states, respectively. To apply the graphical construction, particular stresses and strains, or functions of these, must be selected to yield a suitable stress-strain relation. It would be desirable that various stress states could be represented by a single, or "universal," stress-strain curve, by plotting a suitable function of the three principal stresses versus a suitable function of the three principal strains. There are several possibilities, and the question as to which is the most suitable is still a matter of considerable argument. In most problems of plasticity the simplest possible condition has been found to yield sufficiently accurate results.

The following analysis applies only to biaxial-tension stress states, defined by the fact that the algebraically smallest principal stress s_3 is zero. In this case the larger of the two tensile stresses s_1, may be plotted versus the numerically largest of the three natural principal strains, as the simplest possible conception that yields a nearly universal stress-strain relation.[5]

Other stress and strain functions yield stress-strain curves for various stress states which agree more closely, but also which require more elaborate calculations. It should be noted that two of the stress states which are considered particularly in this paper, namely, pure tension and balanced biaxial tension, yield identical stress-strain curves, according to any of the recognized theories. The stress state which may be particularly affected regarding the accuracy of the solution by any such assumption would be the condition of plane strain which is intermediate between pure tension and biaxial tension.

The present approach to the problem has the particular advantage that the resulting differential equations allow the direct determination of the necking point on the experimental or equivalent stress-strain curve, using a simple geometrical construction. Also, the equations derived in this paper are basic, and may be extended to include any desired universal stress-strain relation. Finally, the stress may be approximated algebraically as a function of the strain, to permit an algebraic rather than a graphical solution. However, considering the rather large amount of work which such an algebraic analysis requires, it appears that the graphical method of solution is more flexible, is more lucid, and offers less possibility of error; consequently, this will be used in the analyses in subsequent publications.

Regarding the effect of the part geometry on the instability strain for balanced biaxial tension, it will be shown that the results are rather different for the three types of curvature, or changes in curvature, represented by (*a*) a flat sheet, (*b*) a sphere under internal pressure, or tubing under longitudinal tension and internal pressure, and (*c*) a circular hydraulic bulge formed by pressure from flat sheet. Previous experimentation confirms the results of some phases of the theoretical analysis, and additional evidence will be submitted in subsequent publications.

Necking of a Tensile Test Specimen

The well-known necking of a ductile tensile test specimen has been recognized by Considére (1) and Ludwik (2), as a phenomenon of instability. It is associated with a maximum in the load-strain diagram. As long as the load F increases, the specimen stretches approximately uniformly over its length,[6] while a decreasing load indicates necking.

(*a*) If s_1 is the true principal stress, i.e., the load F divided by the actual cross section A of the metal, the beginning of necking is given by the condition (see Sachs, 7)

$$F = s_1 A = \text{maximum}$$

$$dF = 0 = A ds_1 + s_1 dA$$

$$\frac{ds_1}{dA} = -\frac{s_1}{A} \qquad [1]$$

As illustrated in Fig. 1, the point of necking, or maximum load point, is a point in the s_1 versus A diagram, such that the tangent at this point intersects the ordinate at $A = 0$ at a height

[5] This is a special case (for biaxial tension) of the conception that all stress states yield identical stress-strain curves if the maximum shear stress $\left(\frac{s_1 - s_3}{2}\right)$ is plotted versus the maximum (absolute) natural strain.

[6] The "uniform" strain is considered as the presumably constant value of strain encountered at room temperature outside necked areas along the length of a sufficiently long tensile specimen. This value represents the greatest strain the metal will exhibit without necking under ideal conditions.

$\frac{2F_{max}}{A}$, giving a slope value of $-\frac{s_1}{A}$ (see footnote[7]).

This solution becomes particularly simple if the s_1 versus A diagram is a straight line in the vicinity of the maximum load point, as shown by Koerber (4), and pointed out previously by Moellendorff and Czochralski (3); see also Koerber and Rohland (6).

(*b*) The strain may also be expressed by the stretch e_1 of a certain length, $L = L_0\,(1 + e_1)$, determined by the constancy of volume V

$$V = L_0A_0 = LA = L_0\,(1 + e_1)A$$

$$1 + e_1 = \frac{A_0}{A}$$

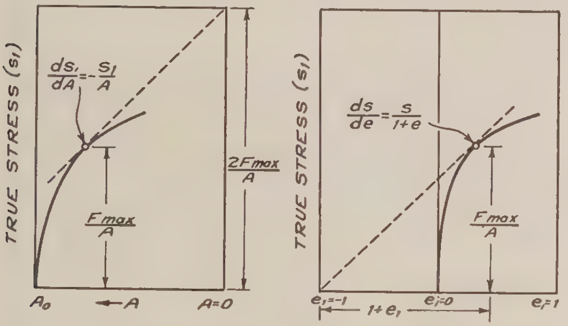
where the subscript zero denotes conditions before straining. The condition of necking then becomes

$$F = A_0\left(\frac{s_1}{1 + e_1}\right) = \text{maximum}$$

$$dF = A_0\left[\frac{ds_1}{1 + e_1} - \frac{s_1de_1}{(1 + e_1)^2}\right] = 0$$

$$\frac{ds_1}{de_1} = \frac{s_1}{1 + e_1} \qquad \text{[1a]}$$

In the s_1 versus e_1 diagram, Fig. 2, the maximum load point is



FIGS. 1 AND 2 CONSTRUCTION OF THEORETICAL NECKING CONDITION IN PURE TENSION FOR s VERSUS A AND s VERSUS e CURVES

determined by the condition that its tangent shall intersect the abscissa at a value $e_1 = -1$, yielding a slope equal to $s_1/(1 + e_1)$, see Considére (1), Nielsen (5), and Gensamer (13).

(*c*) By a third method which will be used generally throughout this paper, the strain can be expressed as the natural strain

$$d\epsilon_1 = \frac{de_1}{1 + e_1}$$

The necking condition then can be written (see Equation [1*a*])

$$\frac{ds_1}{d\epsilon_1} = s_1 \qquad \text{[1b]}$$

As illustrated in Fig. 3, the maximum load point may be determined by the condition that its tangent intersects the abscissa of the s_1 versus ϵ_1 diagram at the value $-(1 - \epsilon_1)$, yieldi :g the slope $s_1/1$.

[7] In the graphical solution for a particular metal, using experimental data, it is more accurate actually to plot the slope (ds_1/dA) and the ratio (s_1/A) against A and note their intersection (see also Fig. 9), rather than use the type of construction indicated in the various figures.

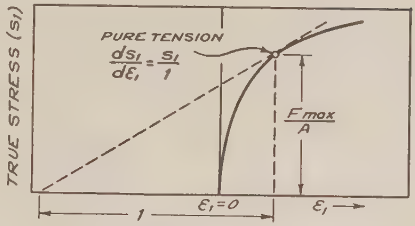


FIG. 3 CONSTRUCTION OF THEORETICAL NECKING CONDITION IN PURE TENSION FOR s VERSUS ϵ CURVE

NECKING OF FLAT SHEET UNDER BIAXIAL TENSION

When a flat sheet is subjected to biaxial tension, the normal stress s_3 is zero, and the maximum shear-stress condition indicates that the largest principal stress s_1 (2 times the largest shear stress) is always the decisive stress.

Under these conditions, the stress-strain curve becomes very similar to that for uniaxial tension if this decisive stress is plotted against the decisive strain, i.e., the numerically largest principal strain. Considering the intermediate natural strain ϵ_2, two general cases of biaxiality arise. When ϵ_2 is less than zero, ϵ_1 remains the decisive strain; when ϵ_2 is positive (but smaller than ϵ_1, according to definition), ϵ_3 becomes the decisive strain.

(*a*) The general condition of instability (necking) for a flat sheet will now be postulated to be the occurrence of a maximum in the force applied in the direction of the maximum tension s_1, this resulting in the same equation as for uniaxial tension Equation [1]

$$F = s_1A = \text{maximum}$$

$$dF = 0 = s_1dA + Ads_1$$

$$\frac{ds_1}{s_1} = -\frac{dA}{A} \qquad \text{[2]}$$

Using the constant-volume condition

$$\left.\begin{aligned} A &= A_0\,(1 + e_2)\,(1 + e_3) \\ dA &= A_0\,(1 + e_3)de_2 + A_0\,(1 + e_2)de_3 \\ \frac{dA}{A} &= \frac{de_2}{1 + e_2} + \frac{de_3}{1 + e_3} = d\epsilon_2 + d\epsilon_3 \end{aligned}\right\} \qquad \text{[3]}$$

The general instability condition, Equation [2], becomes

$$\frac{ds_1}{s_1} = -\,d\epsilon_2 - d\epsilon_3 \qquad \text{[3a]}$$

$$\frac{ds_1}{s_1} = d\epsilon_1 \qquad \text{[3b]}$$

(*b*) Strain ϵ_1 remains decisive for any biaxiality where $0 > \epsilon_2 > -\frac{\epsilon_1}{2}$, the limiting conditions being uniaxial tension ($\epsilon_2 = -\epsilon_1/2$) and plane strain ($\epsilon_2 = 0$). For this whole range of biaxiality, therefore, the same condition Equation [3*b*], applies as that for uniaxial tension

$$\frac{ds_1}{s_1} = d\epsilon_1$$

For the case of plane strain, Baranski (10) has observed previously that the natural necking strain is practically the same as for pure tension.

(*c*) For biaxialities where $\epsilon_1 > \epsilon_2 > 0$, ϵ_3 becomes the decisive

strain, the limiting conditions being plane strain ($\epsilon_2 = 0$) and balanced biaxiality ($\epsilon_1 = \epsilon_2 = -\epsilon_3/2$).

Introducing the quantity n, defined by

$$\epsilon_2 = -n\epsilon_3 \qquad [4]$$

where $1/2 > n > 0$ (for ϵ_3 being decisive), the basic Equation [3a] becomes

$$\frac{ds_1}{s_1} = -d\epsilon_3(1 - n) \qquad [3c]$$

This equation can also be solved graphically.

(*d*) In the special case of balanced biaxial tension, $\epsilon_2 = -\epsilon_3/2$, $n = 1/2$, and the instability condition assumes the following form

$$\frac{ds_1}{s_1} = -\frac{1}{2}\, d\epsilon_3 \qquad [5]$$

or

$$\frac{ds_1}{d\epsilon_3} = -\frac{s_1}{2} \qquad [5a]$$

As shown by Gensamer (13), the graphical solution of this equation can be obtained by the same method as employed in Fig. 3 and illustrated in Fig. 4.

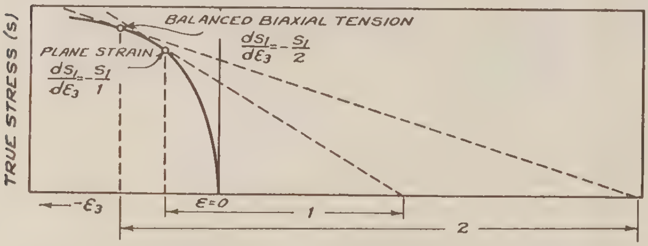

FIG. 4 CONSTRUCTION OF THEORETICAL NECKING CONDITION IN BIAXIAL TENSION FOR s VERSUS ϵ CURVE

(*e*) In the limiting case of plane strain, $\epsilon_2 = 0$, $\epsilon_3 = -\epsilon_2$, $n = 0$, the two solutions, Equations [3b] and [3c], yield identical results (see Figs. 3 and 4)

$$\frac{ds_1}{s_1} = -d\epsilon_3 = d\epsilon_1$$

It can be seen that for identical stress-strain curves, as noted previously, ϵ_3 at the maximum load point of balanced biaxial tension is much larger than ϵ_1 at the maximum load point of uniaxial tension, Fig. 3. Thus the uniform stretch in balanced biaxial tension, $\epsilon_1 = -\epsilon_3/2$, must be greater than one half the uniform stretch in pure tension, and may be either larger or smaller than the uniform stretch in pure tension, depending upon the strain-hardening characteristics of the metal.

INSTABILITY OF THIN-WALLED TUBES SUBJECTED TO INTERNAL PRESSURE

The condition for the necking of a thin-walled tube subjected to internal pressure has not been thoroughly understood up to the present time. Some attempts by Laszlo (8, 9) and Siebel and Kopf (11) indicate that such a tube will neck at considerably smaller strains than a tensile test specimen of the same material.

It appears that the uniform strain of a tube subjected primarily to an internal pressure p, is determined by the condition that this pressure reaches a maximum. For a thin-walled tube having an initial inside diameter $2R_0$ and an initial wall thickness h_0, this pressure is given by the well-known equation

$$p = s_1 \frac{h}{R} = s_1 \frac{h_0\,(1 + e_3)}{R_0\,(1 + e_1)} \qquad [6]$$

where e_1 and e_3 are the circumferential and normal strains, respectively.

This condition should apply for any condition of biaxiality where the circumferential stress is the decisive stress (and possibly also for conditions where the longitudinal stress is the decisive stress).

Regarding the decisive strain, again two conditions arise, where $0 > \epsilon_2 > -\frac{\epsilon_1}{2}$, and where $\epsilon_1 > \epsilon_2 > 0$.

(*a*) The general condition of instability, Equation [6], can now be written as follows

$$dP = 0 = \frac{h_0}{R_0}\left[ds_1 \frac{1 + e_3}{1 + e_1} + s_1 \frac{de_3}{1 + e_1} - s_1 \frac{de_1\,(1 + e_3)}{(1 + e_1)^2}\right]$$

This yields the final equation

$$\frac{ds_1}{s_1} + \frac{de_3}{1 + e_3} - \frac{de_1}{1 + e_1} = 0 \qquad [6a]$$

or

$$\frac{ds_1}{s_1} + d\epsilon_3 - d\epsilon_1 = 0 \qquad [6b]$$

(*b*) For pure (uniaxial) circumferential tension, ϵ_1 is the decisive strain, and $\epsilon_3 = \epsilon_2 = -\frac{\epsilon_1}{2}$. Consequently, the instability condition, Equation [6b], assumes the following form

$$\frac{ds_1}{s_1} = \frac{3}{2}\, d\epsilon_1$$

or

$$\frac{ds_1}{d\epsilon_1} = \frac{s_1}{2/3} \qquad [7]$$

This latter form can again be solved graphically by the method of trial and error, Fig. 5. A comparison with the condition for pure tension for which the same stress-strain curve exists, Equation [1b], shows clearly that the tube would become unstable at a smaller circumferential strain than the (longitudinal) necking strain of a tensile test bar. This difference is due to the change in curvature, rather than to differences in the stress state.

(*c*) If $0 > \epsilon_2 > -\frac{\epsilon_1}{2}$, the decisive strain remains ϵ_1. Introducing the relation

$$\epsilon_2 = -n\epsilon_1;\ \epsilon_3 = -\epsilon_1 - \epsilon_2 = (+n - 1)\epsilon_1 \qquad [8]$$

where $1/2 > n > 0$, the general condition of instability can be written as follows

$$\frac{ds_1}{s_1} = d\epsilon_1\,(2 - n) \qquad [6c]$$

(*d*) For plane strain, $\epsilon_2 = 0$, $n = 0$, and the instability condition then becomes

$$\frac{ds_1}{d\epsilon_1} = \frac{s_1}{1/2} \qquad [9]$$

The graphical solution for this case of biaxiality is also illustrated in Fig. 5. The circumferential strain at which the tube would become unstable, under such conditions, would be still smaller than that for a tube subjected to pure circumferential pressure.

(*e*) If $\epsilon_1 > \epsilon_2 > 0$, the decisive strain becomes ϵ_3. Using the relation of Equations [8]

$$\epsilon_1 = \frac{\epsilon_3}{n - 1} \qquad [8a]$$

where $0 > n > -1$, the general condition of instability can be written as follows (see Equation [6c])

$$\frac{ds_1}{s_1} = d\epsilon_3 \left(\frac{2 - n}{n - 1}\right) \qquad [6d]$$

(*f*) For balanced biaxial tension, $\epsilon_1 = \epsilon_2 = -\frac{\epsilon_3}{2}$, $n = -1$ and the instability condition yields the equation

$$\frac{ds_1}{d\epsilon_3} = -\frac{s_1}{2/3} \qquad [10]$$

The same graphical solution now applies as for pure circumferential tension, Fig. 5, the decisive strain, however, being ϵ_3. The circumferential strain, in the case of balanced biaxial tension, however, would be only one half of that for uniaxial circumferential tension, because of $\epsilon_1 = -\frac{\epsilon_3}{2}$. As noted previously, in balanced biaxial tension, approximately the same curve is obtained by plotting s_1 versus ϵ_3 as that obtained in uniaxial tension by plotting s_1 versus ϵ_1. Furthermore, Equations [10] and [7] apply, respectively, to these two curves in the same manner, yielding as the solutions identical values of necking strain (ϵ_3 and ϵ_1, respectively). In the case of balanced biaxial tension, however, the uniform stretch ϵ_1, which is only one half of the normal instability strain ϵ_3 is therefore also only one half of the uniform stretch in uniaxial circumferential tension.

Instability of Thin-Walled Sphere Subjected to Internal Pressure

The same approach as used for a tube should be valid when applied to a sphere subjected to an internal pressure, p. The pressure for a sphere having an initial diameter $2R_0$ and an initial wall thickness t_0, is given by the well-known equation

$$p = 2s_1 \frac{h}{R} = 2s_1 \frac{h_0}{R_0} \frac{1 + e_3}{1 + e_1}$$

where $s_1 = s_2$ is the tensile stress and $e_1 = e_2$ the tangential strain (in the surface of the sphere), and e_3 is the normal (and decisive) strain.

The instability condition then becomes

$$dp = 0 = 2\frac{h_0}{R_0}\left[ds_1 \frac{1 + e_3}{1 + e_1} + s_1 \left(\frac{de_3}{1 + e_1} - \frac{de_1\,(1 + e_3)}{(1 + e_1)^2}\right)\right]$$

or

$$\frac{ds_1}{s_1} + \frac{de_3}{1 + e_3} - \frac{de_1}{1 + e_1} = 0$$

or

$$\frac{ds_1}{s_1} + d\epsilon_3 - d\epsilon_1 = 0 \qquad [11]$$

And using the relation $\epsilon_1 = -\frac{\epsilon_3}{2}$, the same equation results as for tubing under balanced biaxial tension, Equation [10], the graphical solution of which is illustrated in Fig. 5.

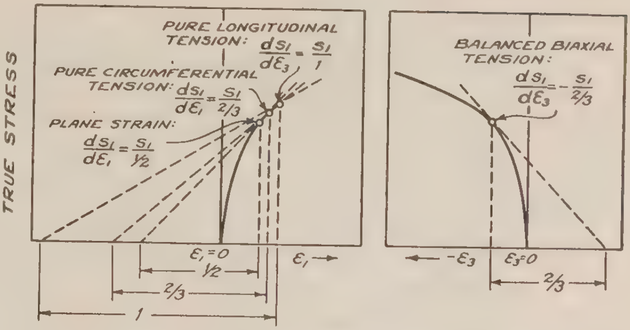

Fig. 5 Construction of Theoretical Necking Condition in Tubing Under Various Stress States

Instability of Circular Hydraulically Formed Bulge

The criterion for necking presented here is limited to uniform stress and strain states over the region in question. This requires that for any section of the specimen both the thickness and radius be uniform at any instant during the test, and that there be no variation of metal properties throughout the specimen.

During the bulging of a thin circular disk clamped at its periphery, neither the thickness nor the radius is uniform over the entire bulge. However, experimentation has shown that at and around the pole there is a rather large area which is close to spherical and where the magnitudes of the stresses and strains are nearly constant. Consequently, an analysis similar to that used for other geometrical shapes should be applicable. The validity of this conception has been verified by experiments which will be presented in a later publication.

Fundamentally, the same condition should determine the strength of a ductile disk, subjected to hydraulic pressure, as that which determines the strength of a sphere subjected to internal pressure, namely, that when the pressure p, reaches a maximum, instability should occur, provided that the metal is sufficiently ductile to "neck" before fracturing. This pressure p is given, as in the case of the sphere, by the equation

$$p = 2s_1 \frac{h}{R} = 2s_1 \frac{h_0(1 + e_3)}{R}$$

where $s_1 = s_2$ is the tension at the pole of the bulge, at which location the highest strains are exhibited, and $e_1 = e_2$ and e_3 are the tangential strains and normal strain, respectively, Fig. 6. The necking condition in terms of the strain e_3 then becomes

$$dp = 0 = 2h_0\left(ds_1 \frac{1 + e_3}{R} + s_1 \frac{de_3}{R} - s_1 dR \frac{1 + e_3}{R^2}\right)$$

or

$$\frac{ds_1}{s_1} = \frac{dR}{R} - \frac{de_3}{1 + e_3}$$

This equation can be written in the logarithmic form[8]

$$d(\ln s_1) = d(\ln R) - d\epsilon_3$$

or

$$\frac{d\,(\ln s_1)}{d\epsilon_3} = \frac{d\,(\ln R)}{d\epsilon_3} - 1 \qquad [12]$$

[8] ln = $\log_e$

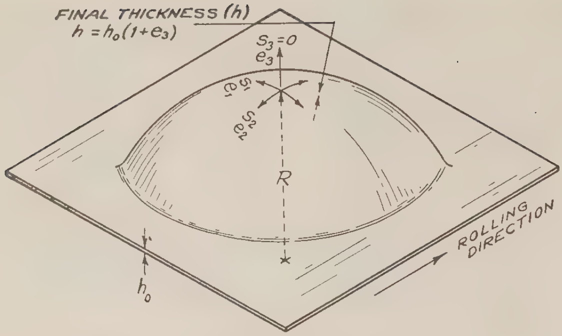

Fig. 6 Stress and Strain State and Geometrical Conditions in a Circular Bulge

This equation differs from that of a sphere because the radius of curvature in this case is an unknown function of the strain. No theory of bulging is yet available which would yield the curvature during bulging if the other quantity were known. Therefore, a graphical solution, based upon experimentally determined values of stress, strain, and curvature, is necessary. The stress-strain curve, s_1 versus ϵ_3, and the radius-strain curve, R versus ϵ_3, are necessary in order to determine the two functions

$$\frac{d\,(\ln s_1)}{d\epsilon_3} \text{ and } \frac{d\,(\ln R)}{d\epsilon_3}$$

The radius is determined experimentally from contour measurements. The normal strain ϵ_3 is calculated from the measured tangential strains $e_1 = e_2$ according to the equation

$$\epsilon_3 = \ln\left[\frac{1}{(1 + e_1)^2}\right]$$

The stress is determined from the experimentally measured quantities, radius, pressure, and tangential strain, related by the following equation

$$s_1 = \frac{pR\,(1 + e_1)^2}{2t_0}$$

These values can be employed in the graphical solution of Equation [12]. Thus, as shown in Figs. 7(*a*) and 7(*b*), ln R and ln s_1 are plotted as functions of ϵ_3, (ϵ_3 being negative). The values of

$$\frac{d\,(\ln R)}{d\epsilon_3} - 1 \quad \text{and} \quad \frac{d\,(\ln s_1)}{d\epsilon_3}$$

are determined from these curves and plotted as functions of ϵ_3, Fig. 7(*c*). The ϵ_3 value at the intersection then determines the strains at the necking point, according to

$$\epsilon_1 = \epsilon_2 = -\frac{\epsilon_3}{2}$$

This strain value is considerably higher than that for the sphere and usually also higher than that for plane biaxial stress, because of the decrease in radius R, with increase in strain.

The Necking of Tensile-Test Specimens[1]

By J. D. Lubahn,[2] Cleveland, Ohio

The conventional tensile test is the basis of acceptance tests, and its results are extensively used to evaluate the structural metals regarding their relative performance in forming and their strength in service. However, it appears that the significance of the phenomena encountered in a tensile test are little understood, in spite of a large number of investigations. In this paper, the strains encountered in long rectangular tensile-test bars of the aluminum alloys 24S-O and 24S-T have been investigated in detail. The theoretical conceptions previously advanced,[3] regarding the necking of tensile-test bars, have been confirmed experimentally.

The present theory of necking correlates the occurrence of a maximum in the external load with a change in the strain condition from a uniform strain state to a nonuniform strain state, i.e., local necking. The simplest example of uniform stress and strain conditions throughout the metal should be that encountered in a regular tensile-test bar which is subjected presumably to "pure tension" before necking occurs.

The validity of the necking condition for test bars strained in "pure tension" has been the subject of numerous investigations listed in a previous paper.[3] Recently, however, the existence of a really uniform strain in a tensile test bar has been considered as doubtful. It must be emphasized that commercial metals are not entirely uniform, and therefore their strains in pure tension will be nonuniform to an extent depending upon the variations in metal properties. Frequently, also, test bars and sections that are stretched commercially lack uniformity of cross section along their length and these variations likewise cause the strains to be nonuniform even before instability, or "necking," occurs.[4]

In addition to the foregoing considerations, the stress state of a standard tensile-test specimen at failure is rather complex as a result of two factors: (*a*) The transverse tension near the ends of the gage length, because of enlarged "heads" of the specimen; and (*b*) the transverse tension in the neck itself, which is in effect a notch of large radius of curvature. In a relatively short gage length, such as that of a standard tensile-test specimen, it has been observed that the regions where lateral contraction is restrained, corresponding to the two regions of lateral tension just described, may overlap. This makes it impossible to determine by strain analysis of a standard (American) tensile-test specimen any such strain as the uniform elongation, or the strain under conditions of uniaxial tension at which local necking begins.

Tensile-Test Procedure

In order to study the phenomenon of necking under conditions which avoid the difficulties mentioned, a few tensile tests were made on aluminum-alloy strips 20 in. long, of bare 24S-O and bare 24S-T sheet, Figs. 1 and 2. The strips were reduced in the center portion from a sheared width of $1^1/_2$ in. to a width of 1 in., in order to form a 13-in. gage length of constant width with edges free from nicks and cold work. The edges were prepared by milling to a depth at least equal to the thickness, followed by polishing on a belt sander. The longitudinal direction[5] of the sheet was selected as the direction of testing, in order to obtain the most nearly constant thickness and the most nearly uniform metal properties along the length of the specimen.

The specimens were subjected to tension loads that continuously increased at a very small rate. During tests, measurements of width and thickness were made at 24 stations spaced $^1/_2$ in. apart. By a process of interpolation, the measurements, and thus also the strains, were computed for the same point of time at all the stations. Thus in Figs. 1 and 2, each curve represents the strain distribution at one particular instant during the test. Such a representation illustrates the gradual change in shape of the strain-distribution curve as the test proceeds.

It is apparent from Figs. 1 and 2 that the strains are nearly constant with position along the length of the specimen up to a strain of approximately 8 per cent. With further increasing strain, small nonuniformities appear which are not local necks in the sense of an instability effect, because they do not represent points where the strain continues to increase in the absence of strain at other points. There is a certain maximum strain, however, which has been denoted as the necking strain, above which the strains continued to increase in only one localized region, called the "neck," Figs. 1 and 2. It can be seen that this necking strain was approximately 18.5 per cent for the investigated 0.040-in. 24S-O bare specimen, and 17.5 per cent for the 0.125-in. 24S-T bare specimen. Apparently, for 24S-T bare, the strain at a load of 8980 lb was the maximum-load strain, Fig. 2, since the strain after fracture differed only by the amount of elastic recovery that is to be expected for this alloy.

The curves of (true) stress versus reduction of cross-sectional area for the two materials were obtained by plotting (for one particular station) the cross-sectional areas corresponding to the various strain curves in Figs. 1 and 2 versus the corresponding stresses. The same stress-strain curve was obtained for various stations, thus indicating the correctness of the interpolation process for obtaining the strain-distribution curves. For the purpose of this investigation, the stress-strain curves were extended only to the largest strain encountered outside the region of fracture, to avoid introducing the effects of transverse tension in the neck. The curves so obtained were found satisfactory for the following analysis, in that they exceeded by a few per cent the theoretical point of necking.

Analysis of Results

The stress versus reduction (of area) curves thus obtained are shown in Figs. 3 and 4, together with the construction lines for determining the strain at necking, according to the theory developed previously.[3] The values of longitudinal strains obtained from the necking theory for 24S-O bare, and 24S-T bare, are 16 and 19.5 per cent, respectively. These values are in good agreement[6] with the corresponding experimentally determined uniform strains of 18.5 and 17.5 per cent, respectively, Figs. 1 and 2.

The accuracy with which the strain at necking can be determined from a stress-reduction curve, such as that in Fig. 4, depends primarily upon the accuracy with which the slope of the stress-area curve is measured. In order to illustrate the probable extent of the scattering of the slope measurements, the necking condition has been solved, in Fig. 5, by intersecting the two functions s_1/A and $-ds_1/dA$. The curve shows that typical errors of slope measurements may result in errors in the strain at necking of approximately plus or minus 1 per cent.

[6] A larger number of subsequent tests show that the necking strain determined theoretically from the stress-strain curve is 1 or 2 per cent above that observed in the strain-distribution curve, and this phenomenon has not been explained as yet. It should be observed, however, that this difference is smaller than the rather large experimental errors associated with instability phenomena.

Instability of Thin-Walled Tubes Subjected to Internal Pressure[1]

By G. ESPEY,[2] CLEVELAND, OHIO

A preceding paper advances the criterion that the maximum-load or pressure conception of instability is applicable to geometrical shapes other than the tensile test. This paper presents experimental analysis to support the theoretical conception advanced for the necking of tubing subjected to pure longitudinal tension, to balanced biaxial tension, and to plane strain with the major strain being circumferential. It also shows that the stress-strain curve in uniaxial tension can be used to predict the necking strain for tubing under various stress states.

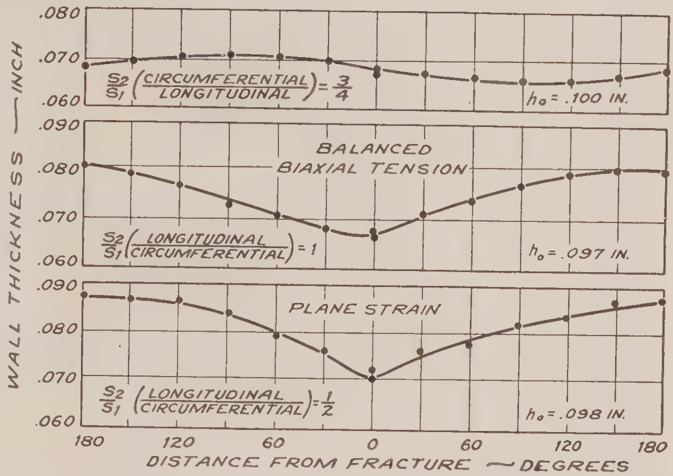

Fig. 1 Distribution of Wall Thickness With Circumference at the Center of Tubes Tested Under Various Stress Ratios and Having Longitudinal Fractures

Load conditions other than pure tension which can be readily investigated are those encountered in tubing which is simultaneously subjected to a major circumferential tension and a minor longitudinal tension.[3]

The following analysis should reveal the validity of the conception advanced[4] that a tube subjected to the stress state mentioned, if it does not fracture in a brittle manner, fails by instability when the internal pressure reaches a maximum. This failure should be of much the same type as that of a tensile specimen which fails by local instability or "necking" when the tensile load passes through a maximum.[5]

Some results have been published recently by Davis,[6] which present a series of tests suitable for a comparison of the theoretical instability strains with experimentally derived forming limits for various stress states. Cylindrical copper tubes 1.45 in. OD, 1.25 in. ID, and having an 8-in. length were machined from solid rod. These were subjected to various ratios of longitudinal and circumferential tension which were kept approximately constant in any one test but which were in different proportions for different tests. Both stresses were progressively increased during a test by increasing the internal pressure and the longitudinal tension. The strains were carefully measured during these tests, and for an investigation of the instability condition the final dimensions of the fractured specimens were also secured later for the purposes of this analysis (lot B of reference 6). Of the tubes tested under combined tensions, the stress and strain conditions of balanced biaxial tension $\left(\frac{s_2}{s_1} = 1, \frac{\epsilon_2}{\epsilon_1} = 1\right)$ and plane strain $\left(\frac{s_2}{s_1} = 1/2, \epsilon_2 = 0\right)$ were available for the analysis.

Correlating Test Results

To correlate the necking performance of tubes under uniaxial tension with those under biaxial tension, a tube tested in pure tension was also investigated. The individual (true) stress-strain curves obtained in the various tests were used as the basis for the determination of theoretical stress and strain conditions of instability under plane strain and balanced biaxial tension.

As might be expected, the tubes which had been subjected primarily to internal pressure failed by splitting longitudinally. The fracture appeared to be rather brittle; furthermore, the occurrence of a longitudinal fracture in the specimen tested with a ratio of circumferential stress to longitudinal stress of 3:4 indicated that the ductility in the circumferential direction was considerably less than in the longitudinal direction and possibly low enough to cause brittle fracture. Measurements of the distribution of thickness h, around the circumference at the longi-

[1] This paper is one of a series of reports on the research program on hot-forming of aluminum alloys conducted at Case School of Applied Science under contract with the Office of Production Research and Development of the War Production Board. [2] Department of Metallurgical Engineering, Case School of Applied Science.

[3] As yet, the condition or combination of conditions determining instability for tubing under a major longitudinal tension and a minor circumferential tension is not clearly understood. However, the limiting conditions of pure longitudinal tension and balanced biaxial tension are known and discussed. The results of tests in the region between these two limits are later reported in Fig. 9.

tudinal center of fracture for this tube showed no definite evidence of local necking, Fig. 1. This therefore indicates that if any instability took place it occurred at a strain very near the limit of ductility.

The instability condition can be applied only if the ductility of the metal is sufficiently high to exceed that required by the necking condition. Measurements of the thickness distribution for tubes tested under balanced biaxial stress ($s_1/s_2 = 1$) and in plane strain ($s_2/s_1 = 1/2$), Fig. 1, reveal the presence of necks. The presumably uniform normal strain under both of these load conditions was considerably less than the normal strain at the fracture, which was approximately the same for all three tubes that failed longitudinally.

Thus it appears that the two tubes representing balanced biaxial tension and plane strain were suitable for a comparison of the theoretical with the experimental instability conditions.

First, however, the validity of the instability condition for the tube tested in pure longitudinal tension was confirmed. The load reached a maximum, Fig. 2, and from measurements of the thickness (radial strain, ϵ_3) and diameter (circumferential strain, ϵ_2) of the fractured specimen, a neck was found to extend over approximately 1 in. on each side of the failure. The remainder of the tube was strained rather uniformly, by a value of natural longitudinal strain, $\epsilon_1 = -2\epsilon_2 = 0.39$. This is practically the same value as that obtained by graphical solution, Fig. 3.

The pressure versus strain curves obtained for the tubes subjected to internal pressure show the decrease in slope which generally precedes a maximum, Figs. 5 and 7. However, no decrease in load was observed because of the explosive failure which occurs. Such failure is expected when the forces become unbalanced, i.e., when instability starts.

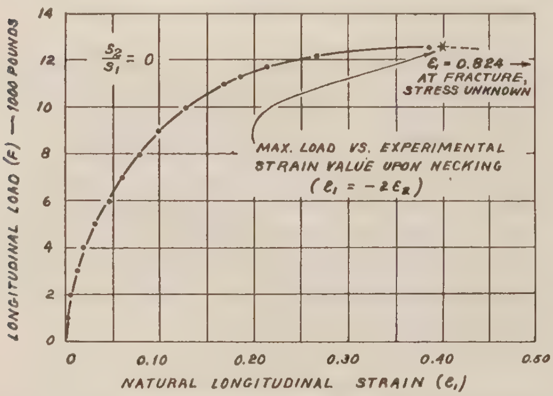

FIG. 2 LOAD-STRAIN CURVE FOR COPPER TUBING IN PURE TENSION

For the two combined tension tests made under balanced biaxial tension and plane strain, the thickness measurements taken around the circumference of the tubes at the longitudinal center of the fracture also showed no pronounced distinction between uniform and local straining, as the thickness gradually decreased toward the fractures, Fig. 1. This type of nonuniformity of strain which may be caused to some extent by slight variations in wall thickness of the original specimens, makes it difficult to determine definitely the circumferential strain at the moment of instability.

However, in the case of perfectly balanced biaxial tension, the uniform strain can be derived indirectly from the condition that before instability occurs the circumferential strain will equal the longitudinal strain; and since the fracture occurs in the longitudinal direction, the longitudinal strain should discontinue as soon

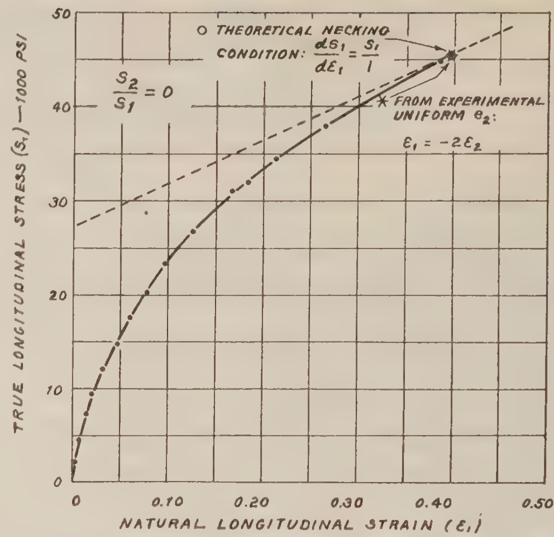

FIG. 3 TRUE STRESS-STRAIN CURVE FOR COPPER TUBING IN PURE TENSION WITH A COMPARISON OF THEORETICAL AND EXPERIMENTAL POINTS OF INSTABILITY

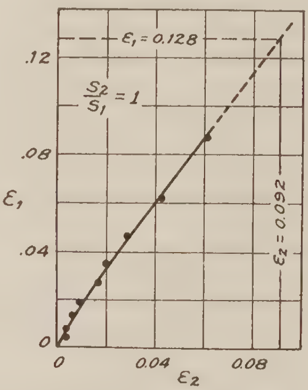

FIG. 4 EXTRAPOLATION OF ϵ_1 VERSUS ϵ_2 TO OBTAIN THE VALUE OF ϵ_1 UPON NECKING FROM THE CORRESPONDING VALUE OF ϵ_2

(Balanced biaxial tension test.)

as instability is initiated. Therefore the uniform strain in the longitudinal direction should be the same as the circumferential strain present at the start of instability. However, for the case considered, the circumferential stress (s_1) was approximately 13 per cent higher than the longitudinal stress when instability started; consequently there was a corresponding difference between the longitudinal and circumferential strains, Fig. 4. A value of circumferential strain equal to 0.128 at the point of instability was obtained by extrapolation of the curve in Fig. 4 to the measured value of uniform longitudinal strain of 0.092. The corresponding value of normal strain is

$$\epsilon_3 = -\epsilon_1 - \epsilon_2 = -0.092 - 0.128 = -0.22$$

The strain values obtained by graphical solution of the necking condition, Fig. 6, were $\epsilon_1 = 0.13$ and $\epsilon_3 = 0.25$. They are again in good agreement with the experimental values.

In the case of plane strain, Fig. 7, the lack of any change in length ($\epsilon_2 = 0$) of the specimen makes it impossible to use this strain as a criterion of the point of instability; and the lack of a

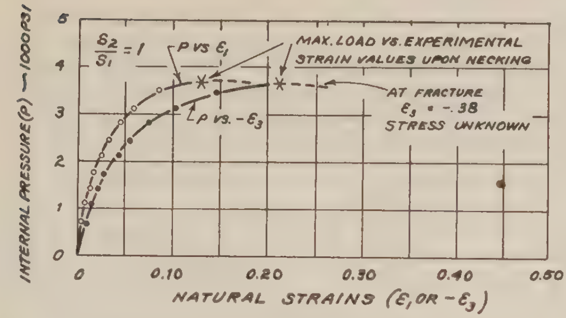

FIG. 5 PRESSURE-STRAIN CURVES FOR COPPER TUBING IN BALANCED BIAXIAL TENSION

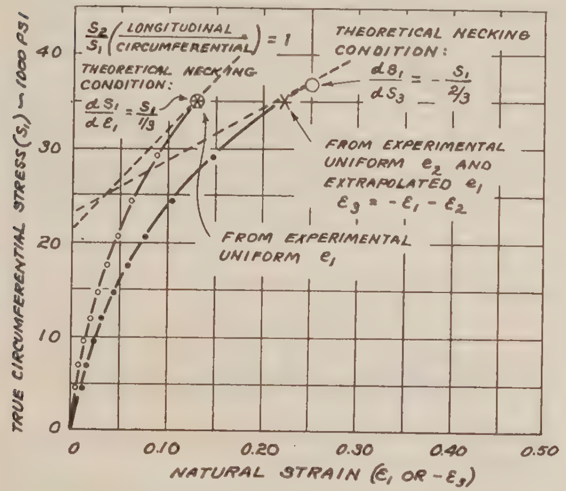

FIG. 6 TRUE STRESS-STRAIN CURVES FOR COPPER IN BALANCED BIAXIAL TENSION WITH A COMPARISON OF THEORETICAL AND EXPERIMENTAL POINTS OF INSTABILITY

region of uniform thickness about the circumference after fracture, Fig. 1, eliminates a second possible method of determining the uniform strain. However, the measured average circumferential strain may be used as the experimental strain at instability, although it is somewhat inaccurate because of the small effect on the average value of the larger strain at the neck. Measurement of the outside diameter after fracture at points $^1/_2$ in. beyond the ends of the fracture yielded a mean value of 1.699 in. This value may be corrected by the corresponding thickness (0.081 in.), obtained by extrapolation of the outside-diameter versus thickness curve, to yield a value of uniform natural circumferential strain of $\epsilon_1 = 0.175$.

As in the case of pure tension, the accuracy of the "theoretical necking strains" for the tubes investigated depends upon the accuracy of the slope measurements. Also, there is likely to be some additional error because of the scarcity of experimental points in the vicinity of the region of necking, with the corresponding uncertainty in the shape, and thus the slope of the curve.

The graphical solution of the instability condition for plane strain yields a strain value $\epsilon_1 = -\epsilon_3 = 0.19$ (approximately) which is again in good agreement with the experimental value $\epsilon_1 = 0.175$, Fig. 8.

Thus the analysis of tubes subjected to internal pressure confirms the conception that a maximum in the internal-pressure curve of a sufficiently ductile metal is associated with a localized

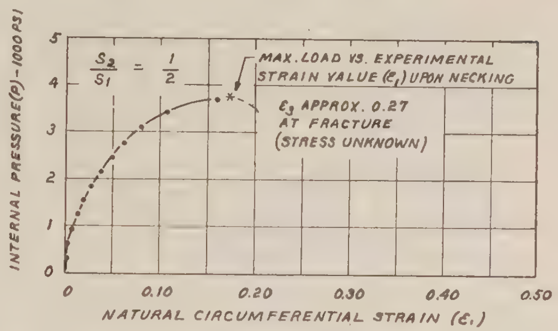

FIG. 7 PRESSURE-STRAIN CURVE FOR COPPER TUBING IN PLANE STRAIN

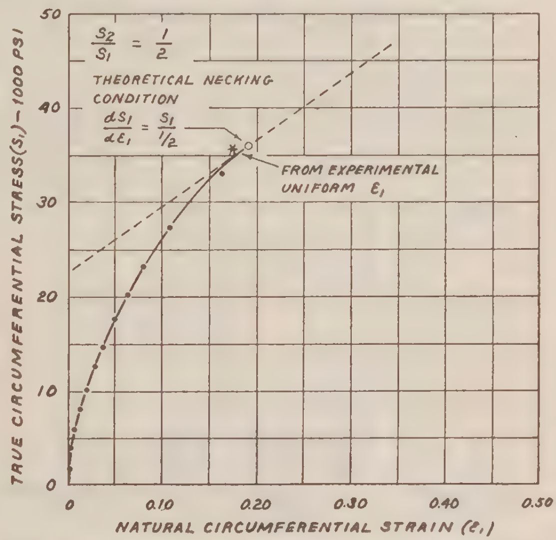

FIG. 8 TRUE STRESS-STRAIN CURVE FOR COPPER TUBING UNDER CONDITIONS OF PLANE STRAIN, I.E., LONGITUDINAL STRAIN = 0, WITH A COMPARISON OF THEORETICAL AND EXPERIMENTAL POINTS OF INSTABILITY

strain region or "neck" in the circumferential direction, and a lack of any further strain in other parts of the specimen.

The investigation of the various load conditions also reveals that in accordance with the theoretical analysis, a thin-walled tube subjected either to "pure" internal pressure (plane strain) or to balanced biaxial tension will fail by instability at a considerably smaller circumferential strain than the longitudinal strain which occurs on necking of a tensile test specimen made from the same metal, Figs. 3, 6, and 8. A tube subjected to pure internal pressure will become unstable at only approximately one half of the circumferential strain as a tube subjected to pure longitudinal tension. It can be shown that the conventional strength is a function of these strains; and the bursting strength of tubes, therefore, should be considerably lower than the tensile strength, the difference depending upon the strain-hardening characteristics of the metal and the degree of biaxiality.

In Fig 9 the three principal strains at the point of instability are represented for the tubes tested by Davis,[6] as obtained both experimentally and by theoretical analysis. The experimentation also covered four tubes not analyzed, which were subjected to a major longitudinal and to a minor circumferential tension. As previously discussed, the experimental evidence indicates

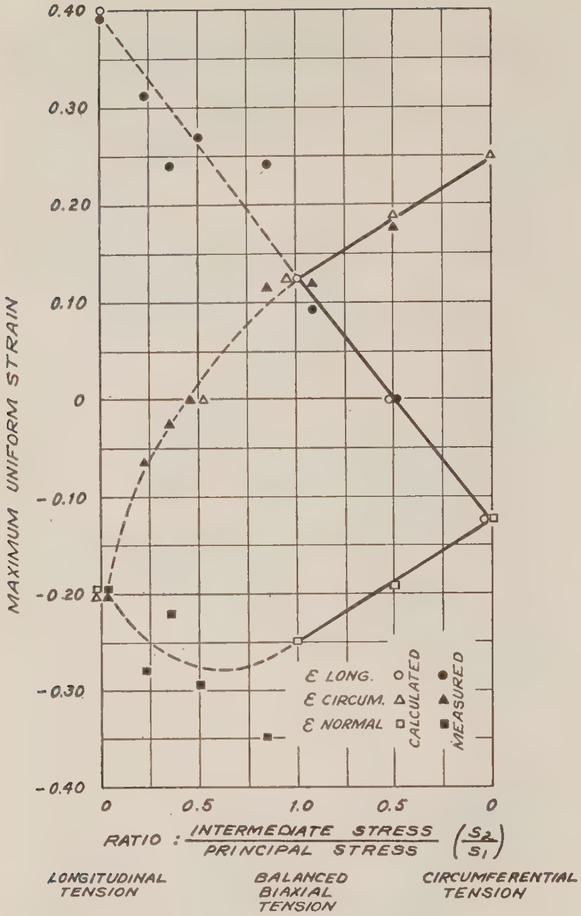

Fig. 9 Maximum Uniform Strains for Various Stress Ratios Existing in Tubing When Necking Starts

that the longitudinal strain at which a circumferential neck occurs should decrease as the internal pressure superimposed on the longitudinal tension increases, Fig. 9. The condition that the longitudinal load reaches a maximum, obviously does not account for the observed changes in longitudinal necking strain with increasing internal pressure, until balanced biaxial tension is

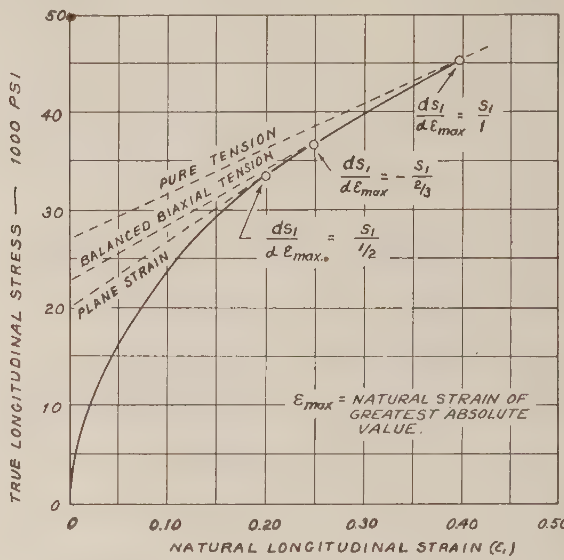

Fig. 11 Necking Condition for Tubing Under Various Stress States as Theoretically Determined, i.e., Graphically From True Stress-Strain Curve in Pure Tension

reached. The effect of the internal pressure in this range has not been accurately investigated as yet.

Prediction of Instability Strains From Stress-Strain Curve in Pure Tension

The instability condition has been developed in such a manner[4] that it may be used to predict the forming limits by necking from

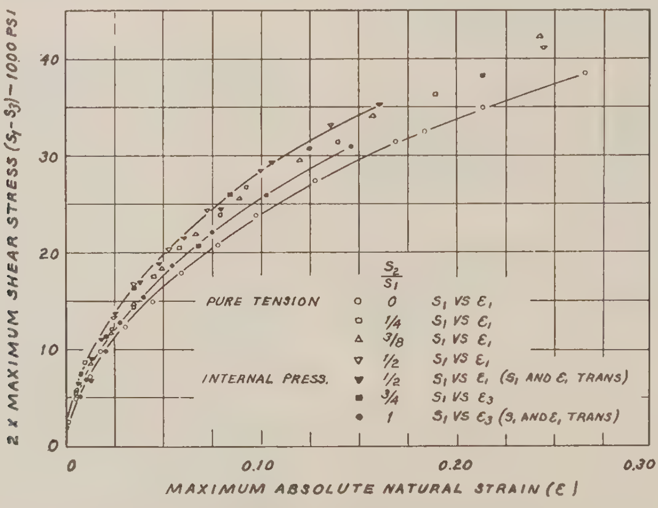

Fig. 10 Curves of Maximum Shear Stress Versus Maximum Absolute Strain for Copper Tubing Tested Under Various Stress States

the true stress-strain curve in pure tension for various conditions of geometry and stress ratios.

The data on copper tubing offer the opportunity to investigate the possibility of predicting the instability strain in this manner since the relation between the stresses and strains are known for this condition of geometry. As was previously mentioned, such application involves the assumption that true stress-strain curves for various stress states will be similar (particularly regarding slope), if the maximum shear stress is plotted against the largest absolute strain. While this maximum shear-stress criteria for flow may lead to considerable error in stress value, it can be shown that no considerable error in predicted strains will result.

In this paper only cases of uniaxial ($s_2 = s_3 = 0$) or biaxial tension ($s_3 = 0$) are considered and therefore the curves for various stress states should be similar if the largest stress s_1 is plotted against ϵ_{max}.

Fig. 10 shows such a plot for copper tubing in various stress states from $s_2/s_1 = 0$ to $s_2/s_1 = 1$. While these curves are not identical, it must be remembered that the slope of the curves is of greater importance than the ordinate value in determining the necking condition and that for a given abscissa value, the slopes for the various curves are nearly identical.

The instability theory has been applied to the true stress-strain curve in pure tension to predict the necking strain for copper tubes in plane strain and balanced biaxial tension, as shown in Fig. 11. Table 1 shows these values together with those obtained by the instability theory from the stress-strain curve for the particular stress state considered and also for the actually measured forming limit. These strain values obtained from the stress-strain curve in uniaxial tension are in good agreement with those derived experimentally.

TABLE 1 STRAIN VALUES FROM STRESS-STRAIN CURVES AND MEASURED NECKING STRAIN

Stress ratio in tubing	Necking strain from stress-strain curve corresponding to stress state	Necking strain from stress-strain curve in pure tension	Measured necking strain
$\frac{s_2}{s_1} = 0$	$\epsilon_1 = 0.40$	$\epsilon_1 = 0.40$	$\epsilon_1 = 0.39$
$\frac{s_2}{s_1} = 1$	$\epsilon_1 = 0.13$	$\epsilon_1 = 0.125$	$\epsilon_1 = 0.11$ $(= -\epsilon_3/2)$*
$\frac{s_2}{s_1} = 1/2$	$\epsilon_1 = 0.19$	$\epsilon_1 = 0.20$	$\epsilon_1 = 0.175$

* Corrected to apply to the stress ratio of $s_2/s_1 = 1$.

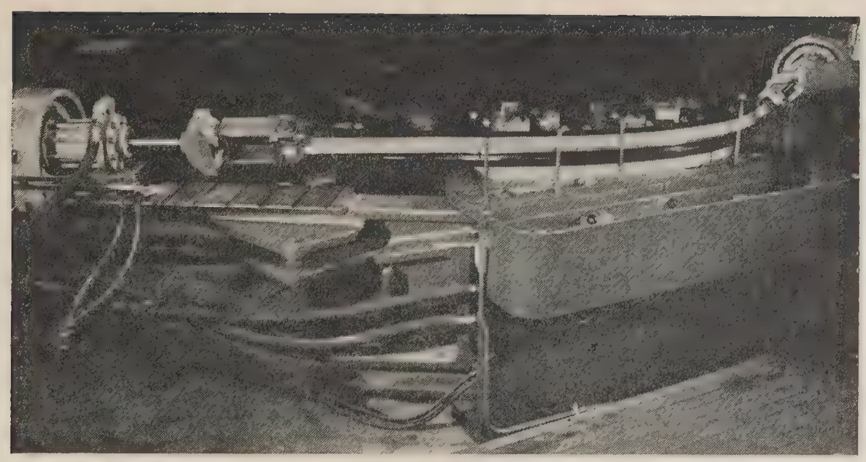

FIG. 1 TYPICAL CONTOUR-FORMING MACHINE IN WHICH TENSION IS COMBINED WITH BENDING

Distortion Due to Contour-Forming of Extrusions and Preformed Sheet-Metal Sections

BY WILLIAM SCHROEDER,[1] BURBANK, CALIF.

The effect of springback on the radius of curvature due to contour-forming of extrusions or preformed sheet-metal sections is analyzed. A number of the commonly used methods of forming are considered. Equations for computing values for change in radius are derived and sample calculations are compared.

NOMENCLATURE

The following nomenclature is used in the paper:

a = area
b = width
c = distance from innermost fiber to neutral axis of bending
d = depth of section
e = strain
e_1 and e_2 = strains due to forming; outer and inner fibers, respectively
ϵ_1 and ϵ_2 = components of elastic strain due to springback that cause a change in radius; outer and inner fibers, respectively
ϵ_x and ϵ_y = components of springback strain at point (x, y) due to elastic bending about the X- and Y-axes, respectively
F = force
I_x and I_y = moments of inertia about the X- and Y-axes, respectively
I_{xy} = product of inertia about the X- and Y-axes
$K = \dfrac{r}{s_0 R_p}$
m = first moment of area
M = moment of force
q_x and q_y = parameters
r = modulus of strain-hardening or slope of true stress-strain curve
R_p = radius of part
R_d = radius of die
R' = transverse radius of curvature due to springback distortion
s = true stress
s_0 = yield strength of material or s_t whichever is greater, see Fig. 5
x and y = co-ordinates with reference to X- and Y-axes
$\bar{x}$ = distance from vertical reference in section to centroid of area
$\bar{y}$ = distance from inner fiber to centroid of area
y_a = distance from inner fiber to axis, parallel to neutral axis, which divides area of section equally

INTRODUCTION

Several methods for computing springback in contour-forming have appeared in the technical literature.[2,3] These, however, apply only to one type of forming, namely, simple bending, and are trial-and-error methods which are very laborious. Many of the present methods of contour-forming have not previously been analyzed.

The springback resulting from contour-forming extrusions and preformed sheet-metal sections may conveniently be classed as

(The part is bent by the rolls to the contour of the curved steel bar.)

consisting of a change in the over-all length or a change in radius of curvature of the part. A change in length of a part is generally of little significance because parts are normally trimmed to the desired lengths after forming; however, a change in curvature usually produces a significant error in contour that must be corrected. For this reason, changes in radius due to springback will be treated as important and changes in length as incidental.

In the hand-forming methods of forming stringer sections, the effect of springback may be corrected in the process of forming. When contour-forming machines[4] of various kinds, requiring dies or form blocks, are used, it becomes desirable to be able to predict the change in curvature due to springback in order to reduce the developmental costs of the dies.

The amount of radius change depends upon the forming method employed. Simple bending methods produce relatively large changes in radius while contour-stretching methods produce much less.[5] Many parts can be formed with these contour-stretching machines without excessive springback; nevertheless, under certain conditions springback allowance in the dies must still be made.

SPRINGBACK DUE TO CONTOUR-FORMING

The phenomenon of springback may be explained in terms of the stress-strain relationship for a bar loaded in tension and compression, as shown in Fig. 3. If the loading is interrupted at some point as at a and the load removed, the stress and strain decrease on the line a to c. The elastic recovery or decrease in strain is from b to c. In a similar manner, unloading the bar from point a' in compression changes the strain from b' to c'. The amount of plastic recovery is indicated for a number of values of strain in order to show the approximate manner of variation with strain.

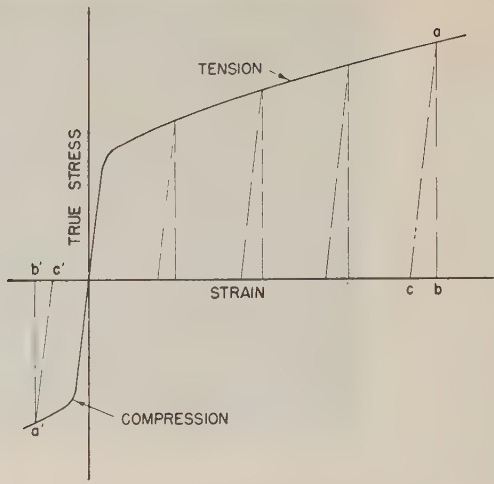

Fig. 3 Stress-Strain Curve and Springback in Tension and Compression

It has already been mentioned that springback from contour-forming depends upon the method and technique of forming. The amount and nature of springback furthermore depend upon the shape of the section. For the purpose of discussion, a number of typical cases will be discussed.

Method I—Forming to Approximate Contour, Heat-Treating, and Stretching to Final Contour

One method which may be expected to give a negligible amount of change in radius due to springback is to form the part approximately to contour by any of the contour-forming methods, follow with a solution heat-treatment or anneal, and stretch the part between 1 to 3 per cent over a block or die. This produces approximately the result illustrated in Fig. 4.

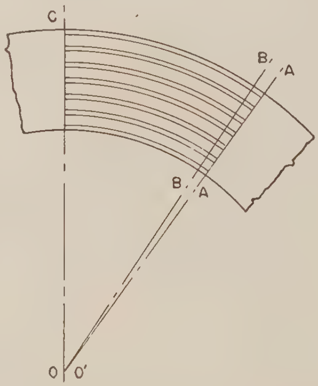

Fig. 4 Effect of Springback by Forming Method I

Owing to the heat-treatment following the forming, all fibers have the same temper at the time of stretching. Furthermore, all fibers are subjected approximately to the same stretching stress and strain since the part is already formed nearly to contour prior

[4] "Methods of Forming Aluminum Alloy Extrusions and Preformed Sheet Metal Sections," by William Schroeder, *Automotive and Aviation Industries*, vol. 90, 1944, pp. 28–31 and 100.

[5] "Elastic Theory in Sheet-Metal Forming Problems," by F. R. Shanley, *Journal of Aeronautical Sciences*, vol. 9, 1942, pp. 313–333.

to stretching. The elastic recovery is therefore proportional to the curved length of the fiber. Hence the fibers terminating on the plane A-A, while under stretching load, spring back to the position in plane B-B. If the line B-B is extended to intersect with line C-O, it is found that the new center of curvature O', coincides with the center of curvature O, before springback. Hence the radius of curvature remains unchanged even though the curved length has decreased.

This result applies equally to all sizes and shapes of cross sections. There is, furthermore, no tendency for the part to distort out of the plane of bending or become twisted.

Inconsistencies in this and all the following methods may result from nonhomogeneity of strength distribution over the cross section of the part. Such nonhomogeneity is sometimes associated with a nonhomogeneous grain structure.

Method II—Forming to Approximate Contour and Stretching to Final Contour

When parts are formed to approximately the correct contour and subsequently stretched without intermediate heat-treatment, a result somewhat different from Method I is obtained. The material becomes strain-hardened nonuniformly in the forming operation, the strain-hardening being greatest in the outer and inner radius fibers and decreasing toward the middle. Springback from stretching a part with such nonuniform strain-hardening will generally produce slight distortion. The amount and type of distortion will depend on the shape of the cross section and the method of contouring. The part will also distort from the plane of bending if the cross section or distribution of strain-hardening is not symmetrical about an axis parallel to the plane of bending. (The plane of bending corresponds to the Y-axis n the figures of this paper.)

Since a wide variety of conditions for this method can exist, each leading to a different result, no attempt to solve any specific case has been made.

Method III Simultaneous Wrap and Stretch-Forming With Constant Force

One rather common method of contour-forming consists of bending and stretching progressively. By this method the part is usually first loaded in tension to a stress corresponding to a very small permanent set. The part is then wrapped around the die. This wrapping action is basically one of bending. It differs from pure bending by the fact that the bending is done under the influence of the tensile force, Fig. 5. Simple bending may be considered as a special case in which the force $T = 0$.

Neutral Axis of Bending With Tensile Force. As a step in analyzing the effect of springback on the radius, the neutral axis of bending will be considered first.

From the geometry of the bend, Fig. 5, it may be seen that

$$d\theta = \frac{dL_1}{R_d + d} = \frac{dL_2}{R_d} \qquad [1]$$

By definition

$$\frac{dL_1}{dL_0} = 1 + e_1 \qquad [2]$$

and

$$\frac{dL_2}{dL_0} = 1 + e_2 \qquad [3]$$

where dL_0 = unstrained length of dL_1 and dL_2.

Therefore

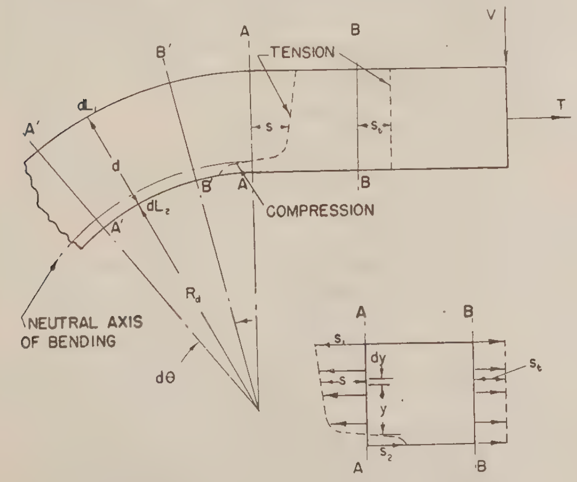
$$\frac{1 + e_1}{R_d + d} = \frac{1 + e_2}{R_d} \qquad [4]$$

or

$$\frac{d}{R_d} = \frac{e_1 - e_2}{1 + e_2} \qquad [5]$$

Stretching of the straight portion of the part may result from the original application of the tensile force; however, the main forming action takes place in the region adjoining section A-A, Fig. 5. The stress conditions are approximately as in Figs. 5(b) and 6. The outside fibers elongate and increase in strength according to the stress-strain behavior of the material. In order for the material between sections A-A and B-B to be in equilibrium, it is necessary that the net force represented by the area under the stress-distribution curves for sections A-A and B-B be equal. This condition is expressed by

$$-\int bsdy + as_t = 0 \qquad [6]$$



(a) Geometry of bend (b) Free body diagram

Fig. 5 Contour-Forming an Extrusion, or Preformed Section, With Constant Tensile Force

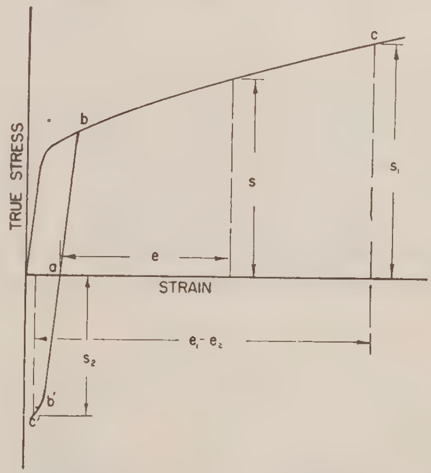


Fig. 6 Stress-Strain Relation for Contour-Forming With Constant Tensile Force

It is assumed that the strain imposed by bending is proportional to the distance from the neutral axis. In this case, the neutral axis of bending is defined as the fiber in the section that has zero stress.

The solution of Equation [6] depends on the relation between s and y, which in turn depends upon the stress-strain diagram. An exact solution is difficult to obtain; however, a useful solution may be obtained by assuming that the stress-strain diagram a-b-c, Fig. 6, may be expressed by

$$s = s_0 + re \quad \ldots\ldots [7]$$

and a-b'-c' by

$$s = -s_0 + re \quad \ldots\ldots [7a]$$

In this expression

$$e \simeq \frac{y}{R_d} \quad \ldots\ldots [8]$$

where y is measured from the neutral axis of bending.

For all cases except $s_t = 0$ (pure bending), it may be assumed that $s_0 = s_t$. For $s_t = 0$, s_0 equals approximately the yield strength of the material.

Substituting Equations [7], [7a], and [8] into [6] gives

$$-\int_0^{d-c} bs_0dy + \int_{-c}^{0} bs_0dy - \int_{-c}^{d-c} \frac{b}{R_d} rydy + as_0 = 0. \, [9]$$

or

$$-s_0(a_a - a_b) - \frac{r}{R_d} a(\bar{y} - c) + as_0 = 0 \quad \ldots\ldots [9a]$$

where

$$a_a = \int_0^{d-c} bdy = \text{area above neutral axis}$$

and

$$a_b = \int_{-c}^{0} bdy = \text{area below neutral axis}$$

Equation [9a] will be evaluated for cross sections composed of rectangular components as in Fig. 7. It may be demonstrated that $(a_a - a_b)$ is equal to twice the shaded area between y_a and c, where y_a is the distance from the inner fibers to an axis, parallel to the neutral axis, that divides the cross-sectional area into two equal parts. Several special cases have been evaluated as follows:

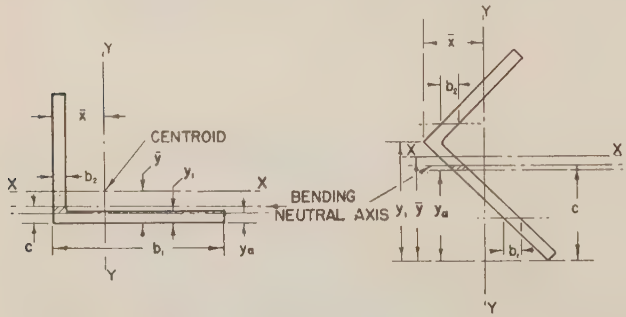

Fig. 7 Dimensions Required for Computing Springback Due to Contour-Forming

Case (a): When $y_a \leqq y_1$, Fig. 7. For this case, Equation [9a] becomes

$$-2s_0b_1(y_a - c) - \frac{r}{R_d} a(\bar{y} - c) + as_0 = 0 \quad \ldots\ldots [10]$$

and

$$c = \frac{2b_1y_a + Ka\bar{y} - a}{2b_1 + Ka} \quad \ldots\ldots [11]$$

where

$$K = \frac{r}{s_0R_d}$$

Case (b): $y_a > y_1 > c$, Fig. 7. Substituting into Equation [4a]

$$-2s_0b_2(y_a - y_1) - 2s_0b_1(y_1 - c) - \frac{ra}{R_d}(\bar{y} - c) + as_0 = 0 \, . . [12]$$

and

$$c = \frac{2b_2(y_a - y_1) + 2b_1y_1 + Ka\bar{y}}{2b_1 + Ka} \quad \ldots\ldots [13]$$

Neutral Axis in Simple Bending:

(*a*) For simple bending the value of c lies between y_a and $\bar{y}$; and $T = 0$. When $c \leqq y_1$ and $y_a < y_1$

$$c = \frac{2b_1y_a + Ka\bar{y}}{2b_1 + Ka} \quad \ldots\ldots [14]$$

(*b*) For $y_a < y_1$ and $c > y_1$

$$c = \frac{2b_1(y_a - y_1) + 2b_2y_1 + Ka\bar{y}}{2b_2 + Ka} \quad \ldots\ldots [15]$$

(*c*) For $c > y_1$ and $y_a \geqq y_1$

$$c = \frac{2b_2y_a + Ka\bar{y}}{2b_2 + Ka} \quad \ldots\ldots [15a]$$

Determination of Part Radius After Springback

The springback in contour-forming with a constant tensile force may be analyzed by considering the moments required for bending and the change in moments due to springback. The bending moment depends upon the shape of the section and the plastic properties of the material, while the moment due to springback depends upon the elastic properties of the section. The following equilibrium conditions must be satisfied

$$\Sigma M_x = 0 \quad \ldots\ldots [16]$$

$$\Sigma M_y = 0 \quad \ldots\ldots [17]$$

$$\Sigma F_n = 0 \quad \ldots\ldots [18]$$

where

M_x and M_y = moments about the X- and Y-axes, respectively

F_n = force normal to X-Y plane

In this case, the X- and Y-axes are taken through the centroid of the section with the Y-axis in the plane of bending.

Since springback is a purely elastic phenomenon, the principle of superposition may be applied and the changes in stress and strain may be resolved into components as due to bending about each of the two axes and a uniform change in strain normal to the X-Y plane. The uniform

strain component produces no distortion, as previously explained, and can therefore be neglected in the following discussion. The other elastic components are related as follows

$$\epsilon = \epsilon_x + \epsilon_y \quad \text{[19]}$$

Since Equation [18] yields information only on the uniform component of strain, it may be omitted from further discussion.

Based on Fig. 5, the moments due to bending are expressed by

$$M_{1x} = \int_s syda \quad \text{[20]}$$

and

$$M_{1y} = \int_s sxda \quad \text{[21]}$$

where $\int_s$ means a surface integral over the cross-sectional area and da refers to an area element with dimensions dy and dx. The changes in moment due to springback are

$$M_{2x} = \int_s E\epsilon yda \quad \text{[22]}$$

and

$$M_{2y} = \int_s E\epsilon xda \quad \text{[23]}$$

Substituting into Equations [16] and [17]

$$\int_s syda + \int_s E\epsilon yda \quad \text{[24]}$$

and

$$\int_s sxda + \int_s E\epsilon xda \quad \text{[25]}$$

The solution of Equations [24] and [25] depends mainly upon the stress-strain curve between points c' and c, Fig. 6. An approximate but useful result is again obtained by assuming

$$s = s_0 + re \text{ and } s = -s_0 + re$$

The elastic bending strain ϵ may furthermore be assumed to be composed of ϵ_x and ϵ_y, where ϵ_x is due to bending about the X-axis, and ϵ_y due to bending about the Y-axis. Assuming that planes before forming remain planes after forming

$$\epsilon_x = \frac{\epsilon_{x1} - \epsilon_{x2}}{d} y = q_x y \quad \text{[26]}$$

and

$$\epsilon_y = \frac{\epsilon_{y1} - \epsilon_{y2}}{d} x = q_y x \quad \text{[27]}$$

For the condition after springback, Equation [5] becomes

$$\frac{d}{R_p} = \frac{(e_1 - \epsilon_{x1}) - (e_2 - \epsilon_{x2})}{1 + e_2 + \epsilon_{x2}} \quad \text{[28]}$$

and

$$\frac{d}{R_p} \simeq \frac{d}{R_d} + \frac{\epsilon_{x1} - \epsilon_{x2}}{1 + e_2} = \frac{d}{R_d} + \frac{q_x d}{1 + e_2} \quad \text{[29]}$$

This may be rearranged to give

$$R_p = \frac{R_d}{1 + \dfrac{q_x R_d}{1 + e_2}} \quad \text{[30]}$$

The distortion arising from springback tending to bend the extrusion from the plane of bending may be expressed in terms of

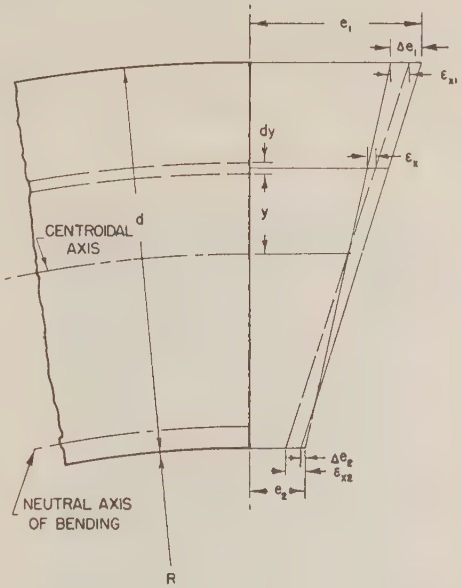

Fig. 8 Strain Relations in Centroidal Plane About X-Axis Due to Forming and Springback

q_y. The transverse radius of curvature R' is obtained by substituting ϵ_{y1} and ϵ_{y2} for e_1 and e_2, respectively, in Equation [5]; thus

$$\frac{d}{R'} = \frac{\epsilon_{y1} - \epsilon_{y2}}{1 + \epsilon_{y2}} \simeq \epsilon_{y1} - \epsilon_{y2} \quad \text{[31]}$$

Combining Equations [31] with [26]

$$R' = \frac{1}{q_y} \quad \text{[32]}$$

Values for q_x and q_y may be obtained by solving Equations [24] and [25]. After substituting for s and ϵ, Equation [24] becomes

$$s_0 \int_{c-\bar{y}}^{d-\bar{y}} yda - s_0 \int_{-\bar{y}}^{c-\bar{y}} yda + \frac{r}{R_d} \int_s y^2 da + E \int_s (q_x y + q_y x) yda = 0 \quad \text{[33]}$$

and

$$s_0(m_{x1} - m_{x2}) + \frac{r}{R_d} I_x + \frac{r}{R_d} a(c - \bar{y})^2 + Eq_x I_x + Eq_y I_{xy} = 0 \quad \text{[34]}$$

where

m_{x1} = first moment of area above the neutral axis of bending taken about the X-axis

m_{x2} = first moment of area below the neutral axis of bending taken about the X-axis

Similarly Equation [25] becomes

$$s_0(m_{y1} - m_{y2}) + \frac{r}{R_d} I_{xy} + Eq_x I_{xy} + Eq_y I_y = 0 \quad \text{[35]}$$

where

m_{y1} = first moment of area above the neutral axis of bending taken about the Y-axis

m_{y2} = first moment of area below the neutral axis of bending taken about the Y-axis

It may furthermore be demonstrated that in Equations [34] and [35]

$$m_{x1} = -m_{x2} \text{ and } m_{y1} = -m_{y2}$$

In computing springback for the conditions of forming with a constant tensile load, specific values are substituted into Equations [34] and [35] to solve for the values of q_x and q_y. The values of q_x and q_y are then substituted into Equations [30] and [32] for R_p and R'.

Forming Method IV—Simultaneous Wrap and Stretch Forming With Increasing Tensile Force

When the extrusion is contoured and stretched with an increasing tensile force the whole section is subjected to tensile stress and the neutral axis, as defined, does not exist. Since the X- and Y-axes are centroidal axes and under the present condition the area above the neutral axis is the whole area a, and the area below the neutral axis is zero, it follows that

$$m_{x1} = m_{x2} = m_{y1} = m_{y2} = 0$$

From Equations [34] and [35]

$$q_y = 0 \text{ and } q_x = -\frac{r}{ER_d}$$

Substituting these values into Equations [30] and [32]

$$R_p = \frac{R_d}{1 + \dfrac{r}{E(1 + e_2)}} \qquad [36]$$

and

$$R' = \infty \text{ (no transverse curvature)} \qquad [37]$$

Discussion of Forming Methods

Comparison of Springback. The relative amounts of radius change resulting from the foregoing forming methods are computed for one specific condition and compared in Table 1. It may be seen that the radius change is negligible for Method I and is progressively greater for Methods IV, III with tensile pull, and Method III without tensile pull (pure bending). The results for Method II are difficult to predict but are expected to range between the results for Methods I and IV. Of the methods discussed, I and IV will produce little tendency to distort the part from the plane of bending even though the section is not symmetrical about the Y-axis.

TABLE 1 COMPARISON OF COMPUTED RESULTS FOR FORMING A $^3/_4$-IN. × 1-IN. BY 0.070-IN. EXTRUSION WITH $^3/_4$-IN. LEG IN PLANE OF BENDING

(Material: 24S-T aluminum alloy; and R_d = 20 in.)

Method of forming	Part radius in plane of bending R_p, in.	Resulting transverse radius of curvature R', in.
I	20	∞ (no distortion)
II (values not computed but range is estimated)	20–20.55	6000—∞
III (a) s_t = 53,000 psi	20.94	6000 (slight)
III (b) s_t = 0 (simple bending)	22.6	71 (appreciable)
IV	20.55	∞ (no distortion)

In any of the methods that involve stretching it is important that the jaws for gripping are so designed that they will develop the necessary gripping force without weakening or twisting the section to be formed. Another serious difficulty of contour-forming by stretching is due to friction between the part being formed and the die. This friction makes it difficult and sometimes impossible to stretch the part throughout the length in contact with the die when using Methods I and II. This factor may also interfere with the proper execution of Method IV. The use of a good lubricant and vibrating the die are beneficial for reducing friction between part and die.

Experience may show that friction between the part and die may make it impractical or impossible to attain the conditions assumed in Method IV, and that minimum amounts of springback in practice will correspond more nearly to those for Method III using a constant tensile force.

Accuracy of Results

There has been little opportunity to compare computed with measured values for change in radius due to springback. Where checks have been possible the results have agreed within the limits of accuracy of the measurements. Due to the simplifying assumptions that were made some slight disagreement between computed and measured values may be expected; however, experience has indicated that the error from this cause is considerably less than the variation that may be expected from nonhomogeneity and variation in physical properties of material used in forming.

(Owing to travel emergency conditions existing when this paper was presented, discussion will be accepted until June 17, 1946)

Design Considerations for Welded Machinery Parts

By G. L. SNYDER,[1] COATESVILLE, PA.

Only some basic considerations for the designer in developing weldments are brought out in this paper, because of the wide scope of the subject. Separately, these basic considerations may seem elementary and self-evident, but when considered collectively in developing a weldment, their complexity becomes apparent. At least twelve different types of components can be utilized by a designer in his weldment and each of these components can be used in several ways. So, the designer must be familiar with limitations in processing weldments and with the scope and limitation of equipment and methods used in their production. These are the factors discussed here. However, this discussion is limited to dynamically loaded welded machinery parts.

HOT-rolled steel plate, a basic element, probably is the most universal component used in welded machinery parts. Undoubtedly, the freedom offered by the many sizing and shaping possibilities of hot-rolled steel plate has much to do with its widespread use as weldment components. Basically flexible raw material from the stand-point of dimensions, hot-rolled plate is obtainable in variable sizes to 195 in. wide or to 25 in. thick.

Flat Components

Shearing usually is the most economical method of sizing or shaping a plate to rectangular or circular dimensions. But when a plate is to be sheared to size, the designer should keep in mind the existence of shear droop which is the abrupt break in flatness that occurs around the sheared edge, because localized stresses imposed by the shearing pressure exceed the elastic limit of the material. Since this effect is confined to the area adjacent to the edge, it can be practically disregarded when the component is subjected to subsequent trimming or when it is in light gages, $^3/_8$ in. and under.

Flame-cutting undoubtedly is the most common method of shaping and sizing weldment components, particularly when the number of duplicate weldments required is small. Probably a big reason for this is the fact that many components of weldments necessarily are irregular in shape.

Since regular configuration generally is cheaper, the designer should think in such terms where possible. However, he need not be concerned if an edge is sheared or flame-cut so long as he designs the part so that the supplier is free to use either method or both on a particular component.

Fig. 1 shows an example of component produced entirely by flame-cutting. Fig. 2 is a plate part produced by a combination of shearing and flame-cutting.

Of course, in addition to shaping and sizing, the cutting torch

Fig. 1 Component Flame-Cut to Shape from Hot-Rolled Plate

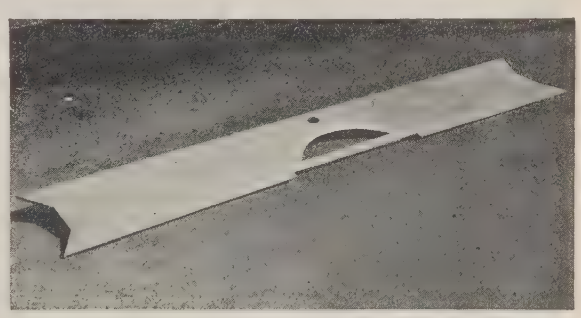

Fig. 2 Plate Component Shaped by Shearing and Flame-Cutting

also makes welding chamfers, or kerfs, on the edges of a component which provide the "grooves" for welds, other than plain fillets, when assembled with adjoining components.

Tolerance on components, disregarding the method used in producing them, merits careful consideration by the designer of weldments for an accumulation of tolerances can cause costly difficulty in fabrication, as is shown in Fig. 3. This illustration pictures a highly improbable coincidence of tolerance accumulation. Nevertheless it could occur within the limits of necessary commercial tolerances on flatness and straightness. Tolerances are important considerations on flatness and straightness, particularly if the fabricator's facilities for performing such operations cannot be operated as cheaply as those of the supplier of components.

Often it is advantageous to size components on machine tools, if only for the reason that much closer tolerances are obtainable. For a complicated assembly with much welding on it, prefabrication machining is indicated. Also, at times, machining of components will help achieve close tolerance on a complete weldment. The more generous the tolerances on components, the more prevalent the gaps in fitting. Gaps require the deposition of a

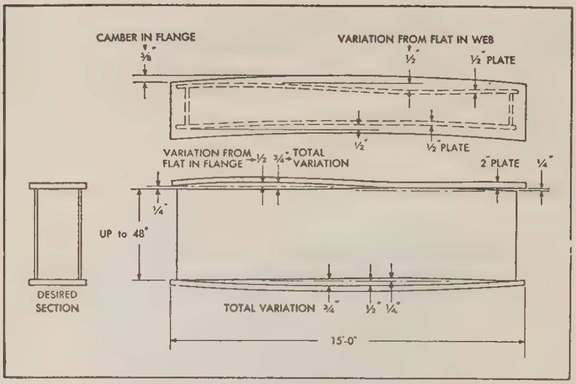

Fig. 3 Box Beam Showing Results of Camber and Flatness Tolerances

greater amount of weld metal, thereby increasing costs and destroying the metal-to-metal contact which resists tendencies to shrink or warp.

The main structural parts of the weldment shown in Fig. 4 are

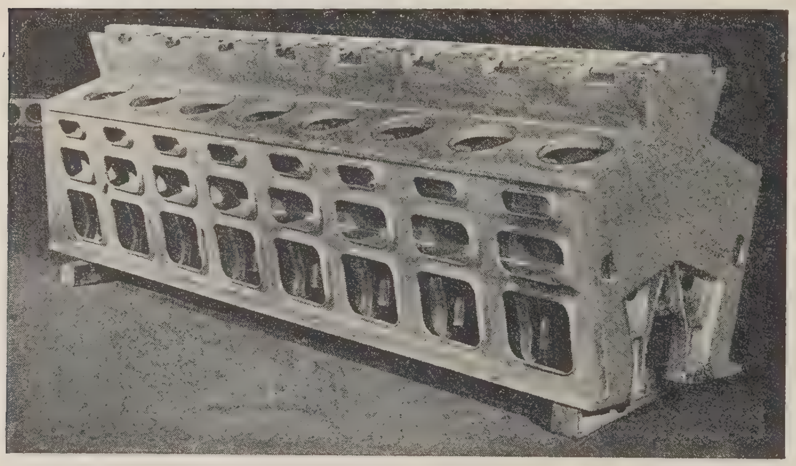

Fig. 4 16-Cylinder, V-Type, Welded Diesel-Engine Frame

premachined. Since this item is one of mass production, individual peculiarities in each weldment caused by the nonuniform accumulation of component tolerances could not be allowed.

Sometimes design considerations dictate prefabrication ma-

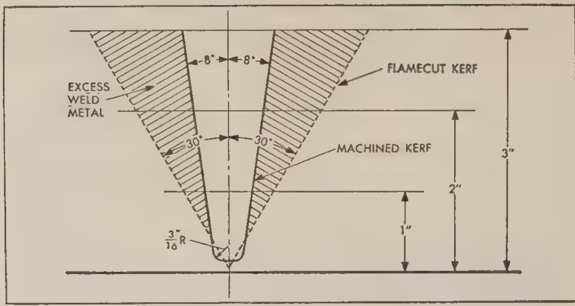

Fig. 6 Comparison Between "U" and "V" Welding Kerfs

chining as in the case of the joint between the heavy web and flange shown at the left in Fig. 5. This might be a detail of construction on the bed of a large hydraulic or mechanical press. The loading in the region of the compression flange of those machines is such that the joint detail, shown at the right in Fig. 5, would be necessary if the edge of the web were not machined. When machined, the metal-to-metal bearing, to withstand concentrated compression loads, is achieved. Fillet welds as indicated in this illustration are adequate then for withstanding the horizontal shear components in this region of the beam. The edging of such webs to a relatively close tolerance is a simple operation on a plate planer.

Another reason for prefabrication machining is the provision of economical welding kerfs in combination with good joint fit-up, particularly in welding thick plates. A kerf must be sufficiently wide to clear the tip of the welding electrode to permit the depositing of weld metal at the root of the weld; for as the plate thickness increases, it is apparent that the amount of metal wasted in the angularity of V-shape flame-cut kerfs in contrast to the U-shaped ones, as shown in Fig. 6, becomes an important factor.

Prefabrication machining is necessary, too, in instances of conflicting tolerances, in the fitting of circular components within each other. Studies of minimum tolerances reveal that gaps between pieces so fitted are inevitable but machine fits reduce such

FIG. 11 WELDMENT SHOWING UTILIZATION OF FLUED OPENING

gaps to a negligible point. Prefabrication machining is necessary at times, also, for providing proper contours in highly stressed weldments, or in those subject to fatigue. Fig. 7 shows such an instance in the bottom plate of a hydraulic cylinder premachined to provide proper curved contour at the corners. This sketch also illustrates an application of machined kerfs on thick plates. Fig. 8 shows the cylinder of a hydraulic press designed on such principles.

Another method used frequently for shaping plate components is "blanking" or "punching" on a power press. This operation which is simply shearing, using knives of special shapes, can be justified, usually, only when quantities required warrant the expense of dies. Fig. 9 shows typical blanked or blanked and punched pieces.

A simple example of blanking or punching is the shearing of a rectangular plate. By blanking the piece only one operation is required in comparison to four operations for each piece which would be necessary in shearing. Hence a comparison of blanking and shearing costs can be made merely by multiplying the cost of the added three shearing operations by the number of pieces required and comparing this with the cost of tooling. Naturally, the estimate will be approximate since the relative cost per hour of the machines used might affect the comparison. Another important benefit gained by blanking is the comparatively close tolerance that can be achieved.

"FORMED" COMPONENTS

Thus far we have considered only flat pieces in the preparation of components but we must give thought also to "formed" type components which are required frequently in weldments. Several methods are in general use for forming components for weldments. One of these is press-bending to make horizontal angular bends as are shown in Fig. 10.

Definite reasons for forming operations such as bending or fluing have been evolved. One is lower cost, for angular bends eliminate one or more welded joints. The cost of bending seldom equals that of the alternative assembly and welding. Careful examination of the design proportions of metal sections might show the economy of using the same metal thickness of web and flange to utilize the advantage of a bent section. A bent com-

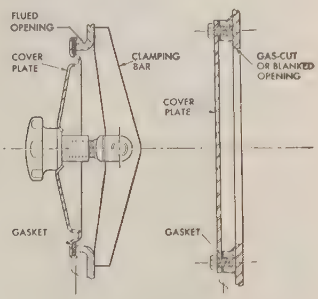

FIG. 12 THE FORMED SEAT COVER AT THE LEFT IS DESIGNED TO BE FASTENED BY AN INNER CLAMP

(Assembly, welding and consequent warpage, and the cost of drilled and tapped holes are eliminated as in the case of the cover at the right.)

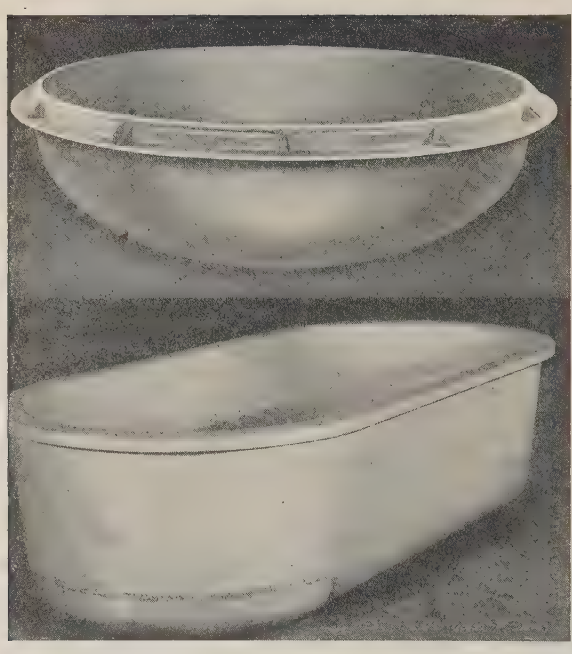

Fig. 13 Melting Pots Using Flanged Products as Components

ponent naturally is more rigid than a flat one. This can be important in the control of shrinkage and warpage.

Another method often of value in component production is the specialized forming operation known as fluing. Flued openings such as shown in Fig. 11, when machined, provide formed seats for covers. Generally, such a cover is designed to be fastened by an inner clamp as shown at the left in Fig. 12. Treatment permitted by the flued opening eliminates assembly, welding, and consequent warpage, and the cost of many drilled and tapped holes as shown at the right in Fig. 12. In addition, weight reduction is achieved.

Another function of flued openings in weldments is to provide stiffening lips which are executed normally by welding a band around the opening where required by design considerations.

Fig. 14 Corner Stamping for Water-Cooled Furnace Door

Fig. 15 Furnace Door Using Corner Stampings Shown in Fig. 14

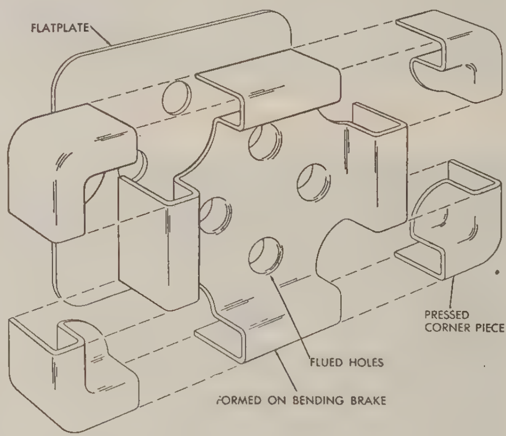

Fig. 16 Exploded View of Water-Cooled Furnace Door Showing Construction

Since dies are necessary, flued openings are unwarranted economically unless the quantity of openings justifies their use. When flued openings are being considered the designer should consult the supplier for it is possible that dies exist which can be adapted.

Products of the flanging or spinning machines often are utilized to advantage in weldments, as their applications in the melting pots in Fig. 13 show. The bottom corners of the pot in the lower illustration are composed of a flanged head split in half, with one half serving for each corner.

The use of flanged products as components may provide component rigidity, possibly simpler welding conditions, or a reduction in welding. Flanging also provides curved contours which may be desired for proper functioning or for appearance.

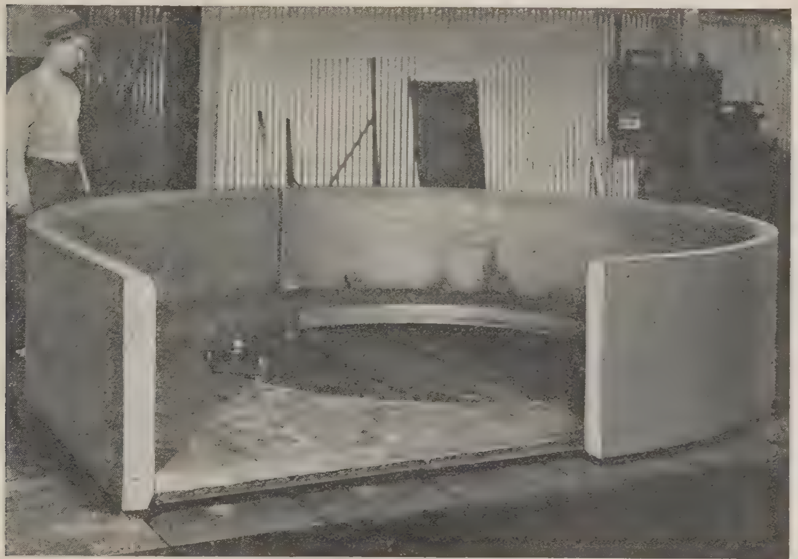

Fig. 17 Plates 4 In. Thick Formed on Bending Roll

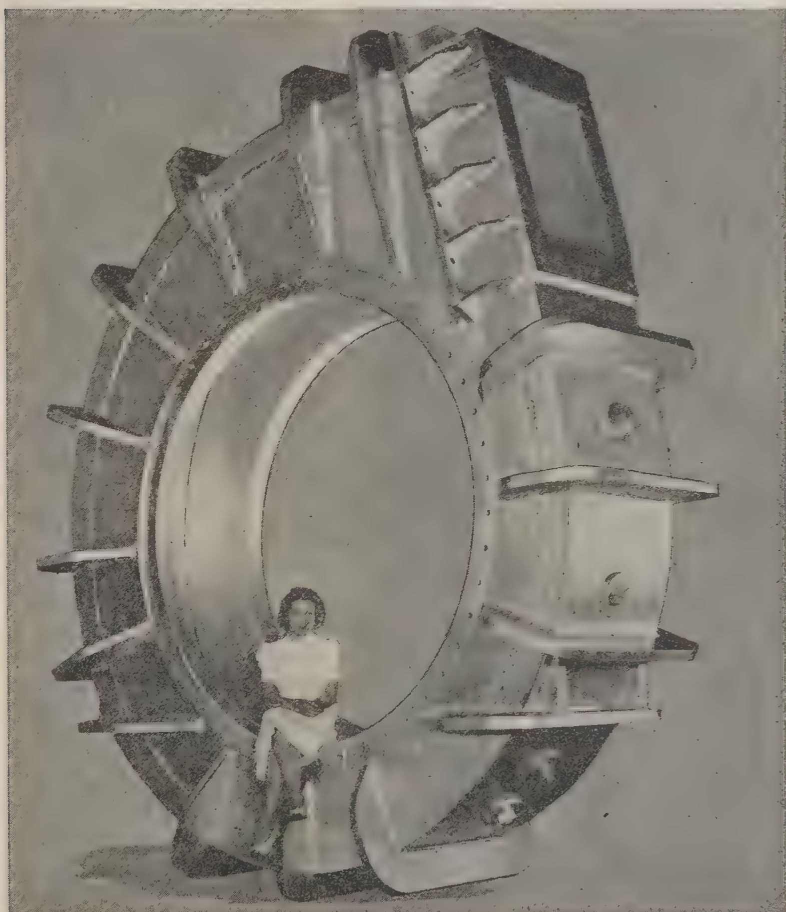

Fig. 18 Pump Casing Utilizing Components Shown in Fig. 17

Stamping and Pressing

When quantities justify, formed components produced in special shapes by forming dies on power presses may be used advantageously. Fig. 14 shows a small stamping and Fig. 15 shows the weldment in which four of these stampings form the corners of the piece. Forming, required on the remaining components, is done on a press brake. Fig. 16 shows the relation of the various components in this weldment.

A useful method of shaping cylindrical contours is provided by bending rolls. A component formed in such a manner is shown in Fig. 17. This component is seen readily in the finished weldment shown in Fig. 18.

Shapes Formed on Rolling Mill

At times, shapes formed on a rolling mill may be used justifiably in weldments. Their value as components results from two factors: A reduction in cost because of elimination of welding and initial rigidity which can tend to simplify fabrication problems of shrinkage and warpage. In considering the use of structural rolled shapes, the tolerances possible in such rolling-mill products should be studied carefully for they may affect adversely the design requirements.

Steel castings are used extensively as components in weldments where economy in producing complicated shape requirements or special contours at given points in a particular assembly are involved. When castings are to be used in weldments their physi-

Fig. 19 Typical Use of Drop Forgings and Flash-Welding to Provide Components of Irregular Shape and Difficult Proportions

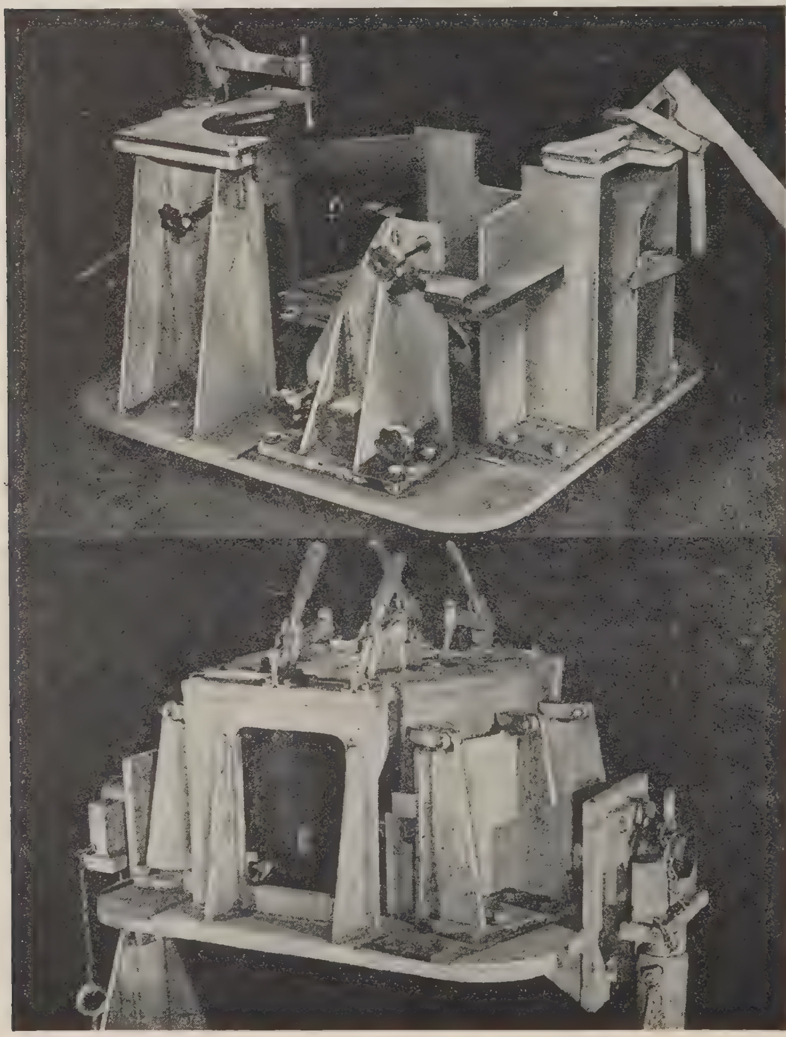

Fig. 20 Two Specially Designed Fixtures for Tooling Weldments in Quantity Production

cal and chemical properties should be specified carefully. Also, where size permits, it is desirable to have castings of electric-furnace steel which seems to possess greater cleanliness. This is important in obtaining good welds with minimum difficulty.

Drop forgings also may be used when their size and quantity justify the investment in dies. This product has good homogeneous properties, and when properly controlled, its tolerances are close. Fig. 19 shows such application where several drop forgings have been joined by flash-welding.

Fabrication of Weldments

Having considered the production and application of components, the subject of fabrication from the designer's viewpoint in developing a weldment is the next consideration. The first aspect covers the type and extent of available equipment in a weldery which will produce the pieces designed. This is important since the more flexible and extensive the equipment, the more freedom there is in design. In addition, when quantities are involved, advantage may be gained in designing the job to suit particular facilities of a weldery. Usually it is well to consult with the engineering staff of the weldery most likely to be involved regarding these matters, particularly if repetitive items are contemplated.

Production methods concerning the fabrication of weldments may be considered from two aspects. The first involves the extent of what might be termed "universal" equipment, such as positioning facilities, automatic welding units, inspection methods,

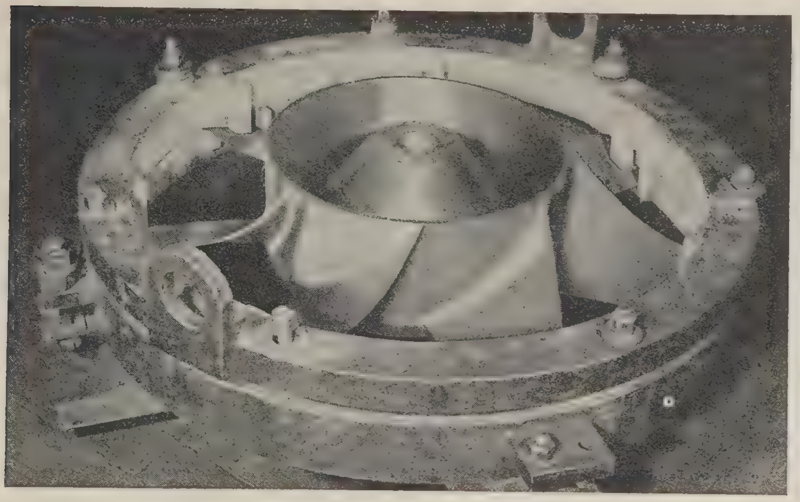

Fig. 21 High-Speed Fan, and Jig in Which It Is Welded

and stress-relieving facilities. Many types and sizes of positioning equipment are in use in welderies today. The other aspect involves special jigs or fixtures or other types of tooling that might be justified or imperative. Usually, if the product is to any degree repetitive in quantity, the possibilities in special tooling should be considered.

Also to be considered by the designer to promote economy and quality is the possibility of breaking up the weldment into subassemblies in sizes to suit production equipment. If the final size of the part as designed exceeds the limits of available equipment, possibly it can be redesigned so that a minimum of handling of the piece in its final size is necessary. Often the use of automatic welding equipment with its finite scope and features merits a thought in designing the weldment, especially in considering the advantage such equipment offers for cost reduction.

Fig. 22 Subassembled Component of a Weldment
(Welding is completed before further assembly is done.)

With special tooling, the designer should keep in mind that he is dealing still with rough component parts despite measures that might have been taken to minimize tolerances. Weldshop tooling naturally is more restricted than that usually available in machine shops. Tools, such as jigs or fixtures, should be designed with the necessity of flexibility in mind. Fig. 20 shows two special fixtures which are typical.

Special tooling also might be mandatory in order to hold components in proper relation to each other during the welding operation. Fig. 21 shows a special fixture with the weldment in place.

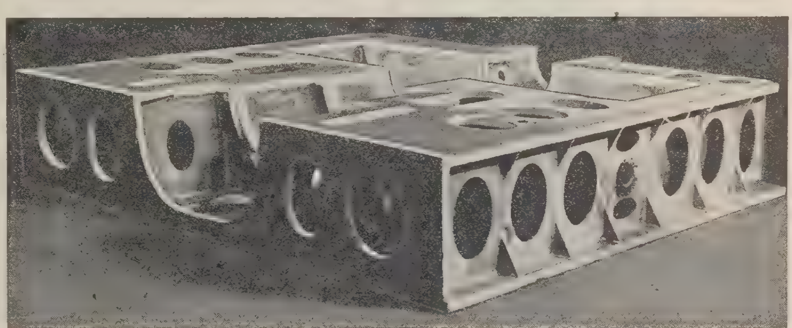

Fig. 23 Lower Section of Welded Gear-Reduction Housing

Although subassemblies frequently are important to the designer of weldments, design limitations often prohibit their use. Obviously, the more work done on small pieces, the easier and quicker will be the completion of the final assembly.

A completely welded subassembly is shown in Fig. 22. The final weldment is pictured in Fig. 23. Here, design controls the method of fabrication, for the lower flange member could be made in one piece. In that case at least a portion of the subassembly welding would have been required on the larger and more cumbersome piece.

Subassemblies of components should be made so that particular portions in certain instances can be sized before they become part of the final weldment. This practice helps insure that the final weldment is close to required dimensions. Where tolerances have accumulated, straightening or trimming might be involved. The effect of the welding on the completed subassembly from the standpoint of warpage or shrinkage has been eliminated as a factor on the finished weldment.

Sometimes in very complicated structures involving considerable welding, various subassemblies are stress-relieved be-

Fig. 24 Welded Subassembly With All Welding Readily Accessible

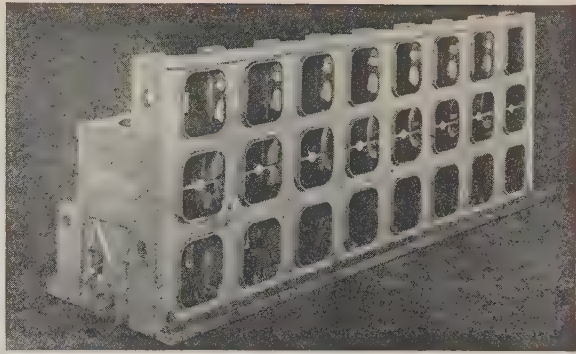

Fig. 25 Weldment of Which Subassembly Shown in Fig. 24 Is a Part

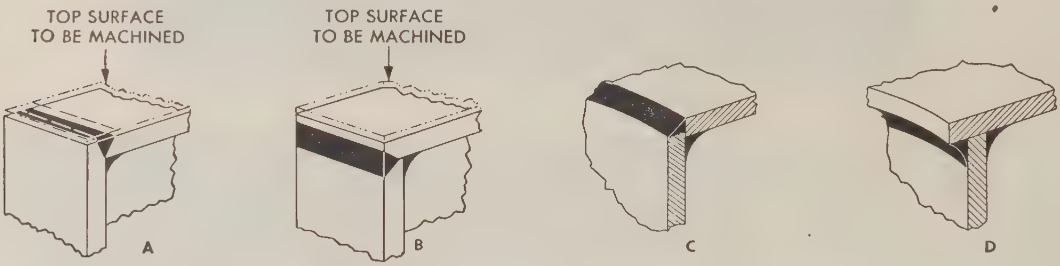

Fig. 26 Types of Welded Joints Which Deserve Design Consideration

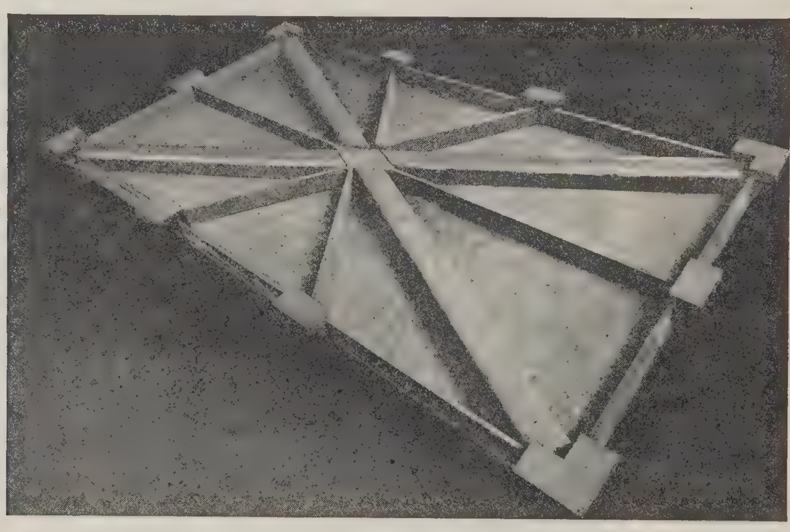

Fig. 27 Stiffener Arrangement on Underside of Machine Bed

fore being assembled into the whole structure to reduce the accumulation of residual stresses. Subassemblies also facilitate inspection of welds. At times, where x-ray inspection is specified, subassembly welding is necessary, for if the welding were not completed and x-rayed in the subassembly, the interference of adjacent components in the completed assembly might make it impossible to x-ray or repair such welds. At times, subassemblies are welded completely when they include compartments subjected to pressure or oil-retention tests.

Tests are made and necessary repairs completed on the subassembly piece. Clearly, such practice is more economical than to attempt such work on the final piece, if only from the standpoint of the relative bulk to be handled in testing and repairing.

An important reason for careful consideration of subassembly possibilities in design is the provision of maximum access for the greatest possible amount of the welding to be done, for the more accessible the welding, the less it will cost. Also, quality is more readily achieved if the welding operator can work under open or accessible conditions. Fig. 24 shows a subassembly on which all welding to be done is before the operator. Fig. 25 shows the

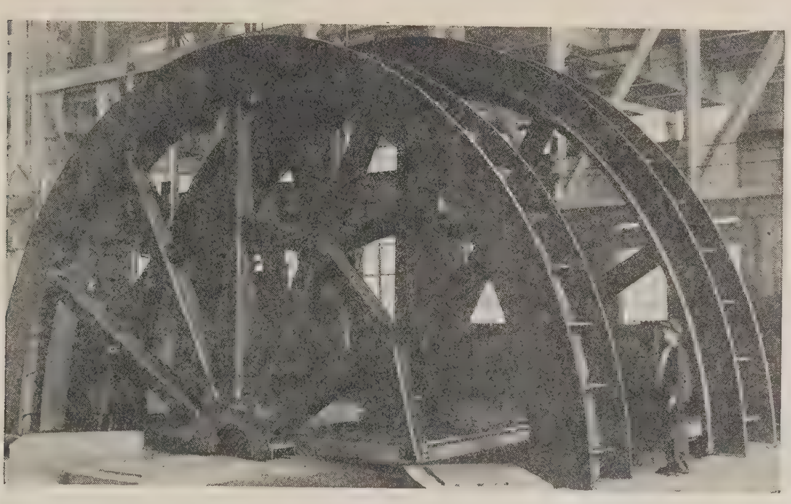

Fig. 28 Two Halves of Large Welded Machine Part Which Are Assembled and Welded Into One Piece After Shipment

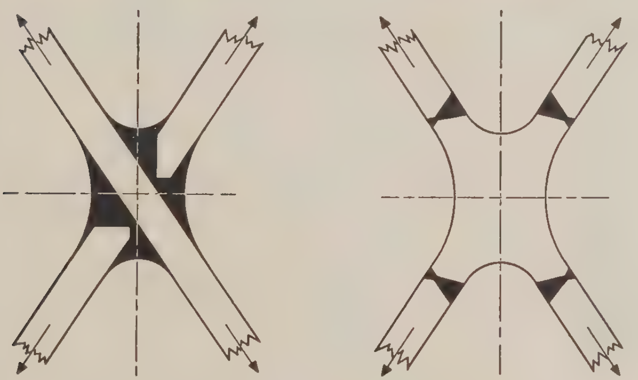

Fig. 30 Types of Intersection Without and With Transition Piece

completed weldment with the subassembly in place. Obviously, welding has been simplified since the joining welds between subassembly and main assemblies are completed by working through the access openings shown. If the welding had not been completed in the subassembly it would have had to be performed through such openings. This would have necessitated the use of a mirror by the welder with resulting slow and consequently expensive welding.

At times it is advantageous to design so that progressive subassembly is possible. Thus one portion of the weldment is completed before it is assembled and welded to other components as a step in the final assembly of the completed weldment.

When maximum access is provided by subassembly practice or other design control, inspection can be more conclusive. Fig. 23 illustrates design for accessibility with elliptically shaped openings, permitting access to the inner side of the joints to be welded. Here desirable structural qualities of a box member are not sacrificed for access but care has been taken in shaping the openings so that abrupt discontinuities in the contour of the members are avoided.

Welded joints of maximum quality and predictability from the standpoint of either external contour or internal soundness are almost impossible to execute with the manual arc if the joint is not reasonably accessible from both sides. However, at certain points

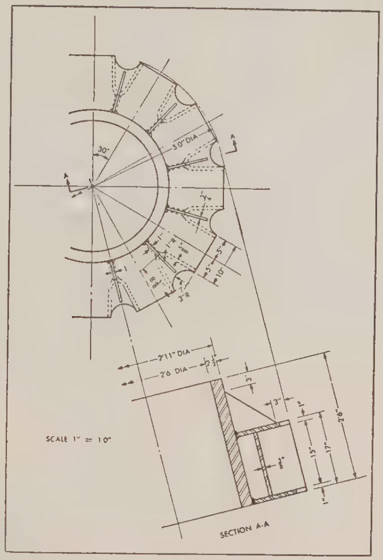

Fig. 29 Detail of Construction of Center Hub on Piece Shown in Fig. 28

where stresses are of secondary nature and fatigue-loading is not present in structures, the joints do not require work on both sides.

In addition to the type of welded joints used, their position in the weldment deserves careful design consideration for several important reasons besides positioning them for maximum access. Where machined surfaces occur in the design, care in placing joints can effect economy, as comparative illustrations given in Fig. 26 show. Clearly, if the joint is placed as in Fig. 26 (A), a portion of the deposited weld metal will be removed in machining operations. Depositing weld metal is expensive and removing it is wasteful. The joint placed in Fig. 26 (B) shows how the amount of necessary weld metal has been reduced. The joint shown need have only the cross-sectional area of that shown in Fig. 26 (A) after it is machined. Economy may be possible by positioning a joint as shown in Fig. 26 (C) which eliminates the kerf and its cost, or Fig. 26 (D) which also simplifies fitting, in contrast to the same joint detailed in Fig. 26 (A).

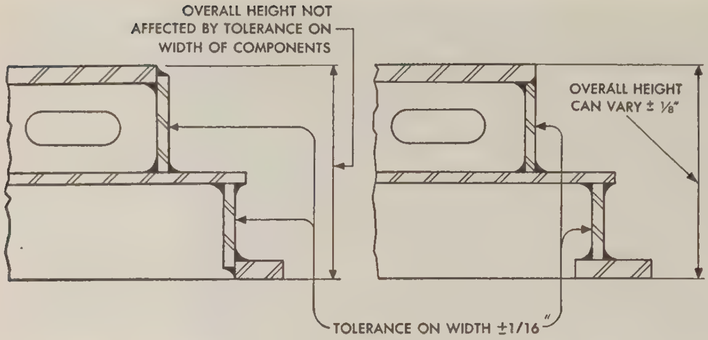

Fig. 31 Effects of Controlling Cumulative Tolerances

At times spoked or diagonal members are indicated by design considerations and their intersection usually presents a type of joint difficult to fit and costly to weld if proper external contours are to be maintained. An example is shown in Fig. 27. Here the diagonal pattern of the box stiffeners on the underside of this machinery bed is highly desirable from the standpoint of maximum rigidity. However, their central intersection presents a problem of the nature just described. By the utilization of a flame-cut central member, square joints at the intersection have been obtained; hence, fitting and welding are simplified.

Fig. 28 shows a simple treatment of an intersection of spokes. The central member in this is a subassembly so designed that the spokes do not converge on each other with obviously poor fitting and welding conditions resulting. An illustrative sketch showing the construction of this central hub is given in Fig. 29.

At intersections of members subject to high stress levels, fatigue, impact, or a combination of these, careful design treatment is imperative. Contrasting designs of such an intersection are shown in Fig. 30, where the left illustration shows the intersection as welded without benefit of a transition member. Clearly, in order to provide curved contours, an inordinate amount of weld metal would be necessary. In addition, it is practically impossible to execute such a welded joint so that full predictable strength will result. If necessary, x-ray inspection is practically impossible. Fitting conditions are poor and the excessive amount of weld metal adds to warpage and shrinkage problems. Desirable features of a similar joint as executed in the right illustration are self-evident.

The designer should remember the generality that in a weldment the fewer separate and different components required, the cheaper and better the design will be.

At times, particularly with secondary members such as ribs or stiffeners, slight changes will permit uniformity in size of different components. Such consideration might make quantity production by blanking economically possible. Another somewhat minor consideration is the difficulty caused the assembler or fitter in trying to identify parts that appear almost the same.

The designer should keep in mind, also, the possible utilization of hot-rolled-bar stock, for often such material can be used by making a slight change in dimension of a given cross section to conform to standards.

All components, regardless of the method of producing them, are subject to dimensional tolerances. The designer must keep this in mind for economy and good fit-up so that he can control the ill effects of cumulative tolerances. Fig. 31 gives a simple illustration of a typical weldment in which the designer has kept cumulative tolerances in mind. The drawing at the left shows a partial cross section, while the drawing at the right shows a similar cross section in which the point has been ignored.

Shrinkage and warpage problems which exist in the production of weldments will continue to be a factor so long as drastic heat gradients occur during welding. A degree of experience is needed to be able to predict such effects and to control and counteract them. It is impossible to discuss this factor here in detail. The designer should, however, sense the general aspects of such phenomena so that he does not develop designs that may be impossible to produce within necessary tolerances.

Warpage will occur to a great or little degree depending on the relative size of given welds and their distances from the neutral axis of the assembly. This is due simply to the relative ability of a member to resist shrinkage stress imposed at different points in its cross section with respect to the neutral axis of that cross section.

Welding results in shrinkage both longitudinally and at right angles to the weld metal. The extent varies for sizes as well as types of welds. When the number of different sizes and types of welds occurring in an average weldment, and their length and position with respect to each other are considered, it can be realized that control of warpage is to a large degree a matter of practical experience. Sequence of welding also should be carefully controlled as a counteracting measure. At times special fixtures are used to restrain warpage during welding.

Conditioning and Inspection Methods

Following completion of welding, it is an established practice to condition the weldment by removing spatter, grinding edges or surfaces where specified because of design requirements, and gritblasting when size permits.

Spatter is removed for appearance and to insure that it will not drop off progressively when the weldment is in service. Spatter can be detrimental mechanically if, for instance, it were left in a lubricating-oil compartment.

Weldments are gritblasted to remove mill scale from plate surfaces and to facilitate visual inspection of welds. Undercuts usually are more difficult to detect before the weld is gritblasted. Welds are inspected visually for proper size, surface cracks or other surface defects. X ray is used to inspect welds for internal defects. Various specifications such as those of the A.S.M.E. and the U. S. Navy provide inspection standards for the acceptance or rejection of welds by means of x-ray photographs.

Hydrostatic testing often is required by design specification. Oiltight compartments should be checked and tested before the part leaves the weldery. Finally, the weldment should be laid out for a final inspection at the weldery to verify that it is dimensionally correct within specified tolerances.

Any weldment to be machined, subsequently, to any appreciable degree should be stress-relieved if the machined surface or other parts of the weldment are to hold their relationship within service life. Any weldment subjected to severe stresses or to fatigue or impact, also should be stress-relieved. Especially is this advisable since locked-up stresses, the magnitude or direction of which cannot be predicted, can be of a high order following welding. If normal service loading imposes design stresses having the same direction at a given point as that of a residual or locked-up weld stress, structural distress or failure can result.

Many weldments are in use that have not been stress-relieved. Hence definite predictions cannot be made that difficulty will result for a given type of weldment in the unstress-relieved state. Stress-relief therefore may be regarded somewhat like insurance having a low premium rate because the per pound cost of stress-relieving is usually only a fraction of a cent.

Specifications for Weldments

A weldment should be specified clearly and concisely so that no misunderstanding results, and to insure from the equitable standpoint, that each potential vendor is quoting on the same conditions. It is important, for instance, that the weldery know if the weldment must be produced under a code requirement.

Over-all tolerance requirements on various dimensions of the weldment should be considered carefully. The designer might be inclined to make everything tight to "be on the safe side." But this can be a costly practice compared to that of evaluating requirements intelligently. Often, a relatively close tolerance, under given conditions of size, shape, and amount of welding, at some point in a weldment can be costly to achieve. Proper study might show that the tolerance can be loosened without affecting the service performance of the weldment. In this instance it is common practice to consult with the weldery to achieve, mutually, the best conditions.

This check list of specifications and drawing information will give the weldery proper and clear directions:

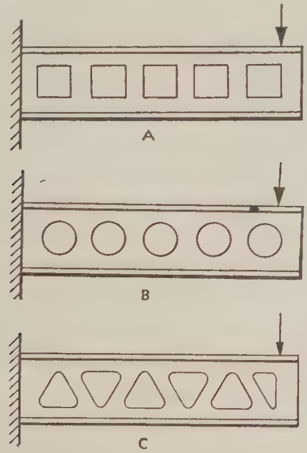

Fig. 32 Cantilever Beam Showing Three Designs in Web Openings

Steel specification?
Inspection agency, if any?

Grind? If so, where?
Stress relieve?
Paint? If so, what type and how many coats?
X-ray requirements? To what code?
Test—hydrostatic? If so, at what pressure?
Test—oiltightness?

Many types of weldments or components for weldments can be designed effectively into welded machinery parts. Categorically, machinery parts, as distinguished from other types of structural members, can be defined as parts required to resist or support moving forces; parts subjected to dynamic loading.

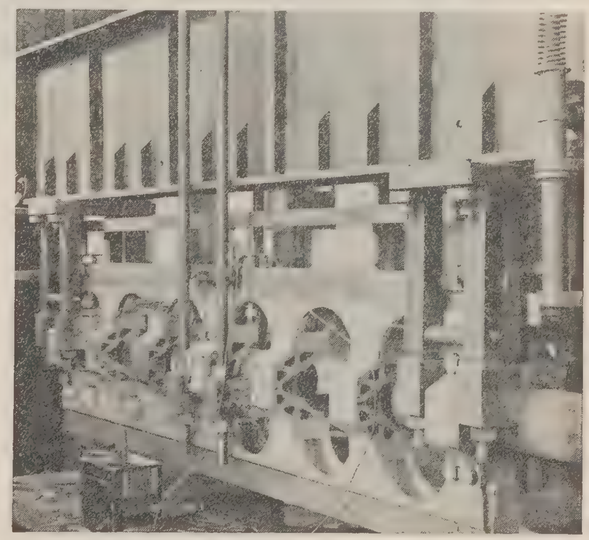

Fig. 34 Analysis on Model of Welded Engine Bed
(Stresses under lateral load can be read from the strain gages visible in the illustration.)

Dynamic loading or applied forces in motion can involve additional factors or criteria, i.e., fatigue and impact, to be considered in the design of the part and the proper selection of its material. These two factors, alone or in combination, often can affect materially, or control the shape, material, and manner of fabrication of a mechanical structural member.

If fatigue and impact are of major consideration, those properties of the material determining its resistance to such loading should be known. As we know, such properties generally are referred to as the endurance limit with respect to fatigue, and impact resistance in relation to impact. This latter property sometimes is related to temperature.

External contours of a part subjected

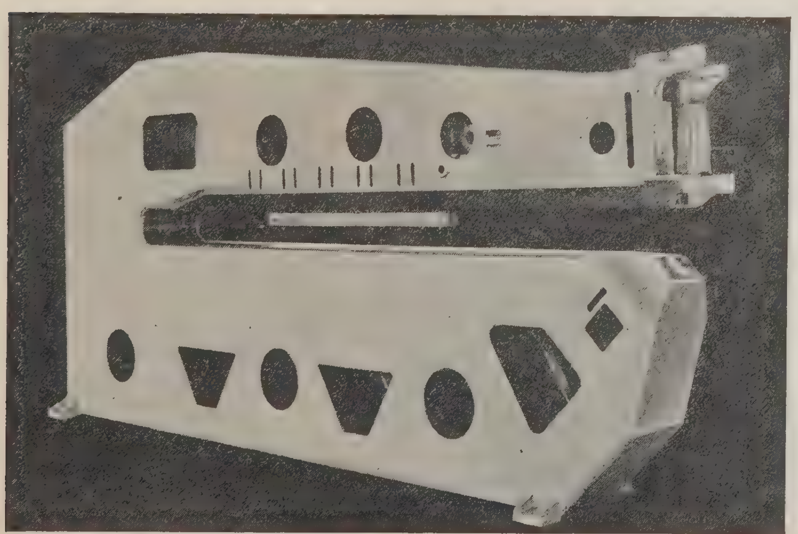

Fig. 33 Circle Shear Frame

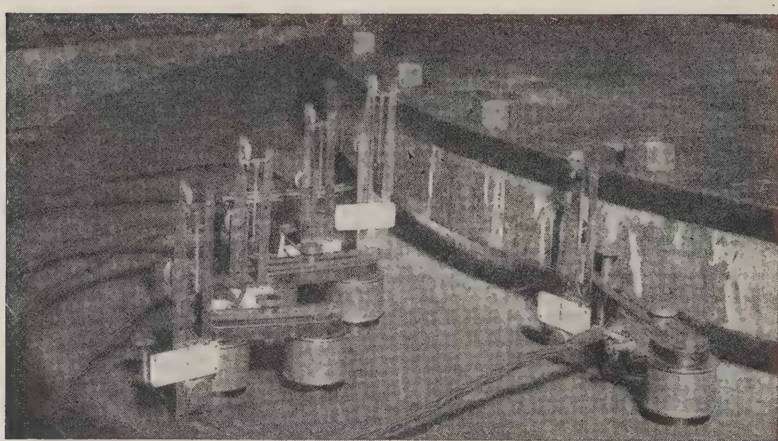

Fig. 35 Test Setup to Determine Actual Stresses Under Load on Piece Subjected to Internal Hydrostatic Pressure

to dynamic loading, particularly when fatigue is probable, are an important consideration especially when the member is subjected to primary loads. They are extremely important at the points of changes in contour in a structure of irregular shape.

Contours influence the effectiveness of a load-carrying member from a general standpoint. Proper contour denotes efficient disposition of material which is fundamental in control of weight. As an example, the component shown in Fig. 32 (A) is less rigid for a given over-all weight than that shown in Fig. 32 (B). Disposing metal as shown in Fig. 32 (C) is more effective from this standpoint. An example of such design thought in an existing welded structure is shown in Fig. 33.

Internal contours, those bounding openings in a structure, are worthy of careful consideration in the design of machine parts, especially since mechanical structures usually require openings of varying sizes and shapes for such reasons as fabricating or operating accessibility, or for mechanical clearance.

Often the effectiveness of proper, flowing contour, particularly its value in rigidity, is mathematically indeterminate. Where maximum rigidity or strength for least weight is important, model analysis is possible. Fig. 34 shows the setup for such an analysis of a welded machine part. Actual stresses in a product also can be determined by the use of instruments such as strain gages shown in Fig. 35.

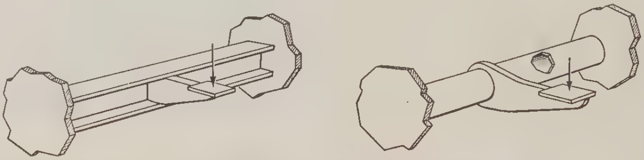

Fig. 36 Abstract Example of Two Methods of Resisting Torsional Force

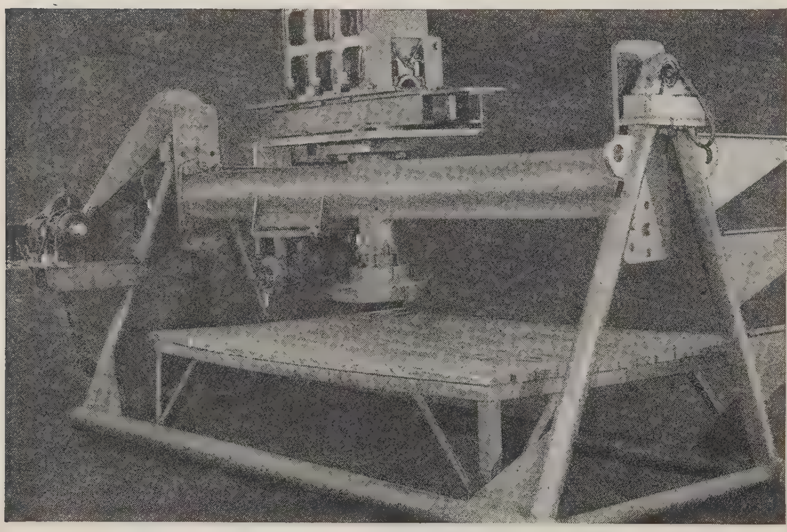

Fig. 37 Application of Welded Tubular Structure
(Main beam of this welding positioner is tubular in cross section. It is subjected to combined bending and torsional stresses.)

Weight Control

Frequently, minimum weight is a major factor in designing structural members of machines, and the weight of a mechanical part can be controlled by one or more considerations. Sufficient strength is the first fundamental. Several considerations can be involved in designing for the strength factor. One is a properly adjusted factor of safety. A minimum factor of safety is important in designing for least weight. If it is known definitely that no internal voids can or need exist in a given cross section subject to primary dynamic stress, one element making up the factor of safety has disappeared, or at least is under control.

This control can be exercised in production of weldments if design permits. It is axiomatic that in designing for least weight the shape should be as regular and flowing as possible, as the previous discussion of contours reveals.

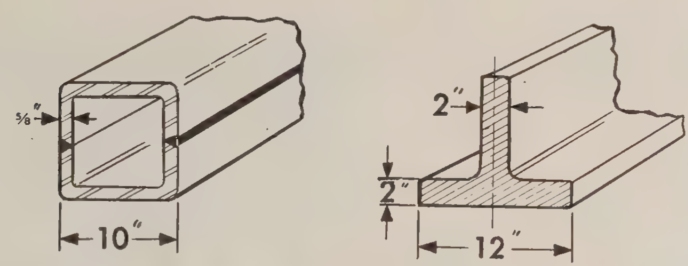

FIG. 38 DESIGN DETAIL OF SPOKES IN A WELDED MACHINE PART

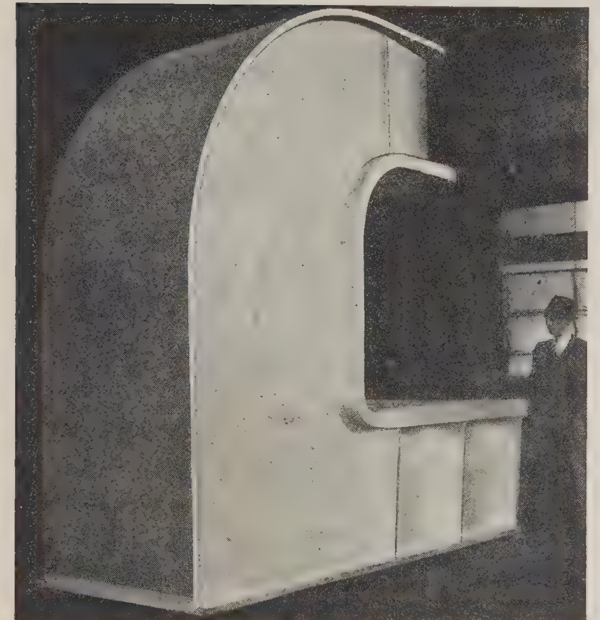

FIG. 39 WELDED FRAME FOR C-TYPE, OR OPEN-SIDE, HYDRAULIC PRESS

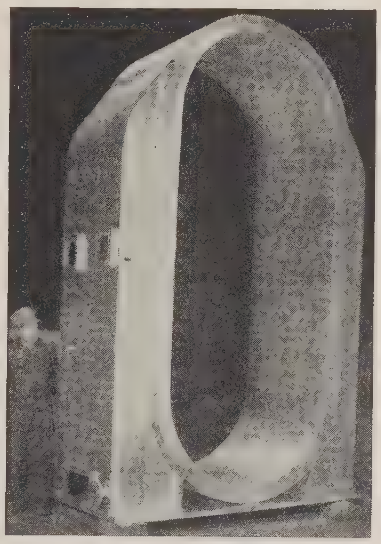

FIG. 40 WELDED-STEEL CONTINUOUS BAND HYDRAULIC-PRESS FRAME

Another consideration in the strength factor is the exactness of knowledge of the magnitude, direction, and location of the dynamic forces with respect to each other and their reactions involved in the machine. In designing machine parts, particularly for least weight, it is important that these be predicted as closely as possible.

After this has been done, the material resisting or supporting such forces or reaction can be disposed in a weldment to best advantage consistent with mechanical clearance requirements balanced against the necessity for least weight.

As an instance, Fig. 36 shows an abstract example of two methods of resisting a torsional force. There is no questioning the effective disposition of metal in a tubular design. Nor is there any questioning that the effective disposition of metal insures least weight. Fig. 37 shows an example of this concept in an existing machine part.

Another example of effective metal disposition is shown in the spokes of an enormous machine part, the cross section of which appears at the left in Fig. 38. The illustration at the right shows the spoke as it was designed initially because of casting limitations.

RIGIDITY A VITAL FACTOR

The dominant factor in the design of structural parts for machines sometimes is rigidity, or stiffness, rather than strength as in the instances just discussed. The primary function of the spokes in Fig. 38 is maintenance of alignment between machined parts in the structure to the greatest possible degree. Rigidity or minimum deformation dominates in the design of the C-type, or open-side press frame shown in Fig. 39. This weldment is composed exclusively of hot-rolled plate with metal thickness at any point dictated solely by design requirements.

A welded design that embraces directional control of rigidity is shown in Fig. 40. Purely vertical deformation or elongation is a secondary consideration in the function of this machine. A somewhat normal design for the structural parts of such a press is composed of top beam or platen, lower beam or bed, and side housings; all separate pieces integrated by two or four vertical tie rods secured by nuts at both ends.

In such a design, it can be seen readily that in addition to vertical, straight-line elongation, the upper and lower beams will tend to deflect as beams in a manner detrimental to the alignment of tools and work in the press. That such detrimental tendency is practically eliminated is shown in this design where the single structural member resists the working forces imposed on it in direct uniform tension.

The stabilization of thin and unsupported expanses of metal is a new element which requires watchfulness in the design of weldments for machinery, since the basic properties of the component materials are more predictable and process limitations on the thinness of metal sections are nonexistent. These thin and un-

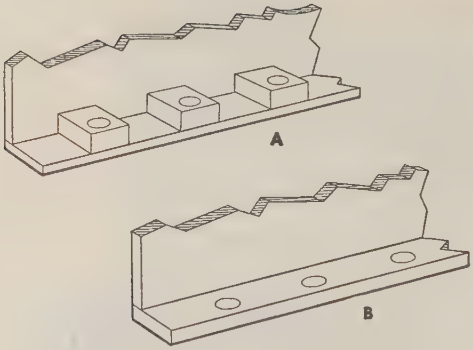

Fig. 41 Comparative Treatments of Bolting Flanges in a Welded Part

supported expanses of metal may be detrimental to the operation of the machine for several reasons. One is the possibility of "drumming" or vibration, another is fundamental instability, and the third is the possibility of dents or distortion in normal handling of the structure.

Many possible methods of stabilizing expanses of cross section exist. Usually the imagination of the designer is fertile in the solution of the problem, if it is recognized.

Size Limitation

Generally, the fewer number of pieces required to make up a machine structure, the less it will weigh and cost, and the stiffer it will be in contrast to a one-piece structure. The only limitations on the size of a weldment are those imposed by stress-relieving facilities and shipping clearance.

Another type of freedom that should be kept in mind by the designer of weldments is the possible use of higher-strength weldable alloys in highly stressed portions of the structure. The secondary components or elements of the piece can be of cheaper, plain carbon steels. Weldable alloys, of course, add nothing in rigidity or stiffness since the modulus of elasticity remains practically the same.

Factors of primary importance in the economic balance or competitive comparison of a welded-steel design must be evaluated clearly. The fundamental reason for assuming that a weldment is the proper medium must be unmistakably defined. This reason may include natural adaptability, and predictability, minimum weight, and initial cost. Having established this, it must be realized that the weldment undoubtedly will not re-

Fig. 42 In These Two Components, the Upper One Was Designed for Minimum Weight by Cutting Out Areas of Full Thickness Between Functional Holes and Filling Them With Thinner Plate. The Lower Component Is Composed of One Flame-Cut Plate

semble a casting in appearance. This does not imply that the welded machinery part will be displeasing to the eye. It means simply that anything produced by a radically different process logically will be different in appearance. If it is not, the design should be reviewed critically because the chances are that it is not economical as a weldment.

A simple instance is shown in Fig. 41 where at A, the common detail of a bolting flange is shown. In a casting many changes in contour do not affect the cost particularly. In a weldment such details necessitate a greater number of components and consequently a larger number of manhours to join them. At B an alternate detail is shown which fulfills the same function. These are examples of actual applications in use in thousands of weldments.

On the other hand, if weight reduction is of critical importance, the over-all economic balance might dictate the added complication in the weldment. A natural question here is, "why not cast it?" The answer has been found to be that if weight reduction is the primary criterion for given requirements of space and over-all size, a weldment can be designed which will weigh less than a casting and not affect the strength or rigidity.

Another comparison between two components of a weldment that perform the same function is shown in Fig. 42. The upper

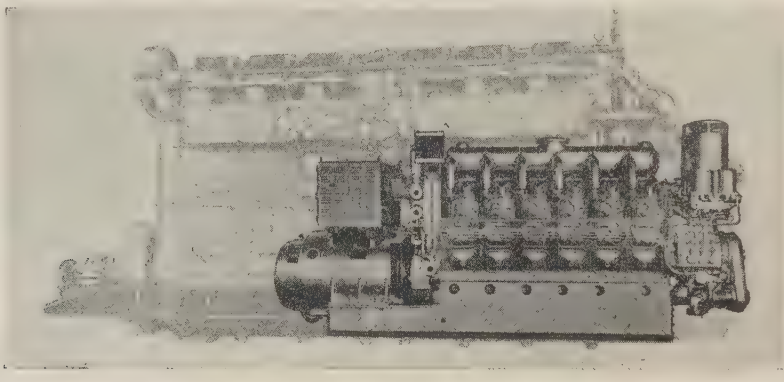

Fig. 43 Comparative Illustration Showing a Direct-Drive 4-Cycle Diesel Engine of 1926 With an Electric-Drive 2-Cycle Diesel Engine of Today

detail is more costly but lighter in weight than that shown in the lower half. If quantities of duplicate parts are involved, other methods of achieving minimum weight at lowest cost also are possible.

In making a decision on the value of weldments as structural members in a machine, the broad measures of their desirability should be known and considered. Logically, a weldment should not be used simply because a desire exists to design in this medium. By the same token a casting or forging should not be used if a weldment presents greater advantages.

In this discussion weight control or reduction may seem to have been emphasized. This is due simply to the progressive recognition of the fact, particularly in relatively large pieces weighing 200 lb or more, that weldments have been applied admirably where weight is important. Undoubtedly, the inherent features making this possible are predictability and the fact that the process practically imposes no limit on the thinness of sections. The weight factor can be important in machine design for many reasons. Fundamentally, it is the minimizing of inertia forces in moving parts of machinery. Another is the pyramiding of the effects of weight or mass in mechanisms subject to high velocity, as the modern railroad passenger car.

Conclusion

In conclusion, the result of the practical application of the many factors discussed probably can be best illustrated by a particular instance of weight and space efficiency in the use of weldments. A comparison, in Fig. 43, of a direct-drive four-cycle Diesel engine of 1926 with an electric-drive two-cycle Diesel engine of today shows that the modern smaller engine represents a reduction of 67.39 per cent in cubic feet occupied per brake horsepower, and also a reduction of 58.40 per cent in weight per brake horsepower. The development of welded-steel-type construction has materially helped in reducing weight. At the same time, the lighter engine of today is 50 per cent more efficient than the heavier engine of 20 years ago.

Stress-Rupture Characteristics of Various Steels in Steam at 1200 F[1]

By J. T. Agnew,[2] G. A. Hawkins,[3] and H. L. Solberg[4]

Small tensile specimens made from low-carbon, carbon-moly, 2¹/₄ Cr- 1 Mo, 5 Cr-Mo-Si, 9 Cr-Mo-Si, 12 Cr, 18 Cr-8 Ni, 25 Cr-20 Ni, and 5 Cr-Mo-Ti steels were placed in a steam reaction chamber at 1200 F and stressed in tension for periods of time ranging from 10 hr to 7700 hr. Data were taken on time to rupture, elongation, reduction in area, depth of scale layer, effect of type of flow, and type and angle of fracture. A photomicrographic study was made of the ruptured specimens. The straight-line relationship between stress and time to rupture on log-log co-ordinates postulated by White, Clark, and Wilson for tests in air also holds for tests in steam.

As the conditions of temperature and pressure to which alloy steels are exposed in modern steam power plants and other industrial apparatus become more severe, the need for experimental data concerning the behavior of these alloys under such conditions becomes more acute. This paper describes an investigation in which small steel specimens were placed in tension in an atmosphere of steam at 1200 F until rupture occurred. The stress-rupture data for various alloy steels in contact with high-temperature steam are needed for the design of various types of high-temperature steam-generating equipment.

Description of Apparatus

Small steel specimens were placed in tension inside four horizontal steel reaction chambers, each of which consisted of a 10-ft length of extra-heavy 2-in. steel pipe. These reaction chambers were uniformly heated externally to the test temperature by means of resistance heaters. The steam entering the reaction tubes was presuperheated to test temperature by means of gas-fired superheaters and, after leaving the reaction chambers, was conducted to water-cooled copper-tube condensers. In each reaction chamber, several specimens were connected end to end by universal joints and were loaded in tension by means of rods which passed through packing glands at either end of the reaction tubes. One end of each tension rod passed through a calibrated spring which, when compressed, caused the specimens to be placed in tension. Chromel-alumel thermocouples were used to measure the temperature at several positions along each reaction tube. The temperatures were evaluated by means of a Leeds & Northrup portable potentiometer.

The chemical analysis and heat-treatments of the various steels used in these tests are reported in Table 1. The numbers used to designate a specimen, for example, 913, have the following significance: The first number is the type of steel, as given in Table 1, the second number is the test number, and the third (or third and fourth) number is the specimen number. Therefore, 913, would be the third sample of 5 Cr-Mo-Ti steel used in test No. 1.

TABLE 1 CHEMICAL ANALYSIS AND HEAT-TREATMENT FOR STEELS USED IN THE TESTS

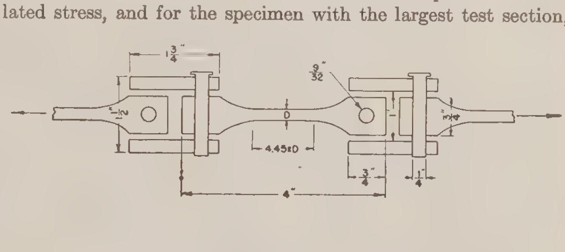
Test specimens similar to the one shown in Fig. 1 were machined from round stock of 1 in. diam. The dimensions of the straight central section of the test specimens were in the same proportions as the standard tensile specimen which is 2¹/₄ in. long and 0.505 in. diam. The straight central section of each specimen was machined to a tolerance of ±0.01 in. in length, and the diameter of the test section was held to ±0.001 in. For the specimen with the smallest test section, 0.138 in. diam and 0.61 in. long, this could result in an error of ±400 psi in the calculated stress, and for the specimen with the largest test section,



DIMENSION "D" DETERMINED BY STRESS DESIRED WITH ABSOLUTE LOAD OF 500 LBS

0.366 in. diam and 1.63 in. long, an error of ±30 psi in the calculated stress would be possible. Holes $^9/_{32}$ in. diam were drilled in the large ends of the specimens, as shown in Fig. 1, for the purpose of allowing several specimens to be coupled together. Eight specimens were coupled together and placed in each tube by means of collars and pins shown in Fig. 1. The collars consisted of $1^3/_4$-in. lengths of $1^1/_2$-in-OD × 1-in-ID 18 Cr-8 Ni stainless-steel tubing. Stainless-steel pins $^1/_4$ in. diam were passed through the holes in the collars and specimens to hold the specimen train together. The pinholes in each collar and specimen were placed 90 deg apart around the circumference in order that each collar might act as a universal joint. The end collars of the specimen train were drilled and tapped with a standard $^1/_4$-in. pipe thread. Tension rods were screwed into the end collars and extended to the outer steel framework. The outer ends of the tension rods passed through holes in parallel I-beams which formed the end pieces of a rectangular frame around the reaction chambers. A collar, thrust bearing, and nut were placed on the end of the extension rod nearest the superheater to transfer the tension load to the I-beam frame. The tension rod at the other end of the specimen train passed through a calibrated coil spring which was compressed against the I-beam frame by means of a collar, thrust bearing, and adjusting nut on the tension rod. The springs were compressed to exert a constant force of 500 lb on the train of specimens.

By using specimens whose test sections were of various diameters, any desired value of stress could be obtained. The diameters and stresses used for the various specimens are indicated in Tables 2 and 3. The compression of the calibrated loading springs was checked continuously by means of gage bars, and the springs were held to the correct length with an accuracy of ± 0.005 in. so that the absolute force exerted by the springs was 500 lb ± 4 lb. For a specimen 0.2 in. diam this would mean a stress of 15,900 ±100 psi. A stop was provided to restrict the movement of the broken assembly to not more than $^1/_2$ in. Approximately 45 min were required to remove a ruptured specimen and replace it with a new one. The temperature at one end of the tube dropped to approximately 1150 F during this operation but returned to 1200 F within 1 hr after a new specimen was inserted.

Test Program

It was decided to conduct a short preliminary test on several specimens of the same steel to investigate the effect of type of steam flow and pressure upon the corrosion rate. Eight specimens of 5 Cr-Mo-Ti steel, designated as series 9 in the tests, were machined so that, with a load of 500 lb, four of the specimens would be under a stress of 6900 psi, and the other four under a stress of 6200 psi. One specimen corresponding to each stress was placed in each reaction chamber so that each chamber contained two specimens. The temperature, pressure, and steam-flow conditions were maintained as indicated in Table 2. The results of the test are also given in Table 2.

Specimens 916, 917, and 918, under a stress of 6200 psi, were not ruptured during the test. While waiting for specimens 911, 912, 913, 914, and 915 to break, additional specimens of three different types of steel were inserted into the reaction tubes to gather what additional stress-rupture data could be obtained. The results obtained from these additional specimens are included in Table 2. Since the results from this preliminary test were not conclusive, it was decided to maintain different flow and pressure conditions in the four reaction chambers during the remainder of the test program with several samples of each steel being exposed to the various conditions.

On the basis of the data of the relation of stress to time to rupture in steam, as determined from the preliminary test, the second or regular test was started with eight specimens in each reaction tube. The results of this test are given in Table 3. Flow rates were adjusted to maintain laminar flow with a Reynolds number of 1100 in the reaction chambers containing steam at 5 psig, and turbulent flow with a Reynolds number of 5500 in the reaction chambers in which steam was used at 75 and 100 psig, as indicated in Table 3. Each time a specimen ruptured it was replaced by a new specimen. A complete history of each specimen including temperature, type of steam flow, stress, time to rupture, type and angle of fracture, elongation in area, etc., is given in Table 3. The stress-rupture results are plotted in Fig. 2, with stress as the ordinate and time to rupture as the abscissa on log-log co-ordinates.

The elongation of the ruptured specimens is reported in Tables 2 and 3 as a percentage of the original length of the specimen and was determined by measuring with a pair of dividers the length of a straight section of each test specimen between two punch marks before insertion into the reaction chamber and repeating the measurement on the ruptured specimen with the two sections of the broken specimen placed as close together as possible in the positions they occupied prior to rupture.

The reduction-in-area data presented in Tables 2 and 3 are reported as the ratio of the difference between the original

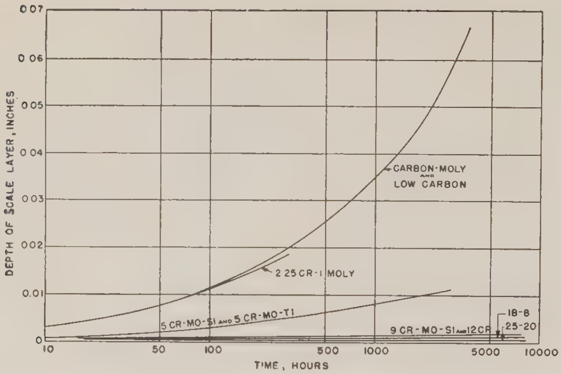

Fig. 3 Stress-Rupture Characteristics of Nine Alloy Steels in Steam at 1200 F

and final areas to the original area in per cent and are based on a measurement of the original diameter of the specimen by a micrometer and a measurement of the final diameter, not including the scale layer, by a pair of dividers.

Due to the size and shape of the specimens it was not possible to determine the loss of metal due to corrosion by electrolytic stripping as was used in previous corrosion studies (1, 2, 3, 4, 5)[5] at Purdue University. Some of the specimens were exposed to the steam for a short time interval, thereby producing a thin layer of oxide which could not be removed by the electrolytic stripping method. For the small specimens used in these stress tests a satisfactory method of determining the penetration of the scale layer was developed. A small section of the scale-covered ruptured specimen approximately 1/4 in. long was cut off by means of a cut-off wheel. This section was molded in bakelite and polished. By means of a precision microscope it was possible to measure the thickness of the scale layer quite accurately. The results of the corrosion measurements are given in Tables 2 and 3, and in Fig. 3.

Discussion of Results

The slopes of the stress versus time-to-rupture lines for the various alloys, as plotted in Fig. 3, are as follows: Low carbon, 0.147; carbon-moly, 0.200; 2 1/4 Cr-1 Mo, 0.128; 5 Cr-Mo-Si, 0.154; 9 Cr-Mo-Si, 0.095; 12 Cr, 0.105; 25 Cr-20 Ni, 0.172; 18 Cr-8 Ni, 0.157; and 5 Cr-Mo-Ti, 0.121. The significance of these various slopes is that a steel with a large slope would not be expected to have a high rupture stress for long time intervals such as 100,000 hr. Table 4 presents the stress required to rupture each of the steels for time intervals of 10, 1000, and 10,000 hr.

Of the nine steels tested, carbon moly is sixth in order at 10,000 hr, whereas it was third at 10 hr. 9 Cr-Mo-Si was eighth at 10 hr, is fifth at 10,000 hr and would be third at 100,000 hr if the straight-line relationship continued to hold.

In general, the stress required for rupture in a given time in an atmosphere of steam at 1200 F is higher than the stress required for rupture in the same time in air at 1200 F, the air values being taken from the data of the Timken investigators (6, 7, 8). The nine alloys which were included in this investigation are listed in Table 5, in the order of decreasing magnitude of the differences between the stress in steam and the stress in air required for rupture in 10,000 hr. The magnitude of the ratio of stress in steam to stress in air is indicated following each alloy.

[5] Numbers in parentheses refer to the Bibliography at the end of the paper.

TABLE 4 STRESS REQUIRED TO CAUSE RUPTURE OF VARIOUS ALLOY STEELS AT 1200 F

	In 10 hr		In 1000 hr		In 10,000 hr[a]	
(1)	18 Cr-8Ni	35000	18 Cr-8 Ni	16800	18 Cr-8 Ni	11600
(2)	25 Cr-20Ni	25000	12 Cr	12000	12 Cr	9400
(3)	Carbon-moly	21500	25 Cr-20 Ni	11200	25 Cr-20 Ni	7550
(4)	12 Cr	19500	2 1/4 Cr-1 Mo	9400	2 1/4 Cr-1 Mo	7000
(5)	2 1/4 Cr-1Mo	17000	Carbon-moly	8600	9 Cr-Mo-Si	6800
(6)	5 Cr-Mo-Si	15500	9 Cr-Mo-Si	8500	Carbon-moly	5450
(7)	Low carbon	13500	5 Cr-Mo-Si	7600	5 Cr-Mo-Si	5300
(8)	9 Cr-Mo-Si	13200	Low carbon	6900	5 Cr-Mo-Ti	5000
(9)	5 Cr-Mo-Ti	11500	5 Cr-Mo-Ti	6700	Low carbon	4900

[a] Extrapolated.

TABLE 5 DIFFERENCES BETWEEN STRESS IN STEAM AND STRESS IN AIR REQUIRED FOR RUPTURE IN 10,000 HR OF VARIOUS ALLOYS

	Type of steel	Ratio of stresses in steam to air
1	Low carbon	3.6
2	12 Cr	3.2
3	Carbon moly	1.8
4	25 Cr-20 Ni	1.4
5	5 Cr-Mo-Si	1.2
6	18 Cr-8 Ni	1.2
7	2.25 Cr-1Mo	1.2
8	9 Cr-Mo-Si	1.1
9	5 Cr-Mo-Ti	0.98

The results of the attempt to determine the effect of turbulent or streamline flow upon the stress-rupture results were inconclusive and no definite conclusions could be drawn concerning this effect.

The results of the measurement of the thickness of the scale layers are given in Tables 2 and 3, and in Fig. 3. As in previous tests at Purdue University (1, 2, 3, 4, 5), the chromium content of the alloy is the critical factor in the determination of the depth of corrosion. The alloys can be divided into four general groups relative to the type and extent of corrosion. The two alloys, low carbon and carbon-moly, show serious corrosion, having a thick, porous but tightly adhering layer of scale. Alloys 2 1/4 Cr-1Moly, 5 Cr-Mo-Si, and 5 Cr-Mo-Ti show appreciable corrosion and have a brittle flaky layer of scale. Alloys 9 Cr-Mo-Si and 12 Cr exhibit a slight amount of corrosion, while the corrosion of alloys 18 Cr-8 Ni and 25 Cr-20 Ni is very slight. It is to be noted that the corrosion results of the stress-rupture tests cannot be directly compared to the corrosion results obtained previously at Purdue University (1, 2, 3, 4, 5), since in the previous tests the results were reported as penetration in inches as computed from measured loss of metal, whereas in the stress-rupture tests the results are reported as depth of scale layer on the ruptured specimen. An examination of the data reveals no correlation between type of steam flow and depth of scale layer.

A comparison of the types and characteristics of the fractures of the various alloys is of considerable interest in that it gives some indication of the type of fracture that can be expected in service. A discussion of the fracture of each alloy will be given. A metallographic study was made of the original microstructure and the microstructure of two fractured specimens of the longest and shortest fracture time and the following comments are a result of these studies:

(*a*) Low-Carbon Steel (Alloy No. 1). Of the eight specimens tested, three had ductile fractures, four had brittle fractures, and one had an intermediate fracture. However, the values of ductility as measured by elongation were consistently low (from 12 to 37 per cent) with the ductile fractures giving the greater elongation. By an intermediate fracture is meant a fracture with just a slight amount of necking at the break as compared to no perceptible necking for a brittle fracture and considerable necking for a ductile fracture. This method of classification holds for all nine alloys. The three low-carbon specimens with the ductile fractures, 126, 127M, and 128M, and the one with the intermediate fracture, 1210, had the largest elongation and reduction of area at rupture. The short-time ductile fracture of specimen

126 was characterized by stretching of the grains while the long-time brittle intergranular fracture of specimen 121 was characterized by the remaining equi-axed grains pulling apart at the grain boundaries. In both the long- and short-time specimens a dark intergranular material appeared which was probably an oxidation product together with voids resulting from parting of the grains. Spheroidization of the carbides present in the original sample occurred in both the long- and short-time specimens of this alloy with considerable agglomeration of the spheroids present in the long-time specimen.

No clearly defined graphite was detected in the structure of the specimens.

(*b*) Carbon-Moly (Alloy No. 2). All of the carbon-moly specimens had the brittle type of fracture except specimen 2210 which showed a slight amount of necking and was classified as having an intermediate fracture. All of the specimens had low values of ductility as measured by elongation (13 to 36 per cent). As in the case of the low-carbon alloy, the only appreciable change in the microstructure was general spheroidization of the carbide structure. Very little agglomeration was present in the microstructure of the short-time specimen, 221, the original normalized structure still being somewhat in evidence. Considerable agglomeration of the carbides was present in the long-time specimen, 226. Parting of the grains had occurred in both specimens 221 and 226, but to a greater extent in the short-time specimen 221. This parting resulted in intergranular fracture for both the long- and short-time intervals and also resulted in the presence of dark areas between the grains, probably consisting both of oxidation product and voids.

No clearly defined graphite was observed in the microstructure of the carbon-moly specimens.

(*c*) $2^1/_4$ Cr-1 Mo (Alloy No. 3). In contrast to the carbon-moly steel, all of the specimens of $2^1/_4$ Cr-1 Mo steel had the ductile type of fracture as evidenced by the higher values of ductility as measured by elongation (21 to 71 per cent). Without exception, all of the specimens necked considerably at the break, resulting in high values for reduction in area. Another peculiarity of this alloy was the very brittle flaky type of scale which curled away from the parent metal as the corrosion progressed, thus continuously leaving fresh metal exposed to the steam. Due to the excessive necking at the break, the metal there should have been very highly strained. The microstructure of the short-time specimen 328 showed considerable elongation of the grains. The microstructure of the fractured specimens showed coalescence of the carbides which were present in the original steel before testing. The degree of coalescence was considerably higher in the long-time specimen 325 than in the short-time specimen 328. The specimens showed more than normal inclusions which, however, did not appear to be graphite when examined unetched. Since there was evidence of some inclusions in the original microstructure of this steel, it is not believed that the inclusions present in the microstructure of the fractured specimens is due to any appreciable extent to oxidation and stress. This steel is to be contrasted to the low-carbon and carbon-moly steels which did show parting of the grains and a resultant dark constituent at the grain boundaries.

(*d*) 5 Cr-Mo-Si (Alloy No. 4). This alloy was characterized by a very ductile fracture resulting in high values for elongation and reduction in area, the values of elongation ranging from 52 to 158 per cent. The surface of the scale was lined with deep cracks but the scale itself adhered very tightly to the parent metal. The comments made concerning the microstructure of $2^1/_4$ Cr-1 Mo steel (Alloy No. 3) in paragraph (*c*) apply equally well to the microstructure of Alloy No. 4, that is, the amount of inclusions did not increase over those present in the unstressed steel, no clearly defined graphite was detected, and coalescence of the carbides originally at the grain boundaries occurred.

(*e*) 9 Cr-Mo-Si (Alloy No. 5). This alloy was also characterized by high values of elongation (from 68 to 155 per cent) and reduction in area which indicated a ductile fracture. The fracture specimens were covered with a smooth tightly adhering layer of scale which was lined with a fine network of cracks. Photomicrographs of the microstructure of this alloy indicated that the only significant change was an increasing degree of agglomeration of the carbide spheroids with time under the test conditions. In the long-time specimen, 526, a preferred orientation and stretching of the spheroids and other elements of the microstructure could be detected.

(*f*) 12 Cr (Alloy No. 6). The fractures for this alloy varied considerably. Of the twelve specimens tested there were three with brittle fractures, five with ductile fractures and four with intermediate fractures. The ductility as measured by elongation was fairly low, ranging from 20 to 71 per cent. The scale formed on fractured specimens of this alloy resembled very closely that formed on specimens of Alloy No. 5 (9 Cr-Mo-Si). There was practically no change in the microstructure of specimens of this alloy except for enough agglomeration of the carbide spheroids to make them appear to have a uniform and random distribution, whereas in the original structure the outline of the austenitic grains was indicated by the chain of spheroids.

(*g*) 25 Cr-20 Ni (Alloy No. 7) and 18 Cr-8 Ni (Alloy No. 8). Both of these alloys were characterized by very brittle fractures for both the long- and short-time intervals, resulting in low values for reduction in area and elongation. The values for elongation for the fractured specimens of 18 Cr-8 Ni ranged from 8 to 51 per cent while those for 25 Cr-20 Ni were a little higher, ranging from 32 to 75 per cent. Specimens of these alloys were covered with a thin film of scale which visually appeared to be thicker on the stressed test section than on the relatively unstressed part of the specimen. The only noticeable change in the microstructure of the 25 Cr-20 Ni specimens was the growth and coalescence of the carbides and of the peculiar black phase which has been reported by other investigators (9). The exact identity of this black phase is not yet known. The short-time specimen, 824, of 18 Cr-8 Ni which was very highly stressed (33,400 psi), resulting in a very short time to rupture (15 hr), suffered a decided change in grain size; the grain size for the ruptured specimen being much smaller than that of the original structure. Considerable carbide precipitation at the grain boundaries and inside the grains appears to have taken place. Also, the black phase which is known to appear in 25 Cr - 20 Ni steel as just described appears to be present in the microstructure of the long-time specimen, 826, of the 18 Cr - 8 Ni alloy. It is doubtful that this black phase is graphite since chromium is known to be a very effective inhibitor of graphitization and the carbon content of this steel is only 0.06 per cent.

(*h*) 5 Cr-Mo-Ti (Alloy No. 9). This alloy tended to be somewhat erratic in its behavior. Referring to Tables 2 and 3 it can be seen that of the twelve specimens tested, eight had ductile fractures, three had intermediate fractures, and one had a brittle fracture. However, it should be noticed that the one brittle fracture was the longest time specimen, 924, whose time to rupture was 3109 hr and whose value of elongation was 52 per cent. The values for elongation (45 to 104 per cent) and reduction in area tended to be somewhat lower than those for Alloy No. 4 (5 Cr-Mo-Si), an alloy differing only in the content of Si and Ti. The scale formation was identical to that of Alloy No. 4, the specimens having a fairly thick layer of scale heavily lined with deep cracks. The only appreciable change in microstructure was spheroidization of the carbides which were originally present at the grain boundaries.

Referring again to the data in Tables 2 and 3 concerning the measurements of reduction in area and elongation, it would appear that the relative ductility of the nine alloys as measured by these two methods is not the same. For example, Alloy No. 3 ($2^1/_4$ Cr-1 Mo) has relatively low ductility as measured by per cent elongation, but as measured by per cent reduction in area, as a group it has the highest ductility. The authors are of the opinion that per cent elongation is the safest indication of ductility because it is a measure of ductility over a longer period of time. Again taking Alloy No. 3 as an example, the high values of reduction in area are due simply to the fact that the specimens necked down considerably before actual rupture, which probably took place during the last few minutes of the life of the specimen.

The carbon steels tested, i.e., low-carbon (Alloy No. 1) and carbon-moly (Alloy No. 2), corroded excessively so that the reduction-in-area values could be attributed both to mechanical shrinkage due to the stress and loss of metal due to corrosion.

It can be seen in examining Tables 2 and 3 that for all of the alloys tested the values of elongation tend to be less when the brittle-type fracture occurs. A good example is Alloy No. 6 (12 Cr) in which the five specimens with the highest values of elongation all had ductile fractures while the specimens with intermediate and brittle fractures all had lower values of elongation. For the other alloy which had all types of fracture, Alloy No. 9 (5 Cr-Mo-Ti), the only specimen with a brittle fracture had the second lowest value of ductility as measured by elongation.

For all of the nine alloys taken as a whole no satisfactory correlation between time to rupture and either elongation or reduction in area could be obtained.

An examination of the microstructure of all the alloys revealed no clearly defined graphite in any case. An extensive study was made of the three alloys most likely to be susceptible to graphitization, low-carbon, carbon-moly and $2^1/_4$ Cr-1 Mo, by the research department of The Detroit Edison Company (13). They reported that while each of the steels responded "abnormal" to the McQuaid-Ehn test, no clearly defined graphite was found in any of the samples examined.

Conclusion

1 The straight-line relationship between stress and time to rupture on log-log co-ordinates, postulated by White, Clark, and Wilson, for tests in air (9) also holds for tests in steam.

2 The break in the stress-rupture line encountered in air tests by other investigators (9, 10) was not found in the present tests in steam.

3 The tests indicate that for the small specimens of the nine alloys tested the stress required for rupture in steam in 10,000 hr or longer is higher than the stress required in air at 1200 F.

4 The type and characteristics of the scale formed on the stress-rupture specimens affects the position of the stress-rupture line on log-log co-ordinates.

5 The slope of the stress-rupture line is important since an alloy whose stress-rupture line on log-log co-ordinates has a low value of slope might not appear to be desirable at short rupture times, but for long rupture times might be better than other alloys which were superior at short rupture times.

6 Ductility values, as measured by per cent elongation, are more reliable values for ductility over a long period of time than are ductility values as measured by reduction in area. Also reduction-in-area values are more affected by the amount of corrosion.

7 For the two austenitic alloys tested, the fractures were the brittle type, even for short time intervals.

8 In general, the ductility, as measured by elongation for all of the alloys tested tends to decrease as the time to rupture increases.

9 Longer times and lower stresses are favorable for the production of brittle fractures.

10 The tests confirm the conclusion based on air tests (11), that elongation for a given steel is always less when the brittle fracture occurs.

11 As in unstressed tests, the chromium content of the alloy is the critical factor in determining the amount of corrosion taking place. The corrosion decreases as the chromium content increases.

Acknowledgments

The authors wish to express their appreciation to the following for their co-operation in the preparation and the analysis of the microstructures of the fractured specimens: Dr. C. L. Clark of the Timken Roller Bearing Company, Canton, Ohio; Dr. H. K. Ihrig of the Globe Steel Tubes Company, Milwaukee, Wis.; Mr. C. H. Fellows and Mr. I. A. Rohrig of The Detroit Edison Company, Detroit, Mich.; Mr. J. P. Magos, Mr. N. A. Ziegler, Mr. J. J. Kanter, and Mr. W. L. Meinhart of Crane Company, Chicago, Ill.; and Mr. R. J. Raudebaugh, Assistant Professor of Metallurgical Engineering, Rochester University, Rochester, N. Y.

Discussion

Arthur McCutchan.[6] The steam-corrosion work at Purdue has been followed with great interest. The stress rupture characteristics of various steels in steam should be of particular value to designers of high-temperature equipment. The choice of 1200 F as the test temperature doubtless was made on the basis of accelerating the scaling effect. Since the field of usefulness

[6] Engineer, Engineering Division, The Detroit Edison Company, Detroit, Mich. Jun. A.S.M.E.

of the low-carbon and carbon-moly steels will, in general, be below 1000 F, and the $2^1/_4$ per cent chrome-moly steel below 1100 F it is of importance to recognize that in some cases the higher temperature of test may give a false indication of the relative value of these materials for high-temperature service.

Through the co-operation of Professor Solberg, a number of the ruptured specimens of low-carbon, carbon-moly and $2^1/_4$ per cent chromium, 1 per cent molybdenum steels were examined for graphite by I. A. Rohrig of The Detroit Edison research department. Despite the fact that all were found to be "abnormal" in their response to the McQuaid-Ehn test, no graphite was reported. Since, in abnormal low-carbon and carbon-moly steels, graphite is readily produced by heating for 1000 hours or less at 1000 to 1100 F, failure to produce graphite in heating periods of 4000 to 7000 hours at 1200 F might be considered unusual. It has been hazarded that the AC_1 temperature of these materials might be lowered sufficiently in the presence of stress so that 1200 F is above the temperature at which graphite tends to precipitate.

Because of the possible precipitation of graphite, particularly at welded joints, the long-time load-carrying ability at, say, 1000 F of the low-carbon and carbon-moly steels is much less than that of the $2^1/_4$ per cent chromium, 1 per cent molybdenum steel. It would seem therefore that the stress rupture data which are given in this paper should be considered as directly applicable only at 1200 F.

On the basis of a rupture time of about 1200 to 1500 hours it is of interest to note the relatively high stress supported by the low-carbon steel in 1200 F steam. The stresses supported by the several materials were as follows:

STRESS CAUSING RUPTURE IN 1200 TO 1500 HOURS IN 1200 F STEAM

	Specimen	Stress, psi
Low carbon steel	129 M	7000
Carbon molybdenum	227	7400
$2^1/_2$ per cent chromium, 1 per cent molybdenum	326	8400

The authors' conclusions regarding the tendency to intergranular fractures are particularly noteworthy. The point that longer times and lower stresses are favorable for the production of brittle intergranular fractures of many creep-resistant steels is not always appreciated. The ductile type of fracture of the $2^1/_4$ per cent chromium — 1 per cent molybdenum steel would seem to be a count in its favor.

Authors' Closure

The authors wish to thank Mr. McCutchan for his interesting discussion. It is true that the temperature of 1200 F is severe for low-carbon, carbon-moly, and $2^1/_4$ Cr-1 moly steels, but it is felt that the data will be applicable in the future when steam temperatures in power plants and other industrial apparatus become higher.

Also it should be pointed out that the effects of specimen size and type and characteristics of the scale formed in a steam atmosphere are two variables which are yet to be thoroughly investigated.

Effect of Molding Pressure and Resin on Results of Short-Time Tests and Fatigue Tests of Compreg

By W. N. FINDLEY,[1] W. J. WORLEY,[2] and C. D. KACALIEFF[3]

Tests were performed on six samples of compressed-impregnated plywood, including static tension tests, static compression tests, static torsion tests, and rotating-beam type of fatigue tests. The results provide data on the effect of different molding pressures and different resins on the "static" strength properties, stiffness, and fatigue strength of "compreg."

THE tests reported in this paper were undertaken in order to provide information on the effect of different molding pressures and different resins on the "static" strength properties, stiffness, and fatigue strength of compressed-impregnated plywood (compreg).

The following tests were performed on six different samples (described later) at a temperature of 77 F and a relative humidity of 50 per cent: Static tension tests, static compression tests, static torsion tests, and rotating-beam-type fatigue tests. All specimens were cut with their long axis parallel to the grain of the wood used in making the compreg. Values of ultimate strength, yield strength, and modulus of elasticity were obtained from all of the static tests. The fatigue tests were carried out as far as 10,000,000 cycles.

Several investigators have reported the static properties (1–9)[4] of compreg and some other investigators have studied fatigue characteristics (10, 11) of this type of material.

Material Used for Tests

Six compreg panels were prepared especially for this series of tests by the United States Forest Products Laboratory, Madison, Wis. The panels were made from rotary-cut sap yellow-birch wood of $^1/_{16}$-in. plies. All veneers were from the same shipment and met the grain requirements of Army Air Forces Specification 15065. Prior to laminating, the $^1/_{16}$-in. birch veneers were cylinder-treated for 6 hr in the case of the water-soluble resin and 16 hr in the case of the alcohol-soluble resin at 75 psi and dried for 18 hr at 130 F. All plies were glued on one face with Bakelite XC7381 resin, using 6.7 g of dry glue per sq ft of glue line; all panels were pressed at the indicated pressure (see Table 1) under conditions such that the center of each panel was held at 305 to 310 F for 15 min. All panels were cooled to 150 F in the press before releasing the pressure. The data in Table 1 were prepared by the Forest Products Laboratory. As shown in the table, three different resins, *A*, *B*, and *C* were used, and two panels were made with each resin. One panel for each resin was molded at 1500 psi; the other panel for each resin was molded at 600 psi.

TABLE 1 FOREST PRODUCTS LABORATORY DATA

Panel number	204	205	206	207	208	209
Type of resin[a]	*A*	*A*	*B*	*B*	*C*	*C*
Resin content,[b] per cent	28.5	28.0	31.5	32.0	28.0	28.5

[a] Resin *A* Bakelite BV 10678 (alcohol-soluble) by Bakelite Corporation, Bloomfield, N. J.
Resin *B* Bakelite BV 15100 (water-soluble) by Bakelite Corporation, Bloomfield, N. J.
Resin *C* Compregnite (water-soluble) by Casein Company of America, Bainbridge, N. Y.

[b] Resin content on basis of dry weight of untreated wood.

[c] Shear tests made by Forest Products Laboratory block-shear method in plane of laminations.

[d] Izod values calculated from notched-toughness values, using empirical conversion factor obtained from Izod and notched-toughness tests on matched specimens.

[e] Measurements made according to Army Air Forces specifications No. 15065 on 3 in. × 1 in. × $^3/_8$-in. specimens (1 in. in fiber direction), immersed in water for 24 hr.

[f] Specimens were cut the full thickness of the panel and $^1/_8$ in. long in the direction of the grain. The specimens were immersed in water for 48 hr at room temperature and were measured in the direction of the thickness of the original panel before and after immersion.

[g] Thickness of specimens used for swelling tests after subsequent air-drying and oven-drying, expressed as a percentage of the thickness of a matched specimen subjected to the same drying cycle but not to the water immersion. The "thickness" measured was in the direction of the thickness of the original sheet.

The test panels were made from large sheets of veneer from which six matched panels were laminated with the grain of all plies parallel. The six panels were matched with two crosswise of the grain and three lengthwise of the grain.

Additional data shown in Table 1 include the percentage resin content, the code number for the resin, number of plies used in the panel, the specific gravity, the shear strength parallel to the laminations, the impact strength (expressed as an equivalent Izod test), percentage water absorption, percentage swelling, and percentage recovery after wetting.

Preparation of Specimens

A drawing of the "static" specimens used in this investigation is shown in Fig. 1, and the fatigue specimen is shown in Fig. 2. All specimens were cut from the panel with their long axis parallel to the grain of the wood. All specimens were machined on a lathe and were finished by polishing with grade 2/0 emery paper. Some of the tension specimens were machined with a straight cylindrical portion and used for stress-strain data; other of these specimens were machined with a reduced section or neck at the center of the gage length and were used to determine the ultimate strength of the compreg in tension.

The compression specimens were turned on a lathe to the two lengths shown in Fig. 1(*c*). The 2-in. specimen was used as shown in Fig. 6, to obtain stress-strain relationships. The short specimen was used to obtain ultimate-strength values only. The torsion specimens were also made by turning on a lathe.

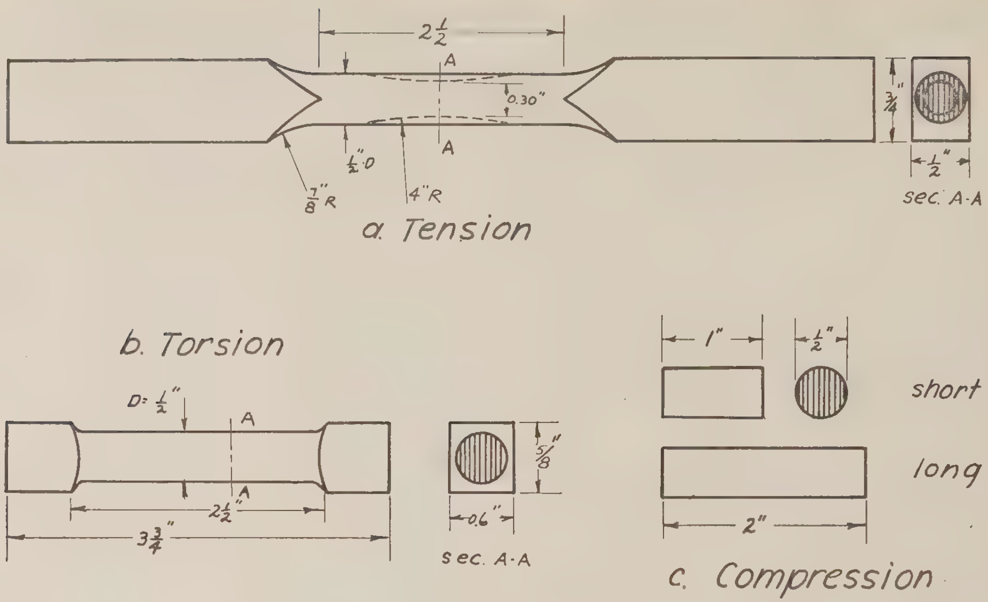

FIG. 1 STATIC SPECIMENS USED IN TEST

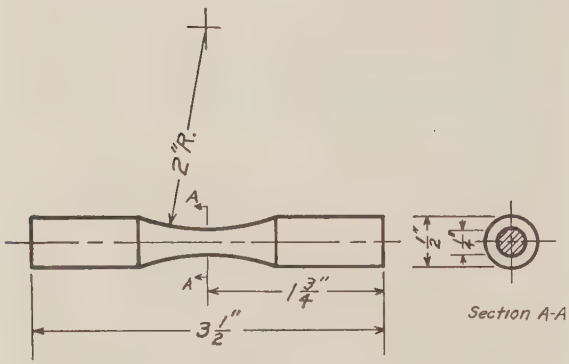

FIG. 2 ROTATING-CANTILEVER-BEAM FATIGUE SPECIMEN

The machining of all specimens was done in a laboratory maintained at constant temperature and constant relative humidity. After the specimens were completed, they were allowed to remain in this room, which was maintained at a constant temperature of 77 ± 1 deg F and constant relative humidity of 50 ± 2 per cent, for at least 2 weeks before the tests were started.

TENSION TESTS

Short-time tension tests were performed on specimens as shown in Fig. 1(*a*). These specimens were tested in tension on an Olsen 10,000-lb four-screw machine, of the beam-weighing type, equipped with a separate variable-speed drive. The specimens were held in Templin wedge grips *A*, Fig. 3, mounted in such a way as to provide an axial load on the specimen. Strain of the specimen was measured by means of a Moore-Hayes 2-in-gage-length extensometer *B*, Fig. 3. This instrument provided a multiplication such that one division on the dial indicated a strain of 0.0001 in. per in. in the specimen. In order that these specimens need not support the weight of the extensometer and to prevent damage to the instrument if the specimen should fracture while the extensometer was attached, the extensometer

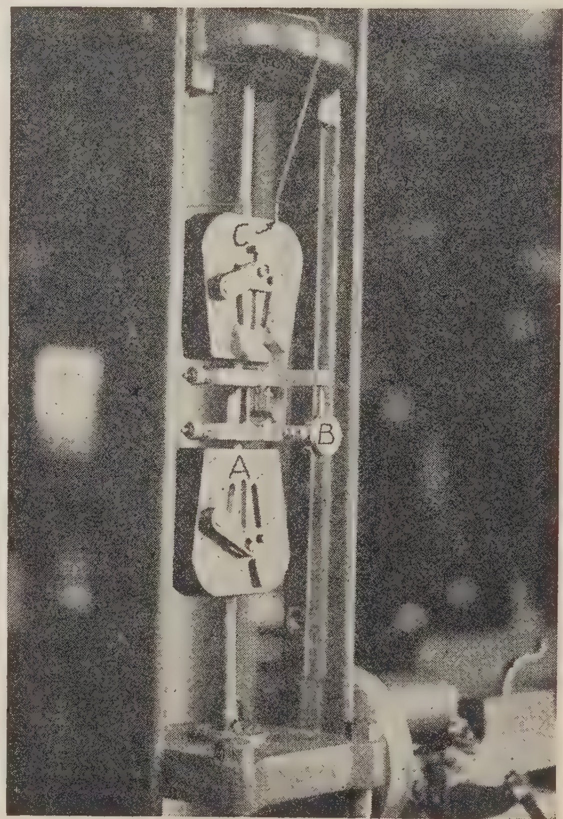

FIG. 3 TENSION APPARATUS

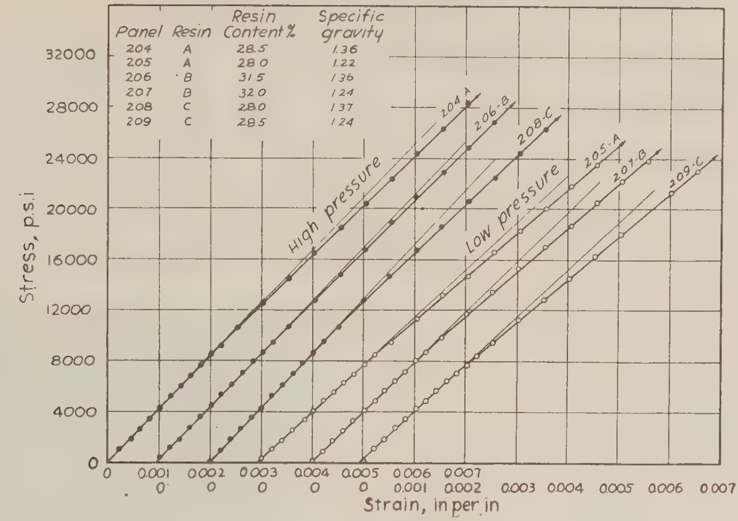

FIG. 4 TENSION TESTS OF COMPREG

was supported by means of the light coil spring C, shown in Fig. 3.

Two sets of tension tests were run; one set in which the stress-strain characteristics were determined, and the other set in which only the ultimate strength was obtained. In the former group the gage section of the specimen was straight and readings of load, deformation, and time were simultaneously obtained "on the run" throughout the test. In the latter case only the load at fracture was recorded. For this purpose the specimens were necked down by turning on a lathe to a 4 in. radius. This was accomplished by rotating the compound of the lathe. These specimens were reduced from $^1/_2$ in. diam at the end of the test section to $^3/_{10}$ in. diam at the center. This reduction was found necessary in order to cause the specimen to fail at the center of the test section rather than in the shoulder of the specimen. Straight specimens failed at the shoulder as a result of the stress concentration.

A preliminary test was made to determine the testing speed required to produce a rate of tensile strain of about 0.0016 in. per in. per min. All succeeding tests were run at or near this rate of strain. This rate was selected in order to permit correlation between the results of these tests and tests performed by the authors on other material (12). This rate of strain corresponds roughly to the rate of strain produced by testing machines operated at a head speed of 0.05 in. per min. However, it should be noted that different machines, and even different materials tested in the same machine at the same rate of crosshead motion will not in general produce the same rate of strain in the specimen. This is due to different relative stiffnesses of the machine, specimen, and auxiliary gripping apparatus.

The rate of strain was made uniform in these tests rather than the rate of increase of stress as used by some investigators, because the same rate of strain can be used without difficulty in testing materials which differ widely in modulus of elasticity, whereas if such materials are tested at the same rate of stressing, the required testing-machine speeds become excessive for materials of low modulus, and the rate of strain becomes too high to follow with ordinary equipment.

Both the tension and the compression tests were performed outside of the air-conditioned laboratory. The temperature of the testing room was about 75 F, and the relative humidity was variable. In order to minimize the effect of differences in temperature and relative humidity, the specimens were placed in an insulated box while being transferred from the conditioned storeroom to the laboratory, and the tests were conducted within 5 to 10 min after the specimen was removed from the insulated box. During the test, readings of load, deformation, and time were recorded up to a point within a few per cent of the load at which failure was expected. The extensometer was removed before failure.

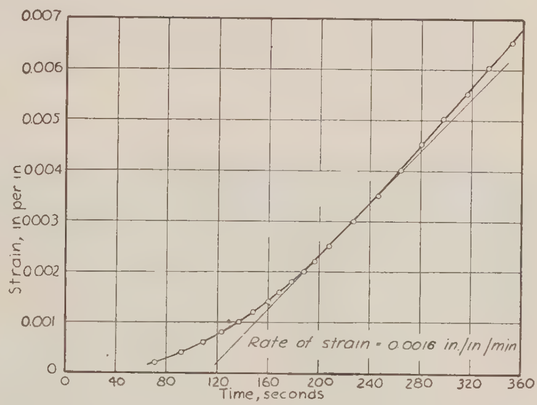

FIG. 5 STRAIN-TIME CURVE OF COMPREG IN TENSION

From these data the stress and strain were computed. Then diagrams of stress versus strain, Fig. 4, and strain versus time, Fig. 5, were plotted. The modulus of elasticity was determined in each case from the slope of the initial part of the stress-strain curve. The yield strength[5] at 0.05 and 0.2 per cent offset could not be determined owing to the fact that the straight specimens failed at the shoulder before the stress in the gage section became high enough to produce an offset of 0.05 per cent.

The rate of strain was determined from a time-strain curve (see Fig. 5), by measuring the slope of this curve in the region just below the value of strain above which the stress was no longer

proportional to strain. The tangent line used is shown in Fig. 5.

Results of the tension tests are shown in Table 2. The average modulus of elasticity in tension was found to vary from 3,720,000 to 4,230,000 psi, depending on the resin and molding pressure used; and the average ultimate strength was found to vary from 43,500 to 54,600 psi, depending on the resin and molding pressure. The data in Table 2 show that both the ultimate strength and modulus of elasticity are higher for compreg molded under 1500 psi pressure than for compreg molded at 600 psi. This is true for each of the three resins investigated. The increase in ultimate strength, resulting from increasing the molding pressure from 600 to 1500 psi, was 23.2 per cent when resin *A* was used, 25.5 per cent when resin *B* was used, and 7.1 per cent when resin *C* was used. The corresponding increase in tensile modulus of elasticity was 10.7 per cent with resin *A*, 7.2 per cent with resin *B*, and 90 per cent with resin *C*.

Short-Time Compression Tests

Compression specimens were tested in the same machine as the tension specimens and under the same temperature and humidity conditions. In order to minimize the effect of possible eccentric loading the specimens were tested by using a compression tool *A*, shown in Fig. 6. A compressometer *B*, of 1 to 1 ratio having a 0.0001-in. "Last Word" dial and 1-in. gage length was used to determine the strain. As in the case of the tension tests, the instrument was supported on a light coil spring.

Two different shapes of specimen, Fig. 1, were required, one to determine stress-strain relations and the other the compressive strengths. The 2-in. specimen $\left(\frac{l}{r} = 16\right)$[6] was used with the 1 in-gage-length compressometer to determine the compressive strength of the material.

[6] $\frac{l}{r}$ is the ratio of the length of the specimen to the radius of gyration of the cross section of the specimen.

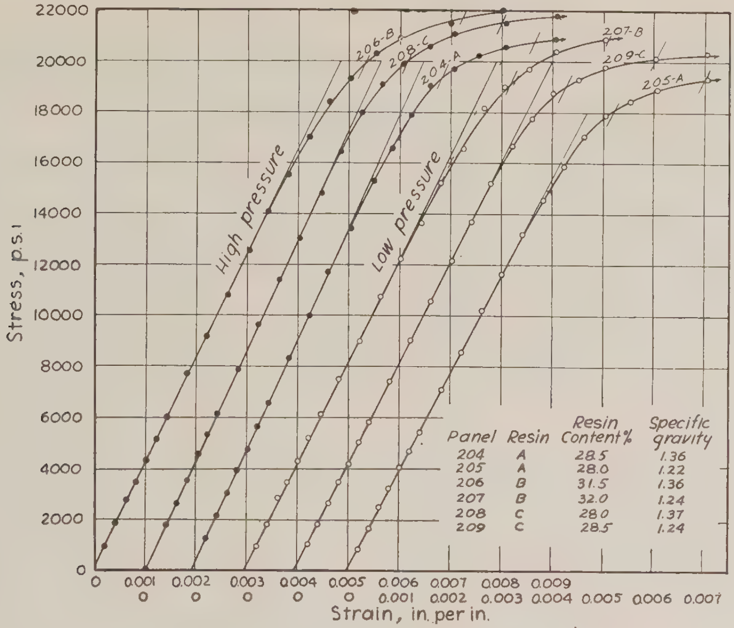

Fig. 7 Compression Tests of Compreg

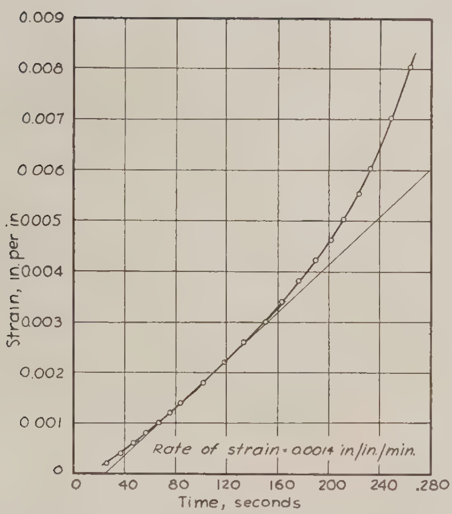

Fig. 8 Strain-Time Curve of Compreg in Compression

During the compression tests of the 2-in. specimens, readings of load, deformation, and time were recorded. From these data the stress and strain were computed, and stress-strain and strain-time curves were plotted. Fig. 7 shows the stress-strain curves for the compression tests, and Fig. 8 shows a sample strain-time curve from a compression test. The modulus of elasticity, yield strength at 0.05 and 0.2 per cent offset, and the rate of strain were determined from these curves. The rate of strain in the 1-in. specimen was determined by comparing the loading rate with the loading rate in a 2-in. specimen. The loading rate was obtained by plotting a load-versus-time curve.

Results of the compression tests are shown in Table 3. The average modulus of elasticity in compression was found to vary from 3,810,000 to 4,330,000 psi, depending on the resin and

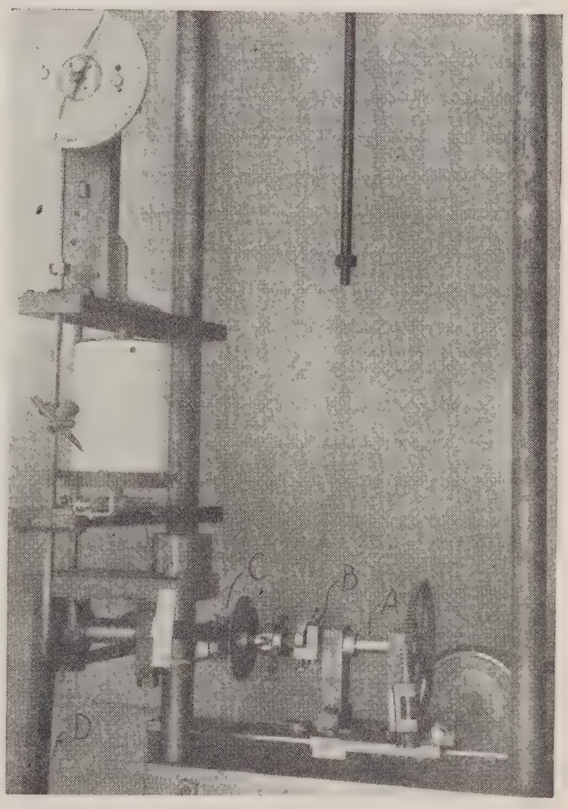

Fig. 9 Torsion Apparatus

molding pressure used, and the average ultimate strength in compression was found to vary from 22,700 to 26,800 psi, depending on the resin and molding pressure. The data in Table 3 show that the modulus of elasticity, ultimate strength, and yield strengths in compression are about 5 per cent higher for compreg molded under 1500 psi pressure than for compreg molded at 600 psi. This is approximately true for each of the resins investigated.

The increase in modulus of elasticity in compression resulting from increasing the molding pressure from 600 to 1500 psi was 10.5 per cent when resin A was used, 2.5 per cent when resin B was used, and 9.9 per cent with resin C. The corresponding increase in ultimate strength was 6.6 per cent with resin A, 6.3 per cent with resin B, and 7.5 per cent with resin C. The increase in yield strength at 0.2 per cent offset was 8.9 per cent with resin A, 4.3 per cent with resin B, and 8.5 per cent with resin C. Corresponding values for the yield strength at 0.05 per cent offset are 9.7, 3.1, and 8.1 per cent, respectively.

Short-Time Torsion Tests. The special torsion-testing machine used for these tests is shown in Fig. 9. The machine was constructed as an attachment for a low-capacity tension-testing machine. The pendulum-weighing system of the tension-testing machine was used as the torque-measuring device for the torsion machine. This was accomplished by attaching to the tension machine a twisting head, A, Fig. 9, driven by a double worm drive. A special chuck B was attached to the shaft of this twisting head and another chuck C to the axis of the pendulum D. These chucks were designed to apply a torque to the specimen with slight danger of inducing bending. This action was further assisted by mounting the specimen on centers and applying the torque as a couple by means of adjustable screws.

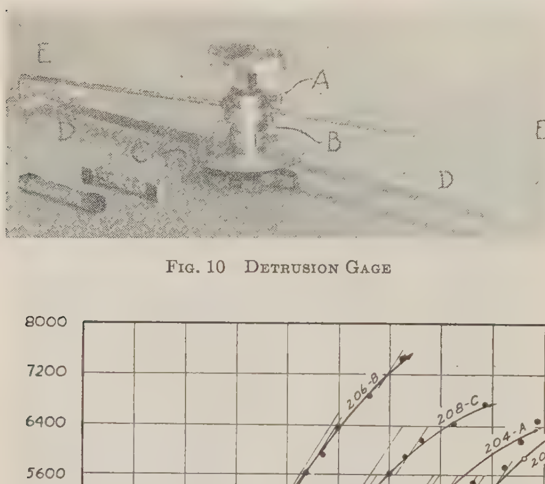

Fig. 10 Detrusion Gage

The gage used for measuring the shearing strain is shown in Fig. 10. It was designed to accommodate materials whose ultimate shearing strain was relatively small and also materials which might twist 2 or 3 revolutions in a length of 2 in. The instrument consisted of two rings A, Fig. 10, which were slipped over the specimen and fastened to it by three adjusting screws in each ring. A gage length of 2 in. was obtained by use of a removable spacer B. To one of the rings was fastened a circular scale C, for measuring large angles of twist. Two 10-in. arms D fastened to the same ring carried scales on the ends, which were used to measure small shearing strain. Adjustable pointers E, were attached to the other ring in such a way as to indicate the readings on their respective scales.

Laminated materials, such as the compreg described herein, are anisotropic, that is, their properties are not the same in all directions. In the tension and compression specimens the maximum normal stress was parallel to the grain direction throughout the test specimen. However, in a torsion specimen with axis parallel to the lamination, both the tension and shearing stresses had different directions (relative to the direction of the wood grain and the plane of laminations) at different points around the circumference of the specimen. Thus the equations of stress and strain for torsion of an isotropic member cannot be expected to indicate accurately the stress or strain in this anisotropic material. Nevertheless, the following equations developed for isotropic materials were used here to give nominal values of shearing stress and strain as a basis for comparison: The equation for shearing stress in a circular member of an isotropic material subjected to torsion is $\tau = \frac{Tc}{J}$, and the corresponding equation for shearing strain is $\gamma = \frac{c\theta}{l}$.

In the case of a laminated material, the torsion test may serve as an indication of the relative shearing strength of the bond between laminations, that is, in a wood-laminated material failure is likely to take place by shearing parallel with the grain.

Short-time torsion tests were performed on specimens, Fig. 1(b), cut from the sheet with their longitudinal axes parallel to the grain.

Approximate rate of strain, in. per in. per min	0.015	0.016	0.014	0.015	0.015	0.016

[a] One specimen.
[b] Two specimens.

During the torsion test simultaneous readings of torque, angle of twist, and time were recorded. The nominal shearing stress at the surface of the cylindrical specimen and the nominal shearing strain were computed from the relationships just given.

Curves of shearing stress versus shearing strain, Fig. 11, and time versus shearing strain, Fig. 12, were then plotted. The shearing modulus of elasticity G and rate of shearing strain were determined from these curves as in the case of the tension tests. It may be observed that the strain-time curve for torsion is practically a straight line, as compared with the curved strain-time diagrams for tension and compression. This is due largely to the greater stiffness of the machine compared to that of the specimen in the case of the torsion tests.

The results of the torsion tests are given in Table 4. The average shearing modulus of elasticity G, as determined from a torsion test, was found to vary from 248,000 to 337,000 psi, depending on the resin and molding pressure used, and the average modulus of rupture varied from 5060 to 9800 psi, depending on the resin and molding pressure. The data in Table 4 show that the shearing modulus of elasticity, modulus of rupture, and yield strengths were higher for compreg molded under 1500 psi pressure than for compreg molded at 600 psi. This was true for each of the three resins. The increase in modulus of rupture was particularly marked. The increase in shearing modulus of elasticity resulting from increasing the molding pressure from 600 to 1500 psi was 16.5 per cent with resin A, 13.1 per cent with resin B, and 21.9 per cent with resin C. The corresponding increases in modulus of rupture were 32.8 per cent for resin A, 40.4 per cent for resin B, and 62.1 per cent for resin C. The yield strengths at 0.2 per cent offset were increased 22.0, 35.4, and 21.2 per cent for resins A, B, and C, respectively; and the yield strengths at 0.05 per cent offset were increased 21.0, 53.9, and 17.1 per cent for resins A, B, and C, respectively.

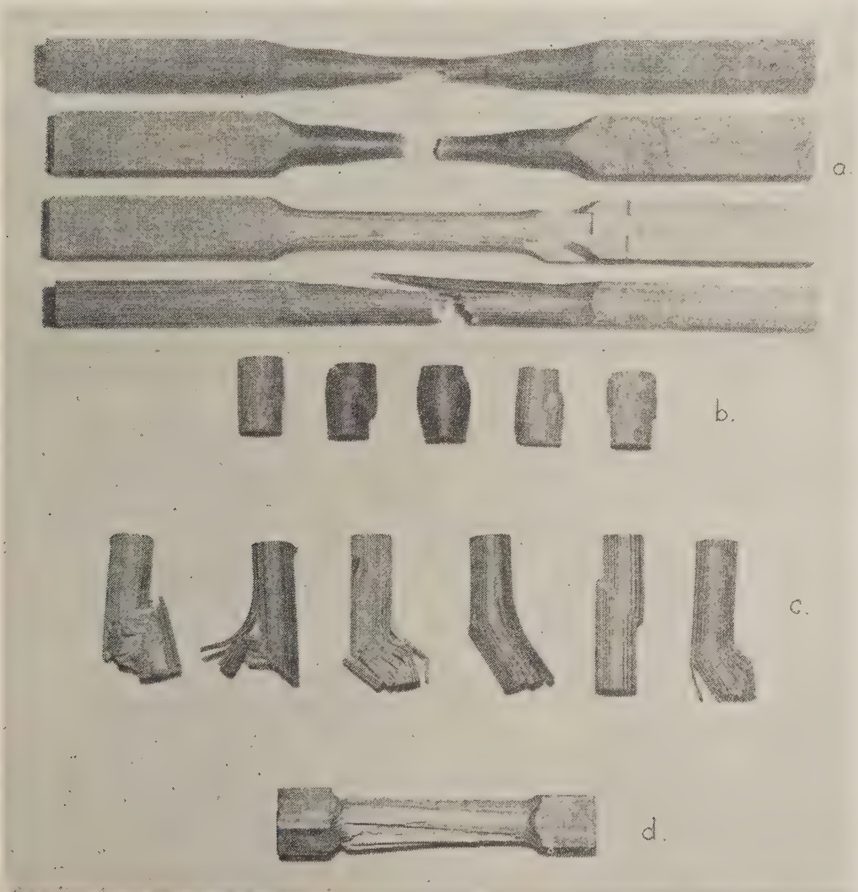

Fig. 13 Fractured Specimens
(*a*, Tension; *b*, short compression; *c*, long compression; *d*, torsion.)

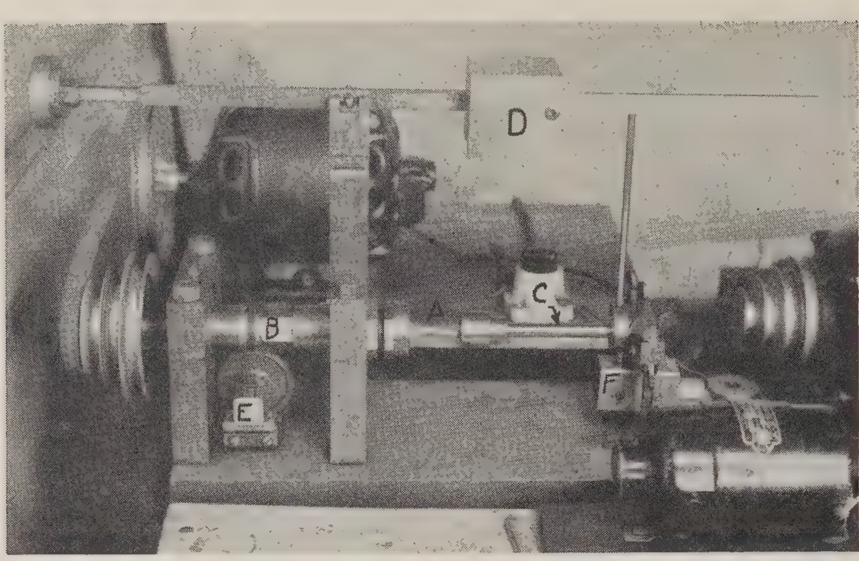

Fig. 14 Rotating-Cantilever-Beam Fatigue Machine

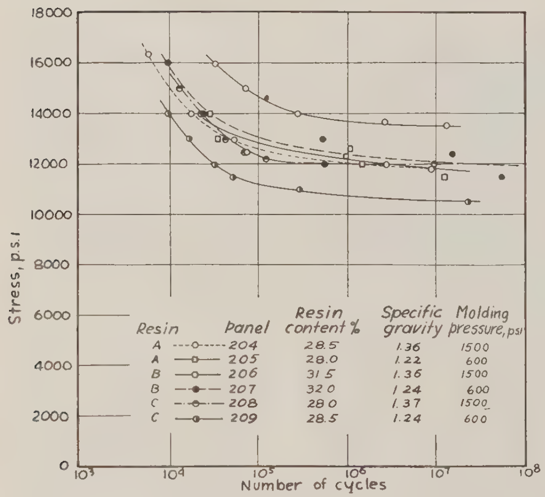

Fig. 15 Rotating-Beam Fatigue Tests of Compreg

Mode of Failure

Fractured tension, compression, and torsion specimens are shown in Fig. 13. Tension specimens are shown in Fig. 13(*a*). One of the straight tension specimens shows the type of failure which frequently occurred at the shoulder. Short compression specimens are shown in Fig. 13(*b*). These failures started as shear failures at 45 deg to the axis of loading.

The long compression specimens, Fig. 13(*c*), failed initially in much the same manner as the short specimens. It was observed that the shear failures which are visible in the illustration did not occur until after the maximum load had been passed. A slight bulging was observed, however, as the maximum load was approached.

A failed torsion specimen is shown in Fig. 13(*d*). This specimen has been severely twisted to show the type of fracture. The initial fracture in each torsion specimen was a slight longitudinal crack resulting from the shearing stress parallel to the axis of the specimen. The crack was parallel to the grain but usually did not follow the glue line between plies.

Fatigue Tests

Fatigue tests were performed on a rotating-cantilever-beam type fatigue machine shown in Fig. 14. This machine consisted of a motor-driven spindle *B* to which the specimen *A* was attached coaxially by means of a split collet. A shaft extension *C* was fastened to the other end of the specimen by means of a collet machined integral with the shaft. The entire assembly (spindle, specimen, and extension shaft) was rotated at a speed of 6200 rpm by a motor driving through a V-belt.

The specimen was bent downward by a load applied through a small ball bearing to the end of the extension shaft. This load

was produced by a beam-and-poise mechanism *D*. The stress σ at the minimum section of the specimen was computed from the equation $\sigma = \frac{Mc}{I}$ in which M was obtained from the load applied by the poise with suitable correction for the moment produced by the extension shaft.

In order to determine the number of cycles to cause failure a counter *E* was attached to record the number of cycles and a microswitch *F* was used to stop the machine when a crack had started in the specimen.

The data obtained from the fatigue tests of the six compreg panels is shown in Fig. 15, plotted as $\sigma-N$ diagrams. The tests were carried out to at least 10,000,000 cycles. It was observed that the fatigue-test results were nearly the same for four out of the six panels. The panel made with resin *B* and molded at the high pressure had the best fatigue characteristics, while the panel made with resin *C* and molded at low pressure had the poorest fatigue characteristics.

Fig. 16 shows the fatigue curves grouped in pairs according to the resin used. This diagram shows that the fatigue curves for resin *A* are almost identical. The different molding pressures made no difference. In the case of resins *B* and *C*, however, the ordinate (stress) of the fatigue curve was about 12 per cent higher when the panels were molded at 1500 psi than when molded at 600 psi.

The fatigue strength at 10,000,000 cycles is tabulated as item number 14 in Table 5. The term "fatigue strength"[7] refers to the maximum amplitude of an alternating stress cycle which will not cause fracture of the material for a given number of cycles of alternating stress. In other words, the fatigue strength is given by the ordinate to the $\sigma-N$ curve at the given number of cycles. In this report, the number of cycles used was 10,000,000.

The fatigue strength at 10,000,000 cycles was 11,800 psi with resin *A* for both molding pressures; with resin *B*, the fatigue strength was 12,000 psi, for the low molding pressure and 13,400 psi for the high pressure, an increase of 11.7 per cent; with resin *C* the fatigue strength was 10,600 psi for the low pressure and 12,000 psi for the high pressure, an increase of 13.2 per cent.

Comparison of Results

Average values of all properties determined for the six panels are summarized in Table 5. A study of this table discloses that panel 206, molded at 1500 psi with resin *B*, showed the best properties in 9 out of 14 items tabulated (numbered 3 through 16). The 17th item, recovery, was difficult to evaluate in this manner and will not be included in the comparison. This panel (number 206) was next to the highest in tensile modulus, compression modulus, and shear strength parallel to the laminations, but was fourth from the highest in impact strength, and of course had a higher specific gravity than the materials molded at low pressure. Panel 204 had the highest impact strength and shear parallel to the laminations; and panel 208 had the highest tension and compression moduli.

When the properties of the three panels molded at low pressure were compared, it was found that panel 207 molded with resin *B* had the best properties in 11 out of 14 items. It had a specific gravity slightly higher than panel 205, a tensile strength inferior to that of panel 209, and had the lowest impact strength of the group.

No account was taken of the specific gravity in comparing the properties of the six panels so that the low-pressure panel of resin *B* may be as good or better (depending on the property and application) than the high-pressure panel with resin *B*, for applications where weight is a prime factor.

Discussion

A. G. H. Dietz.[8] The authors have carried out an excellent series of tests and have obtained information which extends our knowledge of the behavior of compreg.

In an attempt to correlate their results with those reported by the writer and his collaborator in a previous joint paper,[9] the results summarized in Table 5 of the paper have been reduced to a common base by dividing the values obtained in tests 4 to 14, inclusive, by the specific gravities of the individual panels. Furthermore, taking panels 206 and 207 as points of reference, because they have the highest resin contents and also, generally speaking, have the highest values, ratios of values for panels 206 and 207 to those of 204 and 208, and 205 and 209, respectively, have been drawn. The results are summarized in Table 6 of this discussion.

It is, of course, not safe to generalize from these results, but certain factors are worthy of note because they may be indicative of trends:

1 When reduced to a common base (specific gravity reduced to 1.00) most of the values become more nearly equal, but considerable differences still exist. In panel-pairs 204–205 and 206–207, the higher density material has higher tensile strength, but the reverse is true of 208–209. In every pair, however, the lower density material has the higher compressive strength. Furthermore, in every pair the lower density material has higher moduli of elasticity in both tension and compression, although the differences are generally slight.

2 Shear characteristics and impact strength, unlike the general trend in tension and compression, appear to be benefited by higher densities. With one exception, every test, e.g., torsion (shearing) modulus, torsion modulus of rupture, shearing yield strength, shear strength parallel to laminations, impact, the higher density material is superior to the lower. The one exception is in 206–207, shear strength parallel to laminations.

3 In fatigue, the results are apparently not so clear. In pairs 206–207 and 208–209, the higher density material is slightly superior, in 204–205 the reverse is decidedly indicated.

It is interesting to compare panels 206 and 207, which have the highest resin contents, with the other panels made at the same pressures. In the high-density panels, the resin ratios for 206/204 and 206/208 are 1.10 and 1.13, respectively. For the low-density panels, the ratios for 207/205 and 207/209 are 1.14 and 1.12, respectively. With these in mind, the following factors may be worthy of note:

1 Although the ratios of most of the tensile and compressive values of panels 206 and 207, as compared with the other panels, are greater than unity, none of them is as great as the ratios of the resin contents. Increasing the resin content does not appear to increase these values proportionately. As might be expected from the characteristics of wood and resin, compressive strength is most nearly proportional, tensile strength less so.

2 With the exception of shear strength parallel to laminations, all the ratios of shear values, e.g., torsion (shearing) modulus, torsion modulus of rupture, shearing yield strength, are proportionately higher than the ratios of resin content. Increasing resin content appears to aid these properties. Shear parallel to laminations is proportionately lower in the high-density panels but the reverse in low density.

3 Impact values follow previous experience; the higher the resin content, the lower the impact strength.

4 Fatigue values are inconclusive, high-density panels give results favorable to higher resin content, low-density panels the reverse.

In the paper previously referred to,[9] fatigue results were compared with static moduli of rupture (bending). In the present paper no moduli of rupture are given, but if it is assumed, as a rough approximation, that moduli of rupture lie halfway between the tensile and compressive strengths, the fatigue values are approximately 30 to 35 per cent of the moduli of rupture. This is in approximate agreement with the results previously reported.[9]

[9] Reference 11 of authors' Bibliography.

Henry Grinsfelder.[10] The matching of panels is not entirely clear to the writer. Will the authors explain this matter more fully?

Do the values obtained with resin B represent definite proof that this is the best of the three resins tested, or is the improvement obtained by virtue of the higher resin content?

While the properties tested and the values obtained show the merit of compreg as it is prepared initially, is there any knowledge of how much of its strength is retained after outdoor exposure for one year?

[a] Specific gravity reduced to unity.

A. J. Stamm.[11] While the tests on compreg are obviously not extensive enough to afford a close quantitative evaluation of the effect of molding pressure and resin content on static and dynamic strength, the fact that the veneer was carefully matched in making up the samples affords a means of securing fairly accurate comparative values for the three resins and two pressures used. The data, however, should not be construed as necessarily representing average values for compreg made with these particular resins, such as would result from more extensive sampling.

The Forest Products Laboratory has, in the past, advocated the use of a water-soluble phenolic resin in preference to an alcohol resin for making compreg, largely because of the greater dimensional stability and lack of recovery. The alcohol-soluble resin used in the panels described in the paper, however, gave much less water absorption, swelling, and recovery than the alcohol-soluble resins in use in making compreg at the beginning of the war. The explanation is that this alcohol-soluble resin has been modified to make it more like the water-soluble resins with a low degree of condensation and high fiber-penetrating power, and still retain its advantage in giving higher impact strength. The advantages claimed in various Forest Products Laboratory reports for water-soluble resins, although still existing, are no longer as important.

It is felt that all three of the resins used in making the panels for which test data are given in this report are suitable for making high-quality compreg.

Authors' Closure

The authors wish to express their thanks to the discussers for their valuable contributions to this paper. Mr. Dietz has made some very interesting comparisons, but there is one point on which the authors are in disagreement with him. He has implied that dividing the various mechanical properties by the specific gravity reduces them to a common base for all panels.

This seems misleading. The results as reported by the authors were on a common base with regard to actual strength, stiffness, etc., and as indicated in the paper the relative merits of the panels might be different for different applications when weight is considered.

Mr. Dietz has implied that the strength of structural members of equal weight made of materials of different specific gravity can be compared by dividing the appropriate mechanical property by the specific gravity and comparing the resulting quantity. This is true for only certain specific cases, such as: tension members of the same length, short compression blocks of the same length, beams of the same length and depth, and long columns of the same length and depth of section which fail by buckling in the plane of the depth dimension.

However, this is not true for many other cases. The ultimate load-carrying capacity of beams of equal weight having the same length and the same width but made of materials having different specific gravity may be compared by dividing the flexural modulus of rupture for each material by the *square* of its specific gravity and comparing the resulting quantities.

Similarly the ultimate torque-carrying capacity of circular shafts of equal weight and length may be compared by dividing the torsional modulus of rupture of each of the materials by its (specific gravity)$^{3/2}$ and comparing the resulting quantities.

Also the ultimate load-carrying capacity of long columns of equal weight and of the same length and *width* of section which fail by buckling in the plane of the depth dimension may be compared by dividing the effective elastic modulus for bending of each of the materials by the *cube* of its specific gravity.

The stiffness of structural members can be compared in a similar manner. The stiffness of bars of equal length subjected to axial loads of either tension or compression (where no buckling is involved) can be compared by dividing the appropriate elastic modulus of each material by its specific gravity; and the stiffness of circular shafts of equal length in torsion can be compared by dividing the shearing modulus of elasticity of each material by the *square* of its specific gravity.

These relationships can be derived from the equations for load or stiffness and the given restricting conditions such as the same weight for both structural members and the same length for both structural members.

Inasmuch as the panels for these tests were prepared by A. J. Stamm, who has been directly connected with the development of compreg, the authors have referred the questions raised by Mr. Grinsfelder to Mr. Stamm. His reply is as follows:

"The panels were matched as follows: Eighteen sheets of $^{1}/_{16}$ by 28 by 54 in. rotary cut yellow-birch sapwood veneer conforming to AAF Specification 15065 were stacked and cut into 8 piles of plies approximately 14 in. wide and $13^{1}/_{2}$ in. long. The stacks of plies were numbered 204 to 211; 204, 206, 208 and 210 being matched consecutively in the fiber direction, and 204 and 205, 206 and 207, 208 and 209, and 210 and 211 being matched in the tangential direction of the tree. Stacks 210 and 211 were retained by the Forest Products Laboratory for future reference. Stacks 204 and 205 were treated with resin A, 206 and 207 with resin B, and 208 and 209 with resin C. The even-numbered stacks were assembled at 1500 psi and the odd numbers at 600 psi. As matching in the fiber direction of the wood is better than side matching, the matching for the resin type variable was better than for the pressure variable.

"The data presented in this paper are insufficient to draw conclusions regarding the small variations in properties. The only differences which we believe are real on the basis of other data obtained by the Forest Products Laboratory are the water absorption, swelling, and recovery, and the compressive strength and impact strength (Izod). Water-soluble resins of the type illustrated by resin B, we believe, penetrate the cell-wall structure more completely than the alcohol-soluble resins as represented by resin A.

"This greater penetration results in somewhat better moisture stability and makes the cell wall more rigid, resulting in an increase in compressive strength but a decrease in impact strength. Tensile strength, modulus of rupture in bending, and shear strength appear to be affected little by the type of resin used. Little significance can be placed on differences in these values.

"All three of these compregs have excellent properties. From the user's standpoint there is little to choose between them. Resin A, however, is exceptional among alcohol-soluble resins in giving high dimensional stability. More advanced alcohol-soluble resins will give inferior dimensional stability properties."

Glue-Line Stresses in Laminated Wood

By A. G. H. Dietz,[1] Henry Grinsfelder,[2] and Eric Reissner[3]

With intensified use of timber beams, consisting of laminations of relatively thin boards and planks glued together, the problem of glue lines coming apart under changing conditions of moisture content in the timber has become of considerable importance. From an examination of glued timbers undergoing changes in moisture content, it appears that delamination, when it occurs, most frequently does so when the moisture content is being reduced; during such a dehydrating phase not only does shrinking take place but also checking of the wood. Results of experimentation and field trials indicate that thin laminations are better than thick ones for gluing, and wood species with low moduli are better than species with high moduli. Adhesives must be employed which have high shearing strength and high tensile strength perpendicular to the glue line if laminated beams are to be dependable in service.

Introduction

Within recent years, timber beams, consisting of laminations of relatively thin boards and plank glued together to form large curved or straight members, have found rapidly increasing use. It has been customary to employ cold-water-mixed room-temperature-setting adhesives in the fabrication of such timbers. Experience indicates that under conditions of changing moisture content in the timber, glue lines sometimes come apart.

It has been known for some time that thick wood members are more difficult to glue than thin. Plywood has been successfully bonded over a period of years with resin adhesives, but serious difficulty has often been encountered when the thickness of one or more plies has exceeded about $^1/_4$ in. It is also known that plywood made of $^1/_8$-in. veneer is more apt to delaminate during outdoor exposure than is plywood made of $^1/_{16}$-in. veneer. In edge-glued lumber difficulties have been caused by sunken joints. Troubles have arisen in gluing plywood surfaces to lumber cores. More recently, considerable interest has been aroused by the problem of laminating oak for exposure to such severe conditions as are found around ships' keels.

The difficulty has not been one of obtaining a good initial bond but rather one of preventing delamination after relatively short periods of exposure to service conditions. In the laboratory, joints which initially fail in the wood at values above 2800 psi, when tested in compression-shear blocks, are frequently delaminated by immersing in water for 7 days and drying to 8 per cent moisture content. The glues used are those usually considered to be waterproof or water-resistant.

Many theories, i.e., acids of the wood, tannins in the wood, high hydrogen-ion content of the wood in salt water, each or all weakening the adhesive bond, have been advanced to explain this phenomenon. However, no real proof has been produced supporting these theories, and from an analysis of the available facts, it would appear that certain fundamentals concerning wood and gluing need re-examination.

When wood increases in moisture content it expands. If wood is glued and then permitted to increase or to decrease in moisture content, either the wood expands and takes the adhesive with it, the adhesive restrains the wood and prevents expansion, or delamination occurs and the wood leaves the adhesive. However, when wood shrinks due to loss of moisture, wood failure in the form of splits, or "checking," may occur in place of glue failure or delamination. In laminated wood, unlike plywood, noticeable expansion and contraction take place as the moisture content of the laminations changes. Good glue joints, therefore, depend upon the ability of an adhesive to follow or to restrain the wood during the changes in dimensions caused by changes in moisture content.

Glue-Line Stresses Caused by Moisture Changes

In order to obtain an indication of the nature of the stresses set up in the glue lines of laminated timbers as the moisture content changes, two cases have been investigated mathematically. In both, the beam consists of two parallel-grain laminations of equal thickness, Fig. 1(a). They represent the

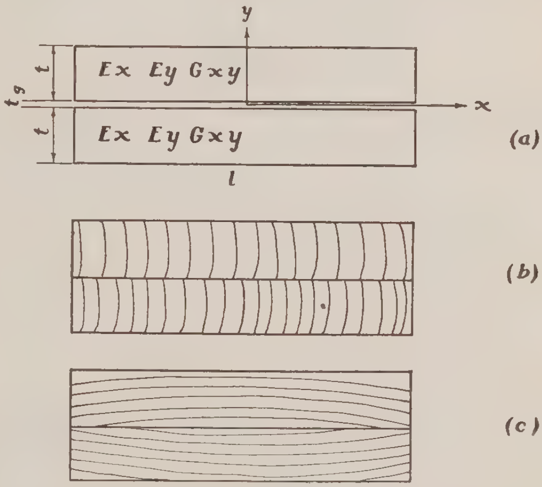

Fig. 1 Types of Laminated Beams

(a, Cross section through two-layer laminated beam of material having Young's moduli E_x and E_y in x- and y-directions; shear modulus G_{xy}, and dimensions shown. b, Two-layer beam of edge-grain wood. c, Two-layer beam of flat-grain wood.)

probable extreme cases; one in which high shear stresses are set up in the glue line without any normal stress perpendicular; the other in which high normal stresses perpendicular to the glue line occur but no shear stresses. For most beams consisting of several laminations, the usual condition would be intermediate between these extremes.

The mathematical analysis, omitted here for the sake of brevity, leads to conclusions which follow:

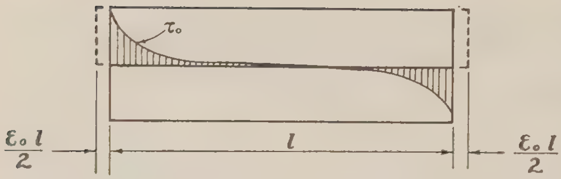

Fig. 2 Case 1—Cross Section Through Two-Layer Beam With One Lamination Tending to Expand or Contract Uniformly Because of Uniform Change in Moisture Content

(Other lamination unchanged in moisture content. Shear stresses have sharp maxima at edges of beam.)

Case 1. Two laminations of equal thickness, one of which undergoes uniform moisture change tending to increase or decrease its width whereas the other remains unchanged, as illustrated in Fig. 2.

No normal stresses perpendicular to the glue line are set up. "Rolling" shear stresses do occur as one lamination tends to expand or contract past the other. These stresses are largely concentrated at the ends of the glue line, decaying toward zero over a distance approximately equal to the thickness t of the lamination. Their maximum intensity is, approximately

$$\tau_{0\max} = 0.7\epsilon_0\sqrt{E_x G_{xy}} \qquad [1]$$

$$\epsilon_0 = \alpha(M_2 - M_1) \text{ (see Fig. 2)}$$

where α = hygroscopic coefficient of expansion
M_1 = initial moisture content
M_2 = final moisture content
E_x = Young's modulus of laminations in x-direction (parallel to glue line)
E_y = Young's modulus of laminations in y-direction (perpendicular to glue line)
G_{xy} = Shear modulus in xy-plane

Case 2. Two laminations of equal thickness, in which the moisture content changes in a parabolic manner, as shown in Fig. 3. Moisture change is symmetrical about the glue line, and no shear stresses are set up in the glue line. Normal stresses σ_0 occur perpendicular to the glue line, with maximum intensities at the ends, as shown in Fig. 3. For isotropic materials their maximum intensity is given by

$$\sigma_{0\max} = 0.45\epsilon_0 E_x \qquad [2a]$$

A modification of this formula for anisotropic materials, such as wood, is

$$\sigma_{0\max} = 0.45\epsilon_0\sqrt{E_x\sqrt{2E_y G_{xy}}} \qquad [2b]$$

where the symbols have the same significance as in Equation [1], except that ϵ_0 is now the difference in hygroscopic strain between the outermost fibers and the fibers at the glue line.

Equations [1] and [2a] have been obtained by minimum energy methods. A stress distribution was assumed of known shape in the direction across the thickness of the laminations while the variation of the stresses in the direction of the glue line was determined entirely by the energy method. A further approximation was made by saying that the state of stress was plane. It is believed that the values of the maximum stresses will be changed slightly only if plane strain is assumed instead of plane stress but this should still be confirmed by calculation. With regard to Equation [2b] it should be said that this is a plausible generalization of Equation [2a] for the isotropic material. Equation [2b] has, however, not been obtained by solving directly the problem for the anisotropic material. It is hoped that the theoretical work leading to the foregoing results may be continued so as to cover the points mentioned, as well as to obtain results which go beyond those given here.

Numerical Examples. In order to obtain numerical values of stress for the foregoing expressions, it is necessary to find values of shear modulus and Young's moduli across the grain, and of expansion across the grain caused by changes in moisture content.

In Table 1 are given some measured and some estimated values of shear modulus and Young's moduli for various species of wood. Shear modulus is in the radial-tangential plane (cross section of the wood); Young's moduli are in the radial and tangential directions of the cross section.[4] In Table 1 are also given estimated average values of the hygroscopic coefficient of expansion α_r and α_t in the radial and tangential directions. These are based largely upon values of shrinkage from fiber-saturation point to oven-dry condition.[5] The hygroscopic coefficients α are therefore the expansion per unit width of material for each per cent increase in moisture content.

Case 1. Example. Suppose, for example, that at the time of gluing the lumber is at 12 per cent moisture content (M_1) and that subsequently one lamination of the glued-up beam rises to the fiber-saturation point (M_2) or 28 per cent. The total expansion per unit width then occurs over a range of 16 per cent, and

$$\epsilon_0 = 16\alpha_r$$

for edge-grain material, (Fig. 1*b*).

$$\epsilon_0 = 16\alpha_t$$

for flat-grain material, (Fig. 1*c*).

For the various species of Table 1, the values of maximum shear-stress intensity, as calculated by Equation [1], are then approximately as given in Table 2 under the heading Case 1.

These values must be considered approximate, because the various constants, especially the moduli, are known only approximately and show wide variation. Nevertheless, it becomes clear that heavy shear-stress concentrations may be set up at the outside edges of glue lines when only the outer lamination under-

Walnut	0.00185	0.00253	172000	92000	34000

[a] Estimated.

goes marked change in moisture content while the others remain unchanged. This "rolling" shear stress would be sufficient to rupture either the wood or the glue line for a short distance inward, and failure would be progessively inward until the ratio of thickness of lamination to width of unruptured glue line became large enough to cause a diminution of shearing-stress intensity. It is worthy of note that stresses set up by edge-grained laminations are generally less than those set up by flat-grained laminations.

This is, of course, an extreme case, and one not apt to occur very often in practice. The usual conditions are more nearly approximated by Case 2, which will be examined next.

Case 2, Example. In this example parabolic distribution is assumed for the change in moisture content across the total depth of a two-layer beam, Fig. 3. It was shown that under these conditions there would be no shear in the glue line, but that normal stresses perpendicular to the glue line would be induced as given by Equation [2*a*] for isotropic materials and by Equation [2*b*] for anisotropic materials such as wood.

Assuming, for the sake of comparison with case 1, a 16 per cent change in moisture conditions; that is

$$\epsilon_0 = 16\alpha_t$$

or

$$\epsilon_0 = 16\alpha_r$$

the normal stresses perpendicular to the glue line for the various species of Table 1, are as given in Table 2 under the heading Case 2. As was true of case 1, flat-grain laminations induce higher stresses than do edge-grain laminations, but the difference is considerably greater than was true of Case 1.

It is to be noted that the normal stresses given in Table 2 are maximum compression when the moisture content is increasing, and maximum tension when the moisture content is decreasing.

Here again we have a case in which extreme conditions are postulated. The beam is only two layers thick and both layers are undergoing extreme moisture changes, tending to cause both of them to bow in opposite directions. It must be kept in mind, also, that all the constants are subject to wide variation and that the data supporting all of them are meager. It is entirely probable that some of them change markedly with moisture content. If so, the computed stresses will be altered.

To summarize, depending upon the distribution of moisture during a change in the moisture content of a laminated beam and depending upon whether the change is an increase or a decrease, the extreme conditions are as follows:

1 No normal stress in the glue line, but shear occurring with a sharp maximum at the ends of the glue line. "Rolling" shear stresses as high as 2100 psi or more are indicated under severe conditions.

2 No shearing stresses in the glue line, but normal stresses occurring with a sharp maximum, either compression or tension, at the ends of the glue line. Theoretical stresses as high as 3240 psi are indicated.

In a laminated beam consisting of a number of pieces, the outer laminations would undergo the most marked moisture changes, and the inner laminations would change moisture content along their exposed edges. Under these conditions both shear and direct stress perpendicular to the glue lines would occur, each perhaps one half as large as indicated in Cases 1 and 2. In any event, stresses would probably be concentrated at the ends of the glue lines, tending to cause delamination there.

TABLE 2 SHEAR AND NORMAL STRESS INTENSITIES IN GLUE LINES

Species	Case 1 τ_{0max} —Shear stresses, psi— Edge-grain laminations	Flat-grain laminations	Case 2 σ_{0max} —Normal stresses, psi— Edge-grain laminations	Flat-grain laminations
Ash	1850	2160	1740	3020
Douglas fir	660	880	940	1580
Mahogany	1060	1150	910	1720
Oak	1660	2020	1360	3240
Spruce	420	550	550	1130
Walnut	1590	1590	1330	2130

Conclusions

From an examination of glued timbers undergoing changes in moisture content, it has appeared that delamination, when it occurs, most frequently does so when the moisture content is being reduced. In other words, the dehydrating phase of a moisture-change cycle is the more severe. Not only does glue-line delamination occur more frequently during shrinkage but so also does checking of the wood.

Extensive experimentation and field trials lead to the conclusion that thin laminations are better than thick for gluing, and that wood species with low moduli are better than species with high moduli. Increased strength of the wood when dry abetted by loss of plasticizing water in the glue line apparently are cumulative and a severe test for a glue.

Consideration of the factors causing glue-line delamination should enable timber laminators to produce better, more durable stock. Lower bonding temperatures or shorter high-temperature schedules may be used if the glue-line stresses are reduced, so that in many instances the extra cost of thinner laminations or a thicker beam of a weaker species may be offset by increased production and durability performance. In any event, adhesives must be employed which have both high shearing strength and high tensile strength perpendicular to the glue line both when dry and when wet if laminated beams are to be dependable in service.

Discussion

F. J. Hanrahan.[6] The authors are to be commended for their exploratory mathematical studies on intensity and distribution of glue-line stresses caused by moisture-content changes in wood; also for suggesting a method of reducing these stresses by interlaying thin veneer in each glue line.

There are some features of the paper on which additional data, explanation or discussion would be desirable.

In case 1, it is stated, "These stresses are largely concentrated at the ends of the glue line, decaying toward zero over a distance

[6] Structural Engineer, National Lumber Manufacturers Association, Washington, D. C. Mem. A.S.M.E.

approximately equal to the thickness t, of the lamination." Is this statement based upon internal stress-strain studies or is it an assumption as to distribution of intensity of stress? Does this statement mean that the shear stresses set up at the glue line are independent of the face width (beyond a width equal to twice the thickness of lamination) of the lumber laminations glued together?

The formula for maximum intensity of stress (authors' Equation [1]), appears to contain no thickness-of-lamination factor. Does this mean that the intensity of the shear stresses set up at the glue line due to moisture change is independent of the thickness of the laminations glued together?

Without further explanation it is difficult to reconcile the foregoing quoted statement with the following statement under Case 1: ". . . failure would be progressively inward until the ratio of thickness of lamination to width of unruptured glue line became large enough to cause a diminution of shearing-stress intensity."

Also it would be of interest if the authors could suggest an explanation of why the use of a thin interlayer of low-density low-moduli veneer between laminations of dense strong woods reduces or prevents delamination. Could it be that the thin relatively weak wood flows plastically, tending to permit some relative lateral movement of the denser layers? Or is the movement believed to be purely elastic?

In such a complicated investigation one should not expect complete answers from early investigations but additional light on the subject, if available, would be helpful.

Verne Ketchum[7] and O. H. Schrader.[8] Fearing the possibility that the opening paragraph of this paper may leave the impression that delamination of glue lines in laminated wood construction is a common occurrence in service, it is suggested that explanation be included that fabricators do not class such types of glue as waterproof or intended for exterior use, except where adequately protected from the elements.

It would also be desirable to explain the reasons for increased difficulty in gluing with thick laminations. At least three factors enter into this relationship: (1) The problem of accurate surfacing; (2) the effect of dimensional changes that take place after surfacing, both of which are emphasized with an increased thickness; and (3) the difficulty of obtaining intimate contact between laminations as pressure is applied.

Both white oak and Douglas fir have been successfully laminated in quantity for ship parts at the two pilot plants, established by the WPB during the war, and numerous laminated boat parts have successful records of years of service under the severest kind of service conditions. In fact, not a single failure by delamination has occurred in these boat parts, and delamination need not be a problem if adhesives now on the market are used under the conditions for which they are fitted.

The authors leave the impression that the cold-water-mixed room-temperature-setting adhesives, such as casein or urea-resin types, should resist delamination after exposure to exterior conditions. Late tests by the Forest Products Laboratory show that under such service conditions only phenol, melamine, or resorcinol-type glues, employed with careful observance of the required curing conditions, will withstand extreme service conditions. It would be well to indicate that "waterproof" and "water-resistant" are not synonymous terms, as the plywood manufacturers have spent a great deal of money in recent years in attempting to make this plain to the buying public, and to engineers and designers who may employ plywood under a wide range of service conditions.

The formulas and calculations seem valid in so far as the constants employed are valid. However, there are also several other factors which might have a bearing upon the mechanics of the problem:

1 It is known that wood possesses certain "plastic-flow" or "yield" characteristics, although at present no accurate determinations of these factors have been reported in literature. This property of wood is now the subject of extended study at the Forest Products Laboratory. The plastic-flow characteristics of wood are materially affected by changes in moisture content and may be responsible for the observed fact that delamination or wood failure along a glue line is far more evident during the drying or shrinking phase than in the swelling phase of laminated timbers.

2 The assumption is made that a glue line in laminated wood is a continuous sheet or film and is capable of transmitting stresses as a continuous member. Actual observations of glue lines, made after delamination tests or shear tests, disclose that the continuous-sheet theory is not entirely substantiated, but it is found that the glue line is frequently broken and separated into strips which often coincide with the distribution of springwood and summerwood on the face of the lamination.

In summarizing, the authors' conclusions 1 and 2 should both be modified by the consideration of the plastic-flow characteristic which will tend to reduce the computed stresses.

Again, under conclusions, the phrase, "consideration of the factors causing glue-line delamination," is so used that it infers that timber fabricators are not concerned with these factors. This is not the case, as witness the many sound efforts made to improve commercial gluing techniques, the interest in specifications that is being manifested, and the research on this subject that has been carried out in recent years. The fabricator is ready and willing to adopt any practice that will improve the quality without undue increase in cost. The use of low-strength interlayers of thin veneer would seem to increase cost and decrease shear and bending strength.

It would be desirable to distinguish between "delamination," and "wood failure at the glue line," as the former may result from improper laminating practices or improper use of adhesives, while the latter would indicate that it results from severe exposure and may be corrected by providing surface protection of paint, boxing or other type water-resisting coverings.

It is important to bear in mind that laminating is a new industry which is laboring under severe handicaps in the development of machinery and methods adaptable to volume production. It is desirable to make every effort to encourage good practices, provided they are not prohibitive from the cost standpoint, as it is certain that the industry will strongly oppose methods which increase the cost differentials that are now encountered in a competitive market.

T. D. Perry.[9] This paper reveals a problem in the use of laminated timber that is fundamental, i.e., the internal stresses that may occur within the timber and independent of any superimposed load. However, it is quite unlikely that two adjacent layers will at any time have a net differential of as much as 16 per cent moisture content, since exterior moisture diffuses inward at a diminishing ratio, and even the imperfect barrier of a glue line will not retard such diffusion to any substantial extent. Do the authors agree with this statement?

Another point to consider is the width of the glue joint across the grain of the lumber. It is conceivable that unit stresses would not be troublesome over a 1-in. width, but they might be very serious over a 12-in. width. It is probably a fair assumption that the percentage of shrinking or swelling over a 16 per cent

[7] Chief Engineer, Timber Structures, Inc., Portland, Ore.

[8] Chief Wood Technologist, Timber Structures, Inc.

[9] Development Engineer, Resinous Products & Chemical Co., Inc., Philadelphia, Pa. Mem. A.S.M.E.

moisture-content range might be as much as 2 per cent, which would not be appreciable for pieces 2 or 3 in. wide, but on a 12-in. width it would amount to $^1/_4$ in. It is doubtful whether any adhesive would maintain a strong joint between two pieces of 4/4-in. lumber, one of which was endeavoring to increase its width by $^1/_4$ in., and was restrained only by the strength of the glue line. If the widths were greater or the percentage higher, the magnitude of this stress would be much more serious. Have the authors any comment to make on this?

It has been a rough and ready rule among plywood manufacturers that test pieces, made with a suitable resin adhesive, of an all-veneer construction with $^1/_{16}$-in. veneer layers, can be put through prolonged wet-dry cycles without delamination. When $^1/_8$-in. layers are used, the case becomes marginal and delamination may occur. If, however, $^3/_{16}$-in. or $^1/_4$-in. layers are glued together, delamination is reasonably certain to take place. This has been explained by the theory that the total expansive power of a $^1/_8$-in. layer is about double that of a $^1/_{16}$-in. layer, and in other ranges varies approximately as the thickness. My observation, without scientific analysis, seems to confirm this theory. Therefore, would the thickness of the adjacent layers invalidate or modify any of the assumptions or conclusions made in the paper?

G. M. Rapp.[10] The paper is stimulative and timely; because, within the writer's knowledge, it is the first time that methods of the mathematical physicist and of the structural engineer have been applied to the long-observed phenomena of delaminating surfaces; and furthermore, because the application of laminating and modern gluing techniques, which have been so notably advanced during the war, gives promise of even greater acceleration and much wider use in the immediate future. With the "rediscovery" of wood as one of our foremost structural materials, it is necessary that we advance our knowledge of its behavior under varying conditions of moisture and temperature, quantitatively, rather than to treat these, as heretofore, as anomalies to be allowed for but not accounted for. The authors are to be congratulated for pointing out a specific problem relating to a very important limitation of wood, i.e., its dimensional instability under moisture change in glued assemblies.

The writer has long been interested in the intrinsic causes underlying the delamination of adhered surfaces. Although the authors have confined themselves to wood, the question really is a far more general one to which mathematical analyses can bring much in the way of a clearer understanding of the adverse actions involved and the remedies possible. Not only wood but most organic materials are susceptible to dimensional change with moisture content, with the inevitable result that stresses are produced in heterogeneous assemblies and even in the homogeneous materials themselves when they are subjected to moist environments. It is the writer's opinion that somewhat the same action as postulated by the authors in a simplified example of a laminate, obtains also in paint coatings on wood, ceramic glazes on clay tile, plaster on walls, in fact, in any combination where materials, which are unlike in their moisture-expansion properties, are adhered to each other. He agrees wholeheartedly with the conclusion that the cause of many observed delaminations is induced stresses. For example, the "popping" of an expanding plaster on a wall, the lifting or peeling of paint, the crazing of the glaze on tiles and of portland-cement-mortar overlays. An extreme illustration, and one intriguing to the analytically minded, is the crackling of glass produced by certain glues; a phenomenon put to practical use by the glass technologists.

Furthermore, like the authors, the writer has attempted to evaluate some of these problems as the stress analyst would investigate a bridge or other structure. After all, with a quantitative knowledge of the moisture change and other elastic properties of the materials involved, the only difficulties in obtaining a solution are those of defining correctly the equilibria conditions, establishing reasonable assumptions for simplification, and solving the mathematical equations. Analogous problems exist and have been solved in such cases, for example, as determining the stress performance of bimetallic elements (from unequal thermal-expansion coefficients) and in the calculating of the shear stresses induced in fillet-welded joints in steel members or, again, in theorizing as to the distribution of bond stresses along a concrete reinforcement bar. In all these cases, as in the authors' case, the general pattern of the stress distribution along the joint follows the exponential (e^x) law, which follows naturally from the fact that the changes in stress along the bond line are proportional in some way to the stress itself. Thus it would be expected, as the authors show, that maximum stresses would occur at the ends of the glue line and dissipate themselves rapidly as the neutral point is approached.

It is impossible to comment authoritatively upon the authors' formulas since their mathematical derivations have been omitted from the paper. It is regrettable that this was done inasmuch as the reasonableness and true significance of the conclusions depend so completely upon the mathematical processes. However, the final equations given appear to be rational though apparently simplified by the insertion of certain limits which, although they serve the purpose of a solution for the specific problem, do not permit of generalization. Obviously, the authors have made assumptions in their analysis which do not appear in the paper. Presumably one of these was that there is no slip in the glue line itself. Such an assumption would complicate the mathematics but might be a valuable addition to the theory in view of the greater attention being given to thermoplastic adhesives and to the use of "cushioning" interlays.

The writer objects to the terminology "hygroscopic coefficient of expansion." He would suggest the expression "coefficient of moisture expansion," which applies regardless of whether absorption or adsorption processes are involved, and whether the environment is air with a high water-vapor content or merely liquid water.

In his own attempts to solve similar problems mathematically, the writer has usually ended up with expressions which include the thickness of the laminate. The necessary summation of the distortions from the tensile, compressive, and shear stresses induced in both cases illustrated is dependent upon this thickness factor. The authors have contented themselves with stating that observation has shown adverse results with thicker veneers.

Also, one's attention is drawn to the statement under Case 1, "no normal stresses perpendicular to the glue line are set up." In considering infinitesmal elements directly beneath and above the glue line and the combination of the shear and direct stresses acting upon these elements, the conclusion is inevitable that there must exist a resultant or principal stress which is not parallel to the glue line. These principal stresses, which also exist in beams, have therefore components normal to the glue line, which predicate the presence of tensile or compressive forces, dependent upon the relative magnitude and direction of the shear and direct stresses. Tensile stresses, if they truly exist, may be significant in accounting for delamination. In fact some theorists go so far as to hypothesize tension as a prerequisite for every material failure.

The authors properly point out the greater susceptibility of flat-grain as compared with edge-grain veneers to delamination and checking. This is accounted for by the relatively greater dimensional change tangentially in most woods. The writer

[10] Assistant Director, John B. Pierce Foundation, New Haven, Conn.

has just seen a somewhat dramatic corroboration of this in certain tests in his laboratory involving the moisture changes in edge-grain and flat-grain laminated oak. It is a fact of practical significance worthy of note by fabricators.

The authors are to be commended for the realistic approach which they take in Case 2, wherein they assume a parabolic distribution of moisture content throughout the depth of their sample beam. Because all wood structures absorb and desorb moisture from the outside inward, this has special significance. It might well be pointed out, however, that the induced stresses will be dependent upon the rate at which such moisture gradients are generated within the wood or, in other words, on the time element. This factor, which is well known to everyone experienced in the kiln-drying of wood, offers a possible means of control against delamination in laminating practice, i.e., controlled curing.

In closing, the writer wishes to appeal to the authors to submit their mathematical analyses either in an appendix to this paper or in a future presentation. It is the only foundation upon which the true significance of their results can be appraised.

C. B. Norris[11] and A. C. Knauss.[12] It is difficult to comment on this paper without the inclusion of the mathematical analysis which leads to the results obtained. The mathematical analysis is exceedingly difficult and has not previously been accomplished. Probably some simplifying approximations have been made and the results therefore may be misleading.

It has been found that wood flows plastically at stresses well below the published proportional-limit stresses. This plastic flow will materially modify results obtained by use of the mathematical theory of elasticity. It does not seem that sufficient is known about the plastic behavior of wood to make the solution of the problem possible.

We believe that some of the assumptions and conclusions drawn are not generally applicable to nor borne out in experience with laminated-timber construction, although they may be applicable in certain specific instances.

C. D. Dosker.[13] The authors' suggestions are in line with the writer's observations of the behavior of laminated timbers when exposed to variable moisture conditions. It is true that delamination tends to take place along the exterior edges of the glue lines. It is true, also, that the first evidence of delamination frequently occurs with the first substantial change in moisture content, but does not continue to increase in depth with subsequent moisture changes. The authors' analysis suggests an interesting and seemingly logical explanation of this phenomenon.

One question which occurs to the writer concerns the distribution of stress assumed in Case 2, as illustrated in Fig. 3. No "rolling shear" stress is assumed and this assumption is undoubtedly correct if it is assumed further that there has been no change of moisture content in the fibers immediately adjacent to the glue line. If a moisture change develops adjacent to the glue line, however, and if the glue exerts a restraining influence, it would seem that some shear stress would be present on both edges of the glue line. In the absence of a moisture change adjacent to the glue line, all stress would be normal to the glue line as indicated by the authors.

It is not apparent, however, why this stress should be zero at the center part of the glue line, as is indicated in Fig. 3. On the contrary, it would seem that in the case illustrated, the maximum tension stress should occur at the center point. This, however, would not in any way tend to invalidate the conclusions derived by the authors.

Authors' Closure

The comments made in the foregoing discussions serve the very useful purpose of emphasizing certain aspects of the investigation and of indicating again its limits.

Only two cases, capable of a reasonably close mathematical solution, were selected. These two cases, furthermore, represent two extreme conditions, one in which only shear stresses are induced at the glue line, and one in which only stresses normal to the glue line are induced. Both of these lead to high stress values. In an actual instance, the true condition would probably be intermediate between these extremes.

The discussion re-emphasizes that a 16 per cent change in moisture content is an extreme case. This case was used in computing the values given in the tables, and would represent material changing from fiber-saturation point (green wood) to air-dry. Such a condition would seldom occur.

Basic to all this discussion, of course, is the uncertainty respecting the constants employed. These are known only approximately, are subject to wide variation, and presumably vary considerably with changes in moisture content. Furthermore, as re-emphasized several times in the discussion, wood is probably subject to plastic flow and therefore the constants are subject to considerable modification.

These factors not withstanding, the principal point brought out by the analysis is that both shear and tension perpendicular to the glue line may be induced by changes in moisture content, the stresses may be high, and the maximum intensity is likely to occur at the ends of the glue lines. It follows, of course, that the same stresses exist in the wood directly adjacent to the glue, and the high-quality glues presently employed in the laminating industry have shown themselves capable of withstanding any stresses which wood itself will withstand. Fabricators of laminated timber, who understand and appreciate these various factors, select their adhesives for the conditions under which they are to be employed, and also understand the necessity of taking into account the moisture content of the wood at the time of fabrication as well as in service. The analysis presented in this paper to a large extent substantiates analytically what has been found in a general way to be true by experience, as pointed out in several of the discussions.

As to the question of the nature of the mathematical analysis employed we should like to quote the following paragraph of the paper which had been inserted after the discussors had seen the paper but before the authors had seen the discussions.

"Equations [1] and [2*a*] have been obtained by minimum energy methods. A stress distribution was assumed of known shape in the direction across the thickness of the laminations while the variation of the stresses in the direction of the glue line was determined entirely by the energy method. A further approximation was made by saying that the state of stress was plane. It is believed that the values of the maximum stresses will be changed slightly only if plane strain is assumed instead of plane stress but this should still be confirmed by calculation. With regard to Equation [2*b*] it should be said that this is a plausible generalization of Equation [2*a*] for the isotropic material. Equation [2*b*] has however not been obtained by solving directly the problem for the anisotropic material. It is hoped that the theoretical work leading to the above results may be continued so as to cover the points mentioned as well as to obtain results which go beyond those given here."

The authors are fully conscious of the fact that they have only made a beginning and that much more remains to be done before

the problem of this paper can be considered to be fully solved. They are confident, however, that within the limitations stated the mathematical results will be confirmed by future work.

Early experiments with the use of thin interlayers had led to the belief that stress relief might be obtained thereby. However, continued exposure to alternate wet and dry cycles proved this belief to be in error. It did appear that the interlayers relieved to an appreciable extent the shear stresses, but did not relieve the normal stresses induced during the drying cycle. Statements regarding the use of thin veneer interlayers were omitted at the oral presentation, but unfortunately were in the earlier copies offered to the discussors. These statements are also absent from the final paper.

Considering the question presented regarding the classification of glues into waterproof and water resistant grades, the paper attempts to indicate that glues may be completely waterproof but not able to withstand the normal or shearing stresses imposed during changing moisture content of a laminated beam. Proper selection of the glue must necessarily be dependent on the wood specie as well as the beam size, lamina size, and service conditions to be expected. It would appear that a glue for spruce need not be anywhere near as strong as a glue for oak. Conditions for use of the glue also must enter into consideration, so that the possibility of using a lower temperature of cure, or a less expensive glue with the less stress inducing joints may be worthy of consideration by the timber fabricators.

Tests of Oil-Film Journal Bearings for Railroad Cars

By S. J. NEEDS,[1] PHILADELPHIA, PA.

This paper presents results of a special series of tests made with fitted and broached railway-car journal bearings as part of the program of the Journal Bearing Development Committee of the Association of American Railroads. Three recently developed bearings, each containing less bronze than the old standard A.A.R. bearing, were tested. Comparative tests were run with bath, pad, and waste-pack lubrication. Quantitative effects of fitted and broached bearing surfaces and method of lubrication on operating temperature, frictional power loss, and the all-important minimum film thickness are given. An attempt has been made to separate the friction of the bearing from that of the pad or waste-pack lubricator. Total frictional power losses of the box are given in terms of drawbar pull.

Introduction

In December, 1941, the Association of American Railroads organized a journal-bearing development committee[2] for the purpose of studying and redesigning the railway-car journal bearing. The main object of this committee was conservation of nonferrous metals. According to recent figures (1)[3] there are about 250,000 tons of nonferrous metals in the journal bearings of railroad rolling stock in this country. Any possible reduction in weight of these bearings, consistent with safety, would mean important tonnages of copper, lead, and tin available for other war purposes. Since there are some 2,000,000 cars in service, and the rate of bearing renewal is about two bearings per car per year, any possible saving would soon become apparent.

The first steps taken by the A.A.R. Journal Bearing Development Committee were to redesign the standard journal bearing and to invite bearing manufacturers and other interested parties having ideas on how strategic metals could be saved, to submit bearings for test. These tests were conducted in the laboratory of the Railway Service and Supply Corporation in Indianapolis under the direction of a full-time resident committee. Bearings successfully passing the laboratory tests were further tested in actual service.

Two obvious methods of reducing the amount of strategic metal in a bearing are to reduce its dimensions, or to replace the metal by some material more plentiful. Since there appears to be no satisfactory substitute for babbitt, reduction in quantity is the only open course. It has been found possible, however, to lighten the bronze back considerably, also to replace a large percentage of the bearing bronze with ferrous metals.

The old standard $5^1/_2 \times 10$ bearing weighed about $25^1/_2$ lb. The bronze back weighed $20^1/_2$ lb, and the $^1/_4$ in. thickness of babbitt lining averaged about 5 lb. In redesigning this bearing the committee reduced the weight of the back by about $2^1/_2$ lb and took the same weight from the lining. Thus 12 per cent of the bronze and 50 per cent of the babbitt were saved. These changes in design not only save 5 lb of metal but have resulted in mechanical improvements by eliminating several sources of trouble in the old bearing. One feature of this improved bearing is the depressed back, patented by E. S. Pearce (2), which applies the load near the ends of the bearing instead of at random, thus permitting the bearing to bend axially and conform to the flexure of the loaded journal. The back is now machined, which increases contact area and thus improves heat transfer to the wedge. Another improvement is broaching or boring the babbitt bearing surface to a uniform diameter which provides a smooth machined surface for the journal instead of the rough cast surface permissible in the old design. The improved bearing, known as the A.A.R. Emergency, D23-5/29/42, is shown in Fig. 1.

A design submitted by the author's company removes another $3^1/_2$ lb from the bronze back of the $5^1/_2 \times 10$ bearing by using ribs instead of solid construction. In this design the load is applied to the back on four properly located bosses. Due to the greater flexibility of the back and the predetermined points of load application, the bearing can flex circumferentially as well as axially. This results in increased bearing area and greater film thickness, which reduces unit load and rate of wear. Thus the $20^1/_2$-lb back of the old A.A.R. bearing has been lightened some 6 lb, or about 30 per cent, with improved bearing characteristics and performance. This bearing is shown in Fig. 2.

A bearing which goes considerably further in conservation of bronze has been submitted by the Railway Service and Supply Corporation. This design, called the "V" bearing (3), abandons the one-piece idea and employs a relatively thin bronze shell fitted into a malleable-iron back. In the $5^1/_2 \times 10$ size this composite bearing requires only 5.7 lb of bronze, as compared with 14.4 lb in the flexible-back bearing, 17.7 lb in the A.A.R. improved bearing, and 20.5 lb in the old A.A.R. bearing. The malleable-iron back weighs somewhat less than $9^1/_2$ lb. This bearing is shown in Fig. 3.

Many other bearings were submitted to the committee for test. The three mentioned are typical examples of practical substitute bearings. They performed well in service and were selected for a special series of tests herein described, to determine their operating characteristics. A full report of the committee's work is beyond the scope of this paper.

Few Improvements in History of Railway-Car Bearings

Despite the importance of the railway-car bearing and the great number replaced annually, little effort has been made to improve its performance. The basic design of the bearing in use today dates back to the early days of the American railroads. Lack of progress has been due to several factors, perhaps most important of which is the fact that the bearing behaves very well in service without requiring too much attention. Considering the vast number of bearings in operation, actual failures are few and far between. The only machined surface required on the prewar bearing was the bore to which the babbitt lining was applied. In many cases the bearing surface and back were used as cast. For example, the lining of the $5^1/_2 \times 10$ bearing was rough-cast to $5^9/_{16}$ in. diam. Corresponding journal diameter could vary from $5^1/_2$ in. when new to 5 in. before the axle was condemned. The $5^9/_{16}$-in-diam rough-cast babbitt bearing surface was applied to the journal with permissible diametral running clearance from $^1/_{16}$ in. to $^9/_{16}$ in. After establishing load-carrying area by wear, the bearing would run for an average of 4 years under loads often exceeding 1000 psi of actual bearing area, lubricated by oily waste usually contaminated by appreciable quantities of dirt, grit, and water. The journal was finished by roller-burnishing, a process hardly conducive to a geometrically perfect surface. In the general case part of the contamination in the lubricant embedded itself in the babbitt and aided by sidesway, the bearing became an effective lap which improved the journal

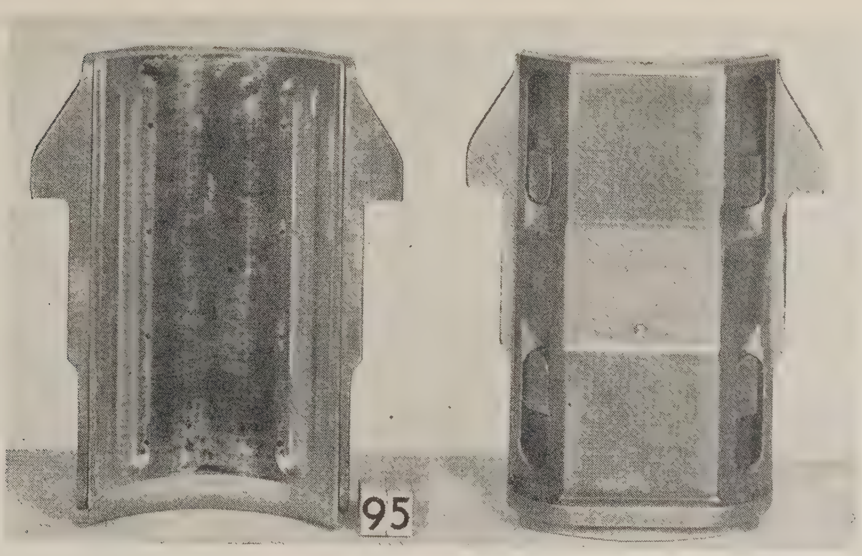

FIG. 3 RAILWAY SERVICE & SUPPLY CORPORATION "V" BEARING 95
(Fitted to test journal under load.)

surface. As bearing area increased with wear, film thickness and load capacity increased and the bearing became safer. After the initial wearing-in period the rate of wear dropped to 0.001 to 0.002 in. per 1000 miles. At the end of its average life of 4 years the bearing was removed for one of many reasons but seldom because of crown wear, since only three in every hundred bearings removed are worn out in the crown.

Considering the geometrical perfection of oil film designed into bearings for modern high-speed machinery, the behavior of the crudely constructed railway journal bearing is most impressive. Occasionally there might be an epidemic of hotboxes but year in and out the general performance has been satisfactory. Hence aside from economic considerations, there appeared to be no urgent necessity for changes.

Regardless of its record, however, the railway-car journal bearing is susceptible of improvement. One reason for improvement is the fact that in 1943 there were about 135,000 "set-outs" due to bearing trouble in freight cars, with resultant loss of time, service, and revenue. It is obvious that the frictional drag of the waste-pack consumes power which could be used in hauling useful load. It is also clear that a better fit between journal and bearing would result in less load per unit of bearing area, increased oil-film thickness, and greater load capacity.

Minimum film thickness is the criterion of bearing safety. In operation a properly fitted bath-lubricated bearing is completely separated from its journal by an oil film of appreciable thickness, except at the moments of starting and stopping. Thus wear is reduced and bearing safety increased. These considerations are not new. Fitted journal bearings are common on European railway cars and replacement of waste pack by bath lubrication has been made successfully abroad (4). The problem has also received some attention here.

To evaluate the possibilities in this direction the committee undertook comparative tests of fitted and broached bearings lubricated by bath, pad, and waste pack. The object of this paper is to describe these particular tests and to draw some general conclusions therefrom.

THE TESTING MACHINE

The machine used for the journal-bearing tests is shown in Fig. 4 and is fully described elsewhere (5). Essential elements of this machine consists of a horizontal axle supported by two roller bearings with a $5^1/_2 \times 10$-in. test journal overhung as in the conventional railway car. The axle is connected through a flexible coupling to a 25-hp d-c motor which draws its power from the city lines through a motor generator set. The machine is able to start under full test load and maintain constant rpm

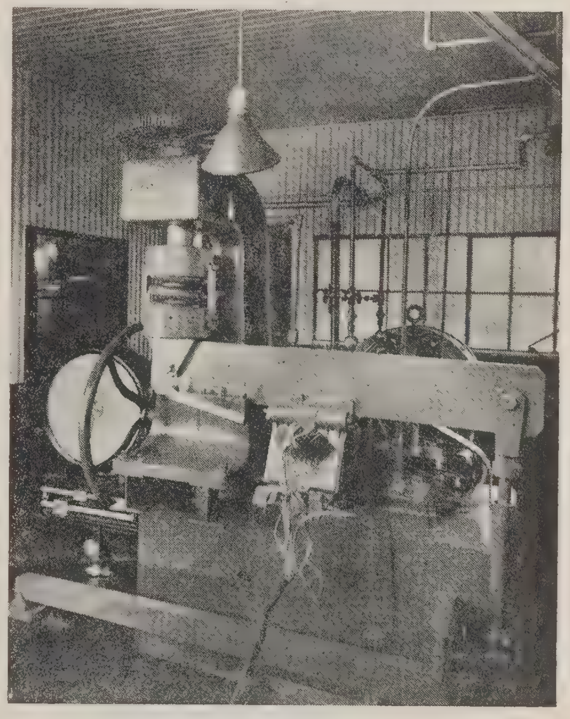

FIG. 4 JOURNAL-BEARING TESTING MACHINE

corresponding to any speed from zero to above 100 mph. An automatic recorder makes a continuous record of speed. A recording wattmeter gives continuous indication of power applied to the motor and more precise readings may be made by ammeter and voltmeter.

The bearing under test is mounted in a conventional box loaded by a beam across the top much as in regular service. Load is applied to the beam by direct-reading scales through an amplifying lever arrangement. During all tests herein described the load was held constant at 16,375 lb. A dust guard was applied to the inside end of the box to control oil leakage. All parts of the box assembly conform to A.A.R. standards.

Temperatures of journal, bearing, wedge, and box were measured by thermocouples located in a plane near the longitudinal center line of the assembly. Journal temperature was measured in a central hole in the journal drilled from the outer end. Bearing temperature was measured in a similar hole drilled in the center of the bronze back parallel with the bearing surface. Wedge temperatures were measured on each side, and box temperatures were measured at several points around the inner side.

Diameter of the test journal was 5.4385 in. A departure from usual railroad practice was made by grinding the journal to size instead of finishing by roller-burnishing. The journal was not reground for these particular tests. An entirely satisfactory surface was obtained with no measurable decrease in diameter by light honing with a fine hard stone.

Bearings, Lubrication, and Oil

Bearings included in this study are shown in Figs. 1, 2, 3, and 5. Bearing 93 is the A.A.R. emergency design D23-5/29/42, manufactured by the National Bearing Metals Corporation. Bearing 94 is the flexible-back design manufactured by the Pennsylvania Railroad from a drawing furnished by the author's company. Bearing 95 is the "V" design of the Railway Service and Supply Corporation, and Bearing 92 is the A.A.R. emergency design manufactured by Magnus Metals Corporation and known as the "Magnus Special."

Analyses of the backs show the metals are closely alike. Average contents are 73.6 copper, 19.8 lead, 5.9 tin, and 0.5 zinc. To eliminate any possible difference in results due to the linings, bearings 93, 94, and 95 were babbitted at the St. Louis plant of the National Bearing Metals Corporation at the same time with metal from the same pot. This babbitt contained 87.1 lead, 8.1 antimony, 4.7 tin, 0.1 arsenic, and a trace of copper. Bearing 92 was lined, by Magnus Metals Corporation, with a metal composed almost entirely of lead. Its contents were 97.6 lead, 1.7 tin, 0.4 calcium, and 0.2 magnesium. The alkali earth was added to harden the lead.

The four bearings were bored or broached to the journal diameter and fitted by hand-scraping under full test load, thus eliminating effects of journal and bearing flexure due to load. Bearings 92, 93, and 94 were each $5^3/_8$ in. long in the direction of motion. This is equivalent to an angular length of 113.2 deg. Actual bearing area was 45.7 sq in. and since the total load in all tests was 16,375 lb, the three bearings carried a unit load of 358 psi of actual bearing area. Bearing 95 was compound-broached, and its fitted length was $2^5/_8$ in. between the two longitudinal grooves. This is equivalent to an angular length of 55.4 deg. Actual bearing area was 22.3 sq in., and the unit load was 735 psi. All bearing surfaces were $8^1/_2$ in. wide at right angles to the direction of motion.

When fitting the bearing surfaces it was noted that the alkali-earth-hardened metal was appreciably harder than the babbitt. This is also shown in the illustrations of the fitted bearing surfaces. Fig. 5 shows the hardened lead lining spotted much as if the metal were tin-base babbitt. Figs. 1, 2, and 3, however, show the spotted areas extending over practically the entire surfaces. This intimate contact was brought about by wear and plastic flow of the high spots under load. The scraper removed most of the metal, and short circumferential back and forth movements of the dry journal under load produced sufficient wear and flow to fit the bearing to the journal. Scratches in the journal, however slight, were imprinted on the bearing surfaces. In fact this metal was so soft that gentle rubbing with clean cheesecloth would produce scratches. Its Brinell hardness was 17.8, as compared with 23.8 for the alkali-earth-hardened lead. Brinell hardness of tin-base babbitt (85–10–5), is about 23.9.

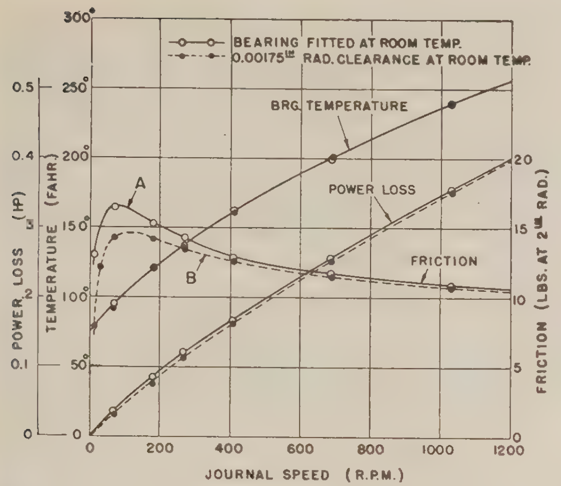

FIG. 6 EFFECT OF BEARING CLEARANCE ON FRICTION AND POWER LOSS

(120-deg centrally loaded bearing; 4 in. diam × 4 in. wide. Load 16,760 lb = 1200 psi of projected bearing area. Atreco XB oil, viscosity 14.4(10)$^{-6}$ lb sec per sq in. at 100 F.)

When bronze bearings are fitted to a steel shaft at a given temperature they remain fitted only at that temperature. Bearings 92, 93, 94, and 95 were fitted at about 75 F. Since operating temperatures were well above room, the bearings automatically provided their own running clearance by differential expansion of bronze bearing and steel journal. The importance of this clearance is shown in Fig. 6 which refers to a bath-lubricated 120-deg bronze bearing 4 in. diam × 4 in. long, carrying a load of 1200 psi of projected bearing area. Curve *A* shows variation of friction with speed when the bearing is running with a shaft fitted at room temperature. Curve *B* shows friction variation when running with a shaft 0.0035 in. smaller in diameter than the shaft to which the bearing was fitted. At higher speeds the temperature rise provides running clearance for the fitted bearing, and the increased clearance with the smaller shaft is not particularly effective in reducing friction. At lower speeds, however, the temperature is not high enough to cause much difference in expansion of bearing and journal and these surfaces remain at substantially equal radii. Under such conditions the friction of the fitted bearing is appreciably greater than that of the clearance bearing. At 10 rpm, friction with the fitted bearing is about 70 per cent greater than with the clearance bearing.

In addition to fitting the bearing surfaces, attention was given to the backs and wedge to avoid possible torsion of the bearings when loaded. Some time was also spent fitting the insert of bearing 95 to its malleable-iron back.

In all tests with bath lubrication the oil level was set at $^3/_4$ in. above the bottom of the journal at the start of each run. Oil circulation, thermal expansion, and leakage altered this level during the test but the quantity of oil in the box was kept substantially constant by replacing the small amount lost with fresh oil.

The journal lubrication pad used in the tests was developed by the Railway Service and Supply Corporation. It is described elsewhere (6) and has been successfully used in railroad service. Oil level with the pad was set at $^5/_8$ in. below the bottom of the journal at the start of each test.

The waste pack used for lubrication in these tests weighed 8 lb. It consisted of $3^1/_4$ lb of oil for each pound of new oven-dried cotton waste.

Oil used in the tests was neutral reclaimed car oil. Viscosity was 348 S.S.U. at 100 F, 154 sec at 130 F, and 53.8 sec at 210 F. Specific gravity was 0.9123 at 60 F and 0.8877 at 130 F. Oil from the same barrel was used throughout the study.

TEST OF BEARING WITH ALKALI-EARTH-HARDENED LEAD LINING

Bearing 92, with the alkali-earth-hardened lead lining, was first run bath-lubricated at 40 mph, which is equivalent to 374 rpm of a 36-in-diam wheel. Bearing temperature became constant at 176 F and the test was discontinued at the end of 6 hr. Upon inspection the bearing surface was found practically unchanged. Fitted spots in the central bearing area seemed to have lost some of their polish but were still quite distinct. Several tiny holes were found in the bearing surface near the lug end from which oil seeped as the bearing cooled. If all oil is removed from the bearing surface seepage will continue even at this writing, more than a year after the bearing was tested.

An 8-hr run was made at 40 mph the following day. Final bearing temperature was 196 F. There was no change in appearance of the bearing surface but a longitudinal seam had opened about $1^3/_4$ in. from the entering edge, running parallel with the bearing axis to within about 1 in. from each end. This seam corresponded to the edge of the large babbitt groove which in this design is cast in the back. No doubt the disturbed metal around the edges of this seam had interfered with action of the oil film and accounted for the higher operating temperature.

A run was made next day at 80 mph (747 rpm). The power-input curve was very uneven, and several times the normal motor input of 3.5 kw increased momentarily to more than 7 kw. After about 3 hr of such operation the bearing temperature reached 300 F and then began to decrease. At 6 hr the temperature had dropped to 275 F, and the machine was unloaded and stopped. Upon removal the bearing area was found badly

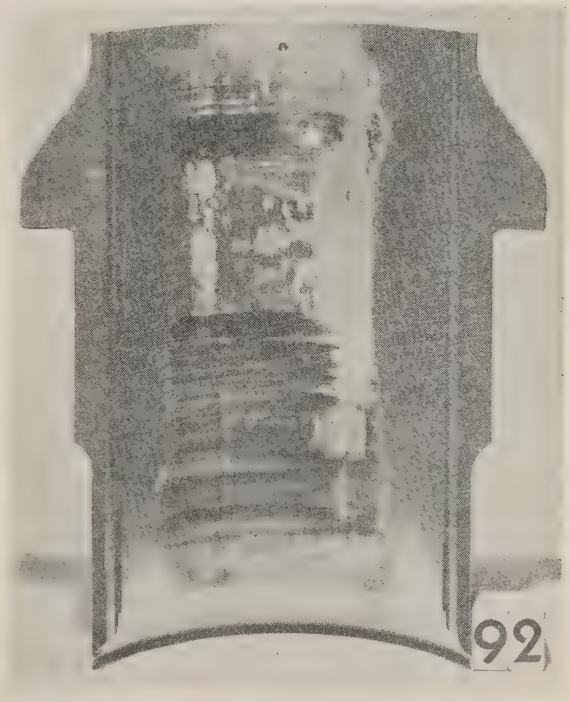

FIG. 7 CORROSION AND WIPING OF ALKALI-EARTH-HARDENED LEAD BEARING METAL

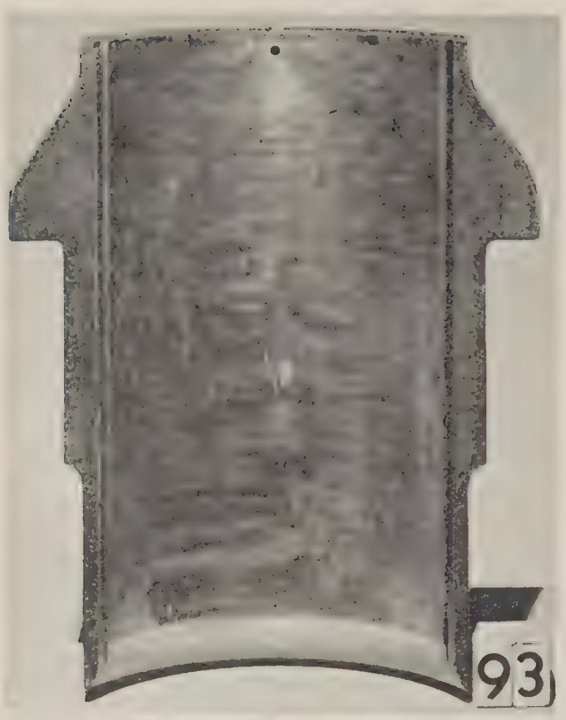

Fig. 8 Fitted A.A.R. Emergency Bearing 93 After Tests
Note that scraped pattern is still visible after bearing has "traveled" 3680 miles, indicating complete separation of bearing and journal.)

corroded and in some spots the corrosion had caused wiping, as shown in Fig. 7. Cause of corrosion remains to be determined but the only obvious difference between this run which resulted in failure due to corrosion, and the previous runs in which no corrosion occurred, was an increase in bearing temperature due to increased speed. Corrosion of high-lead alkali-earth-hardened linings had been observed in earlier tests of broached waste-packed bearings. This lining was included in the present study to discover whether or not the phenomenon would reappear when bearing and journal were more widely separated by the thicker oil film of the fitted bearing.

Tests of Babbitt-Lined Bearings

(a) *Fitted Bearings.* Procedure in all tests with babbitt-lined bearings followed the same routine. All bearings were run bath-lubricated before continuing with pad and waste pack. Fresh oil was used with each change in method of lubrication of each bearing. An 8-hr run was made with each bearing at each speed. Machine and bearing were permitted to cool overnight. Approximately one half the test period was required to warm the parts and reach stabilization temperature at which rates of heat generation and dissipation became equal. From then on there was little, if any, temperature change. No special cooling was provided for the box, hence operating temperatures were appreciably higher than would obtain in service where the box is air-cooled as the car moves along. The machine was started and stopped with the load removed to avoid possibility of surface abrasion in the absence of an oil film.

The fitted bearings are shown after the tests in Figs. 8, 9, and 10. Each bearing had "traveled" 3680 miles and except for circumferential scratches, due to insoluble particles passing

through the oil films, there is little change in appearance of the surfaces. Original scraped patterns are clearly visible indicating complete separation of bearing and journal during the tests. Scratches on the left or trailing side of bearing 95 seem somewhat more marked than in the other bearings. This would be expected since the film thickness of bearing 95 was less because of its shorter bearing arc. Results of the tests are given in Table 1.

(*b*) *Broached Bearings.* Upon completion of the fitted-bearing tests the bearings were broached to $5^{17}/_{32}$ in. diam. To identify the broached bearings the letter A was added to the bearing number. The same shaft was used as in the previous tests, hence the diametral running clearance of the broached bearings was almost exactly $^3/_{32}$ in. The oil used was from the same source as in the previous tests. The bearings were first run bath-lubricated at 40, 80, and 100 mph, followed by pad- and waste-pack-lubricated runs at 40 and 80 mph. Test results are given in Table 2.

Figs. 11, 12, and 13 show the bearings after the tests. Due to load concentration, a worn or crown area was found in the center of each bearing. The greater the difference between journal and bearing diameters, the shorter the arc of contact and the heavier the load concentration. When difference between journal and bearing diameters is appreciable, application of load causes local deformation of the bearing surfaces, possibly accompanied by plastic flow of the relatively soft bearing metal. Thus the line contact of cylindrical bearing surfaces of different radii is increased to contact over an appreciable area. If the bearing surfaces are smooth and sufficient area is in contact, rotation of the journal introduces an oil film which separates bearing and journal and permits running without wear. If sufficient area is not in contact, wear will continue until the contact area is large enough to permit formation of a load-carrying film. Figs. 11, 12, and 13 show these effects. Under load but not running, intimate contact of the bearing surfaces occurred over an area somewhat less than is shown worn in the illustrations. Running under load, a greater area than that worn was effective in carrying the load. The circumferential scratches covering the worn areas were made by insoluble particles passing through the films. In general, the outline of the worn area is more distinct on the left than on the right. Journal rotation was from right to left and the oil film was thinner on the left or trailing side.

Other things being equal, length of crown area in direction of motion depends on the stiffness of the back and the method of loading the bearing. With an absolutely rigid back, bearing area could be developed only by elasticity, wear, or flow of bearing surfaces. In these tests the bearings showed no signs of plastic flow

Fig. 11 Broached A.A.R. Emergency Bearing 93-A After Tests

when examined after the runs. The mean crown length of bearing 93-A was found to be 21 deg by planimeter measurements of tracings of worn area. Due to controlled points of loading which permit flexure in the circumferential direction, the mean crown length of bearing 94-A is $27^1/_2$ deg. Mean crown length of bearing 95-A is $17^1/_2$ deg due, no doubt, to the rigidity of its malleable-iron back. Some area on either side of the worn crown probably is effective in supporting load-carrying film. In the absence of definite information it is assumed that this area is of the order of 20 per cent of the worn crown area. Hence, for calculation, useful length of oil film has arbitrarily been taken as 25 deg for bearing 93-A, 32 deg for bearing 94-A, and 21 deg for bearing 95-A. On this basis the same total load of 16,375 lb gives unit loadings of 1625, 1270, and 1930 psi, respectively.

The foregoing runs were repeated after rebroaching the bearings $^3/_{32}$ in. larger than a new shaft diameter of 5.406 in. In addition to the usual tests, runs were made, pad- and waste-pack-lubricated, at 100 mph. The rebroached bearings are designated by the letter B. Due to rebroaching, babbitt thickness was reduced to about $^3/_{32}$ in. and a porous spot appeared in the lining of bearing 93-B. Results were somewhat erratic with this bearing and are not included with the results of the other bearing tests given in Table 3. Comparison of Tables 2 and 3 shows operating temperatures of the A and B bearings in good agreement.

Average results for the three fitted bearings and the five broached bearings are given in Table 4. Calculated bearing losses refer to the test bearing only. Calculation of these frictional power losses is necessary since this information cannot be found directly from the testing machine. For example, consider the fitted bearing running bath-lubricated at 40 mph. Under stable temperature conditions average power input to the motor is 1845 w, from Table 4. Curves are available giving power losses at various speeds and roller-bearing temperatures when the

machine is unloaded and no test bearing is in the box. According to these curves, 1238 w are required to run the machine when unloaded. With no test-bearing load the roller bearings carry only the weight of the shaft, hence the 607 w difference between power input with and without test-bearing load represents friction of the test bearing and dust guard, and added friction due to the test load on roller bearings and motor. By calculation, test-bearing friction was 0.242 hp or 181 w. This leaves 426-w loss due to dust-guard friction and load on roller bearings and motor. Since the total of these unknown losses is some $2^{1}/_{4}$ times the power loss of the test bearing, it is obvious that there is no hope of arriving at test-bearing power losses directly from motor input.

It is possible, however, to estimate power losses due to pad and waste pack by assuming that at a given load, speed, and roller-bearing temperature, the machine losses will remain constant. With this assumption any difference in power input in the tests with bath, pad, and waste-pack lubrication can be attributed to variation of friction in the box. From Table 4 the power input for the fitted bearing running bath-lubricated at 40 mph is 1845 w. Calculated power loss is 0.242 hp at the bearing temperature of 168 F. The same bearing, running pad-lubricated at the same speed, requires a power input of 1865 w. In the latter case calculated power loss for the bearing alone is 0.189 hp at the operating temperature of 197 F. Difference in box loss between pad and bath lubrication is 1865 — 1845 = 20 w or 0.027 hp. Therefore total box loss is 0.242 + 0.027 = 0.269 hp, and since the power loss of the bearing alone is 0.189 hp, the difference, or 0.080 hp, represents the power loss due to the pad. In like manner power loss in the waste-packed box at 40 mph is 0.173 hp for the bearing and 0.204 hp for the waste pack at the test temperature of 228 F.

Applying this reasoning to the pad-lubricated fitted bearing at 80 mph, it is found that the total power loss for bearing and pad is 0.049 hp less than the calculated loss for the bearing alone. Apparently, observed value of motor input is low. This is not the case, however, with the broached bearings, and since power

($5^1/_2 \times 10$ bearings; load 16,375 lb; average room temperature 93 F.)

losses of the lubricators do not depend on the bearings, the same pad loss would be expected with fitted and broached bearings. To arrive at pad and waste-pack power losses from the test results, lubricator losses in Table 4 are plotted in Fig. 14. Maximum departure of observed points from the curves represents errors in average motor input of about 2 per cent. Since box losses are a relatively small part of motor input, small errors in power measurement are greatly magnified when computing total box loss.

Discussion of Results

Variation of journal temperature rise with speed is shown in Fig. 15, where the solid lines refer to the fitted bearings and broken lines to the broached bearings. Journal temperature rise in all cases is somewhat less with broached than with fitted bearings. Since friction losses of pad and waste pack are independent of the bearing, lower operating temperatures indicate that the broached bearing operates with less friction than the fitted bearing. Calculation also shows this to be true. Against this slight advantage in friction, however, the broached bearing has the serious disadvantages of considerably less oil-film thickness and higher unit loading due to its shorter angular length. Because of its thinner film the reserve load capacity of the broached bearing is much less than that of the fitted bearing. Greater film thickness and reserve load capacity are the real advantages of the fitted bearing.

Maintenance of sufficient oil-film thickness is the deciding factor in successful bearing operation. When due to overload, overheating, or low speed, the oil film becomes thinner than the heights of the irregularities on the bearing surfaces, these high spots are no longer completely separated and metallic wear occurs. Wear may also be caused by particles in the oil too large to pass freely through the film. All wear is accompanied by temperature increase, and if heat is generated more rapidly than it can be dissipated the bearing eventually overheats and fails. If, however, an oil film thick enough to separate the bearing surfaces completely can be maintained under all conditions, metallic wear will be eliminated and the bearing cannot fail. Factors tending to thick films are high viscosity, high speed, and low unit loading.

In the absence of metallic contact, rate of heat generation depends on rate of oil-film shear. With a given load, rate of shear increases with speed, and heat thus generated reduces film viscosity. Operating temperatures will rise until the gradient between oil film and box is sufficient to dissipate the heat as rapidly as it is generated. This stable temperature may be so high that the increase in film thickness due to speed is more than offset by the decrease in thickness from reduced viscosity; and in that case, film thickness decreases with increasing speed. In these tests this decrease was more marked with the fitted than with the broached bearings, as shown by the curves of calculated oil-film thickness in Fig. 16. In service, higher speeds are accompanied by induced air currents which cool the box, thus maintaining lower operating temperatures and thicker oil films.

Effect of speed and method of lubrication on frictional power loss are shown in Fig. 17, in which average curves are plotted for fitted and broached bearings, bath, pad, and waste-pack lubricated. Power losses in the box are made up of bearing and lubricator frictions. Dust-guard friction and losses due to oil churning are comparatively small and are neglected. In each graph the lower curve represents bearing friction calculated for the conditions of the test. With bath lubrication the only source of power loss in the box is the bearing itself, hence there is but one curve in the graphs for bath lubrication. With pad and waste-pack lubrication, however, friction losses due to the lubricators are added to the bearing friction. These additional losses are represented by the shaded areas in Fig. 17, superimposed on the curves for bearing friction. The upper curves then represent bearing and lubricator friction or the total friction of the box. With each of the three types of lubrication, mean power loss in the box averages 16 per cent greater with the fitted than with the broached bearing. This agrees with the lower-operating-temperature curves for the broached bearings shown in Fig. 15.

From comparison of the shaded areas in Fig. 17, and from the curves in Fig. 14, it is interesting to note that the friction of the waste pack is 2.7 times the friction of the pad. Comparison of shaded and unshaded areas shows the waste-pack friction to be 115 per cent of the bearing friction. Similarly, friction loss due to the pad is 37 per cent of the bearing friction. From this it appears that for all practical purposes the friction of the waste pack is about the same as the friction of the bearing, and the friction of the pad is approximately $^1/_3$ that of the waste pack.

In addition to the friction of pad and waste pack, the heat-insulating properties of these lubricators add considerably to the higher operating temperatures. This is clearly shown in Fig. 18, which gives average results for the three fitted bearings at 80 mph. In each test curves were plotted from temperature readings around the longitudinal center line of the box after equi-

librium temperature had been reached. Mean temperature, found from each curve by planimeter, is listed in the tables as box temperature. Temperatures at the top of the box are little influenced by method of lubrication. Temperatures at sides and bottom, however, are greatly affected by the heat-transmission characteristics of the lubricator. When the bearing is bath-lubricated, agitation by the rotating journal facilitates transfer of heat from journal to box where it is dissipated to the atmosphere. In this case the oil is acting as a coolant as well as a lubricant.

With pad lubrication there is some oil cooling of the journal but the bath is considerably less agitated due to the presence of the pad, and heat transfer between journal and box is less efficient than with the bath. Rubbing of the pad on the journal adds to the heat generated by the bearing and this, together with poorer heat-transfer characteristics from journal to box, accounts for the higher operating temperature. Because of the higher operating temperature, however, oil viscosity has dropped to the point where the sum of bearing and pad frictions is about the same as the friction of the bath-lubricated bearing. Since total friction is the same, the higher operating temperature of the pad-lubricated bearing must be due entirely to the heat-insulating characteristics of the pad.

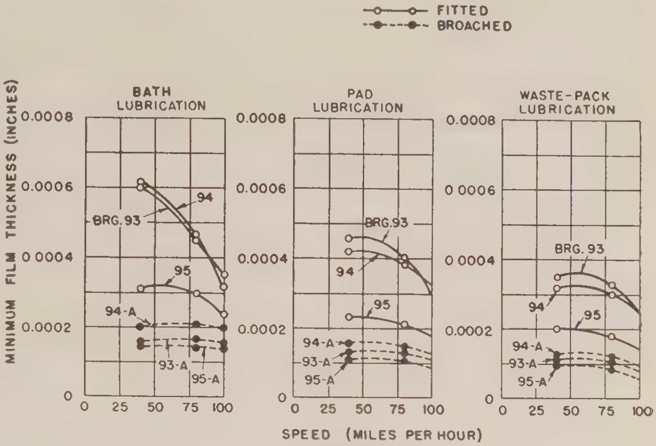

Fig. 16 Variation of Calculated Minimum Oil-Film Thickness With Speed
($5^1/_2 \times 10$ bearings; load 16,375 lb.)

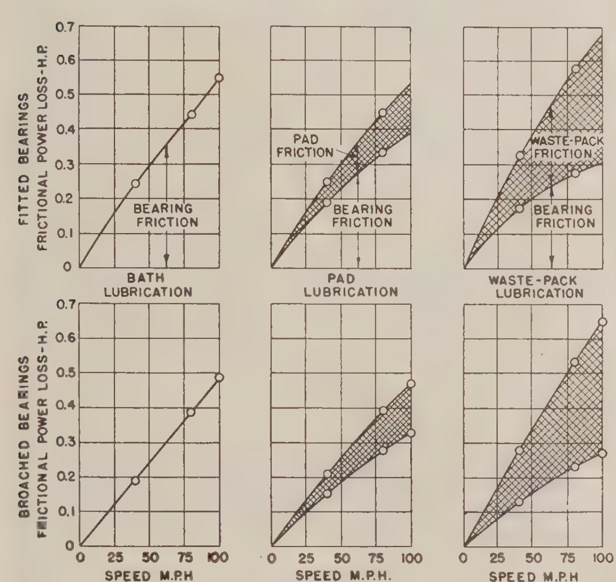

Fig. 17 Variation of Frictional Power Loss With Speed
($5^1/_2 \times 10$ bearings; load 16,375 lb.)

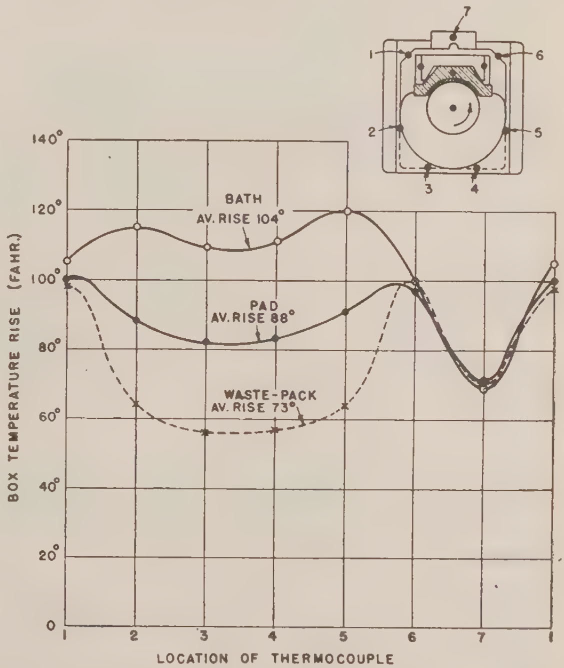

Fig. 18 Temperature Variation Around Longitudinal Center of Box With Bath, Pad, and Waste-Pack Lubrication
($5^1/_2 \times 10$ fitted bearings at 80 mph; load 16,375 lb; average room temperature 91 F.)

The situation becomes more pronounced with the waste pack. In this case there is little, if any, cooling effect of the oil. Friction between waste and journal is relatively high, and the pack acts as an effective heat insulator between journal and box, as shown by the lower box temperature rise. As temperature increases, rate of oil viscosity drop with temperature decreases and decrease in bearing friction becomes less rapid. The sum of waste-pack and bearing frictions becomes greater than with bath or pad lubrication, and temperature gradient between journal and box increases in order to dissipate the additional heat. Higher operating temperatures are undesirable, even when accompanied by reduced bearing friction, since film thickness and bearing safety are less at higher temperatures.

Variation of box temperature rise with journal temperature rise is shown in Fig. 19, for the three methods of lubrication. With perfect heat transmission between journal and box the temperatures would be the same at these points. This condition is represented by the dot and dash line A, the slope of which is unity. Slopes of the other curves show clearly the relative heat-insulating effects of the three methods of lubrication. From Fig.

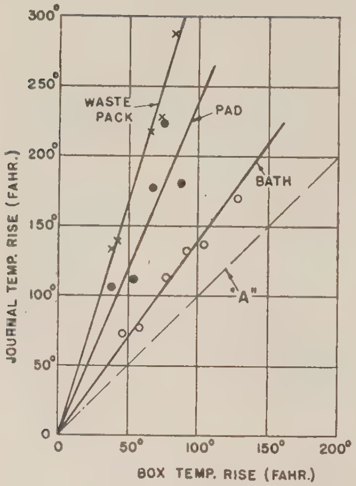

Fig. 19 Temperature Gradients Between Journal and Box
($5^1/_2 \times 10$ bearings; load 16,375 lb; average room temperature 93 F.)

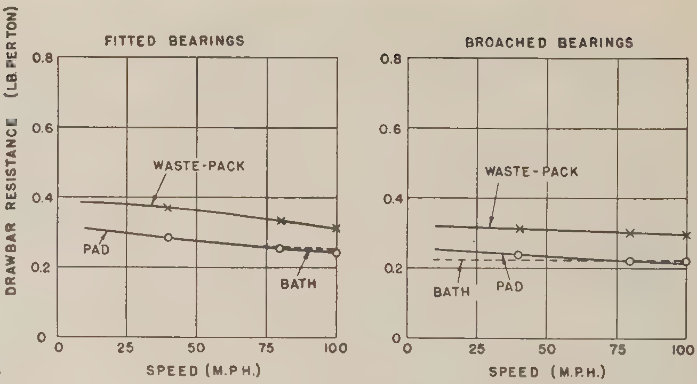

Fig. 20 Variation of Drawbar Resistance With Speed
($5^1/_2 \times 10$ bearings; load 16,375 lb.)

19 average temperature rise of the box is 72 per cent of the temperature rise of the journal with bath lubrication, 42 per cent with pad, and 30 per cent with waste pack. The importance of this relationship in maintaining cool bearings is obvious.

Friction losses given in Fig. 17 are readily converted into drawbar resistance. Variation of drawbar resistance with speed is given in Fig. 20 for the fitted and broached bearings, bath, pad, and waste-pack lubricated. Resistance is expressed in pounds per ton carried by the bearing and, as usual, speed is given in miles per hour. A 36-in-diam wheel is assumed. Since frictional power losses with bath and pad lubrication are closely alike, drawbar resistance is also nearly the same. Due to higher power losses with the waste-packed bearings, average drawbar resistance is about $^1/_3$ greater than with the other two methods of lubrication.

Conclusions

Fitted and broached bearings have been tested at 40, 80, and 100 mph. Data at 20 and 60 mph would have been useful in plotting the curves and for confirming results at the other speeds. On the basis of our present information, however, the following conclusions appear warranted:

1 Pad and waste pack are capable of supplying sufficient oil to maintain complete fluid-film lubrication at speeds at least as high as 100 mph.

2 The railway-car bearing is capable of carrying its maximum load without failure at temperatures at least as high as 375 F.

3 Operating temperatures and frictional power losses are somewhat less with the broached than with the fitted bearing. These advantages are offset by the fact that under similar operating conditions the oil-film thickness of the broached bearing averages only $^1/_3$ that of the fitted bearing. Hence the broached bearing has less reserve load capacity and safety.

4 In a waste-pack-lubricated box, friction of the waste pack is approximately the same as the friction of the bearing.

5 Friction of the pad used in these tests is about $^1/_3$ that of the waste pack.

6 Total friction with bath and pad lubrication are nearly the same, due to the higher operating temperature caused by the pad.

7 Total friction with waste-pack lubrication is higher than with bath or pad despite the higher operating temperatures due to the friction and blanketing effect of the waste pack.

8 Because of its lower operating temperature the bath-lubricated bearing has greater oil-film thickness, hence greater reserve load capacity and safety. This is particularly important at high speeds.

9 Frictional power loss and drawbar resistance of the waste-pack-lubricated bearing are approximately $^1/_3$ greater than with bath or pad lubrication.

10 Method of lubrication has a profound effect on the heat-dissipation characteristics of the box and the temperature gradient between journal and box.

From the foregoing discussion and conclusions it is clear that the crown, or useful load-carrying area of the bearing, should be as large as possible since it results in reduced unit load, increased film thickness, and less wear. It would be interesting to check these conclusions in actual service on a car or tender making considerable mileage per month. The same type bearing could be applied to all journals. One half should be fitted and the other half broached. Wheels, axles, and trucks should be in good condition so that the test would not be terminated by bearing end wear or broken collars. Periodic inspections and careful measurements of wear should give some interesting and impressive information on bearing reliability and life.

Acknowledgment

The author greatly appreciates the assistance of the Resident Committee and the splendid co-operation of Mr. Pearce and his staff. Acknowledgment is especially due L. G. Taylor and J. Roller for the careful manner in which they conducted the series of test runs reported in this paper.

Discussion

P. G. Exline.[4] The writer is particularly interested in this paper because of some work of a similar nature carried out at the laboratories of the Gulf Research & Development Company during 1942. A standard A.A.R., 5 × 9 journal and bearing was used for a series of tests to compare the performance of a bearing having a normal diametral clearance of $^1/_{16}$ in. with that of a bearing having 0.005 in. clearance. The load, 30,000 lb, was above normal, while the speed range was equivalent to $2^1/_2$ to 30 mph on a 36-in. wheel.

Measurements were not made of the coefficient of friction, but the bearing temperatures indicated a qualitative agreement with the data reported by the author.

It was noted that after a period of operation at 30 mph, the standard-clearance bearing would often show signs of distress when the speed was reduced to $2^1/_2$ to 5 mph. This did not occur with the 0.005-in-clearance bearings, indicating a higher factor of safety. The standard-clearance bearing also took a longer time to accommodate itself to a reversal of the direction of rotation even though it had been well run-in in the forward direction. In this respect, the low-clearance bearing behaved as one which had been well run-in for both directions of rotation.

The test journal was mounted substantially the same as the Pearce machine, in that it was supported by a spherical roller bearing at the wheel seat. This bearing was cooled by adjusting the temperature of the stream of oil pumped through it. It was found that changes in the temperature of this bearing could influence the temperature of the test bearing. It seems evident that the wheels of a railroad car can act as cooling fins and dissipate an important fraction of the heat developed in the oil film.

The author's results and those of the writer suggest that a properly designed railroad bearing with bath or oil-ring lubrication and having adequate protection against oil loss and tampering would provide trouble-free performance with less maintenance than the present bearings.

M. D. Hersey.[5] This report not only tells how the problem of conservation of bronze and babbitt was solved, but offers in connection therewith a large amount of carefully checked information on the design and performance of railroad-car bearings. Of special interest is the use made of the theory of lubrication to calculate the "all-important" minimum oil-film thickness, and also the friction loss, with the aid of actual temperature measurements.

Might it not add to the permanent value of this record if the author would refer to the formulas or curves used for these calculations? The necessary procedure is not entirely obvious to the writer, and doubtless many other students of lubrication would appreciate an outline of the steps in a completely worked example.

J. R. Jackson.[6] It was the writer's privilege to be associated with the author during the test program treated in this paper. The data made available through this research constitute a distinct contribution to the knowledge of railroad-car journal-bearing design and lubrication. Furthermore they indicate the direction for the betterment of the journal-box assembly of the future by utilizing more completely the advantages which an oil-lubricated solid-type bearing has over the present conventional waste-pack journal box.

It is perhaps difficult to understand why the present conventional design of railway-car journal-box assembly has been retained down through the years, and why advantage has not been taken of advances in the art of bearing lubrication to replace the waste-pack originally used and continued without essential change on the American railroads for a hundred years. The answer is simplicity and reliability together with long-established standards and practices of operating cars in interchange service, and the relatively large number of units in use.

It probably should be stated that the simple expedient of removing the waste pack and filling the bottom of the journal box with oil, as was done during the laboratory tests, would not work out in service because the oil could not be retained in the box. Bath or flood lubrication would necessitate a redesign of the conventional box to insure oil retention. This question of oil retention in the conventional journal box is also pertinent, in lesser degree, to some forms of pads or wick-type lubricators which have had limited service trials on railway equipment in this country. Completely redesigned journal-box assemblies, employing flood lubrication and other refinements, including provision for oil retention, have been developed and used in considerable numbers on some roads on equipment operated in on-line service. These have not found sufficient favor to be considered for adoption as standard in interchange freight service.

The increasing use of roller bearings for passenger equipment and their development for freight equipment will no doubt result in a reconsideration of the design, service, and economics of railway-car journal bearings in the immediate future. It is felt that this paper is a distinct contribution to the literature on this subject, and that a similar line of investigation of the roller bearing for railway equipment should be carried out.

L. B. Jones.[7] In studying this report it should be borne in mind that the comparison between broached and fitted bearings was made with broached bearings which were just "starting out," so to speak. In other words, in actual service the broached bearing will continue to enlarge its contact area until it approaches the condition of the fitted bearing, with resultant improvement in oil-film condition.

While the tests were run mainly to determine oil-film conditions, it will be of interest to railroad men to note that the A.A.R. standard journal lining gave a good account of itself, and nothing developed in the test to indicate the necessity for a change in its composition.

The two principal indictments of the time-honored waste pack, pointed out by Mr. Pearce in his comments on this paper, are again high-lighted in this report. The actual friction of the waste pack is equal to, or greater than, the bearing friction; and it also acts as a thermal insulator to discourage radiation of heat from the journal.

The drawbar resistance in pounds per ton due to the friction load on the journal, as indicated in Fig. 20 of the paper, shows that the journal friction is a relatively small part of the total resistance of loaded freight cars on level track, as determined by dynamometer tests. It therefore appears that improvements in journal-box performance will pay their largest dividends in hot-box insurance rather than in decreasing the rolling resistance of the train.

F. K. Mitchell.[8] The author prefaces his remarks on the his-

tory of the improvements on railway-car bearings by the statement, "Despite the importance of the railway-car bearing and the great number replaced annually, little effort has been made to improve its performance." If he intended to say by that remark that the bearing itself had undergone very little improvement prior to the war period, his statement is unquestionably true, but the insinuation that little effort has been made to improve the performance of the bearing cannot be substantiated. Over the years, journal boxes, dust guards, wedges, and other related parts used in the assembly, of which the journal bearing is a part, have been subjected to a great deal of experimentation, and many important facts have been learned thereby, and certain very productive changes worked out and put into practice.

It is essentially true that the most extensive changes in the bearing itself have come about since the beginning of the war, and are children of necessity. These changes involved not only the bearing but also the lining and were promulgated through the necessity of minimizing the amount of critical materials required to produce a bearing of a certain size. As to the lining, the efforts in this respect have been confined generally to reducing its thickness and to producing a lining made of substitute material, both in order to save babbitt. It is generally conceded that the reduction in the thickness of the lining accomplished the required end. Substitute lining described by the author as a metal composed almost entirely of lead, alkali-earth-hardened, has not been entirely satisfactory, which fact cannot be discounted. On the other hand, the results so far obtained in the use of such a lining certainly do not warrant the complete discarding of the idea of its use. On the contrary, it is evident from the experience to date that further experimentation and development of such a lining offer worth-while possibilities.

The second series of major changes in the bearing itself, made to reduce the amount of critical material in the bearing back, has been enlightening, and also seems to be producing the desired results. There are still some features in connection with the various redesigned backs which have been offered for this purpose that need further study. These studies will no doubt be undertaken by the committee, of which the author is a member, in due time. Further comment in this regard will be made later.

It is unfortunate that the laboratory test equipment which was used to make the study under discussion does not duplicate in a practical manner the actual service conditions to which bearings are, in fact, subjected. It will be noted that the bearings were subjected to a constant uniform load of 16,375 lb. In actual service the load, of course, varies. Furthermore, in actual service the bearing is subjected to severe vertical and longitudinal shocks which the test equipment as used was unable to duplicate. This, it is felt, in itself materially affects the practicability of the information developed. It is pointed out by the author, under "Discussion of Results," "maintenance of sufficient oil-film thickness is the deciding factor in successful bearing operation." Therefore it would appear quite evident that the maintaining of such an oil film under the conditions imposed by the test apparatus is an entirely different problem from that which is found in actual service where, even under normal conditions, the bearing is constantly being disturbed by vertical shocks originating from uneven rail joints, etc., and longitudinal shocks arising from brake applications, slack action, etc.

While discussing the matter from the point of view of oil film, it should also be understood that with the laboratory test equipment used in these experiments, the journal being the driving instead of the driven element, the greater bearing clearance occurs on the rising side of the journal, whereas in actual practice the journal is driven by the bearing and the greater clearance is on the opposite side of the bearing. Hence under laboratory conditions the oil film produced by any method of lubrication, and under any bearing conditions, would be more favorable than under circumstances of actual usage where the clearance is the minimum on the rising side of the journal.

These facts in themselves make questionable the acceptability of some of the results obtained in this series of tests. They certainly do so to the point of discrediting the definite conclusion that "pad and waste pack are capable of supplying sufficient oil to maintain complete fluid-film lubrication at speeds at least as high as 100 mph, and that "the railway-car bearing is capable of carrying its maximum load without failure at temperatures at least as high as 375 F." Here it might also be noted that because many failures of bearings result from causes other than heat generated, the design of the back is an important factor, and unless it is shown that the back, however physically composed, is not only so designed as to distribute uniformly the load over the bearing area, but also is of such strength as to prevent breakage, then it cannot be concluded that the railway-car bearings tested were capable of carrying their maximum load without failure; this regardless of temperature. It is quite obvious that no failures from causes other than heating would be expected when the tests were conducted with the laboratory equipment which was used in these experiments, and the answer to this question was not obtained for any of the bearings under test.

It might also be said in passing that in the observation regarding heat transfer from the bearing to the related parts of the bearing-and-box assembly two confusing statements are incorporated in the report. The first is that the depressed-back (E. S. Pearce patent) bearing applies the load near the ends of the bearing instead of at random. Actually, this bearing applies the load over all but the one third of the area in the center. The application of the load near the extreme ends of the bearing has long since been proved to be mechanically incorrect. It is further stated that the back of the so-called "depressed-back bearing" is now machined. It will be found on check of the records that only a few railroads actually machine the back of the so-called "depressed-back bearing" for bearings used in passenger service, and that generally no roads are machining the depressed-back bearing used in freight service.

As to the transfer of heat, because of the greater contact area and therefore the improved heat transfer to the wedge, it will be interesting to note that bearings 93 and 95 have the large back area referred to, whereas bearing 94 has only four small bearing areas, nowhere comparable to that offered by bearings 93 and 95, yet the tests show that bearing 94 produced journal-temperature, bearing-temperature, and box-temperature rises at various speeds which generally lay between that of bearings 93 and 95. No explanation for this fact either in the case of the fitted bearing or the broached bearing is offered.

Regarding the question of whether or not the broached and unfitted bearing is more satisfactory than the broached and fitted bearing: The author concludes, and the data developed indicate, that better results can be expected from a fitted bearing. While this is interesting, and no doubt true, it has no practical value for the reason that the expense and delay involved in fitting the bearing, particularly to freight cars, would in no wise be offset by the results obtained.

The data developed and conclusions reached in connection with the relative values of bath, pad, and waste lubricating systems would indicate that the committee has concluded from the results obtained that waste-packed lubrication is less satisfactory than pad lubrication and bath lubrication. This is no doubt true if it were not for the practical side of the problem. Certainly bath lubrication is a far cry from being practical at present. Pad lubrication is more or less in its infancy and offers considerable possibilities, yet, at the moment, the writer knows of no practical means of avoiding excessive loss of lubricant in the present freight-

car box assembly where either bath or pad lubrication is used. Here again a factor arises which the test equipment used by the committee does not bring out. The entire matter does emphasize the necessity for further experimentation and development along the desirable lines indicated by the tests.

As to the effect on drawbar resistance, neither the data having to do with the friction of the broached or unbroached bearing nor pad nor waste-packed boxes are of much practical value.

It is worthy of note that speeds for use in connection with these experiments (40, 80, and 100 mph) were selected. While 40 mph represents pretty closely the present freight-train movement, the immediate future no doubt will mean speeds for freight-train movement between the figures of 40 and 80, throughout which range the report is silent as to what might be expected. The author comments on this fact in his conclusions. It is regrettable that data were not also secured for speeds of 50, 60, and 70 mph.

While as previously indicated, the data submitted in this report are interesting, although in a great many respects somewhat impractical, it is respectfully suggested that either test equipment which will more closely simulate actual operational conditions should be designed and used for such a series of experiments, or final conclusions should be based on actual experience in the field.

E. S. Pearce.[9] On certain phases of railroad journal operation this paper sets out most clearly two points of general and practical interest:

1 The very low power loss chargeable to the conventional journal-box assembly.

Power loss in journal friction as a factor in total train resistance is a particularly timely subject, as the railroads are contemplating operation at higher maximum and higher average speeds. The values given by the author cast considerable doubt on the advisability of substitution of roller bearings for solid bearings as a matter of sound economics.

2 The separation of the power loss between bearing and lubricating medium.

To those confronted with the everyday problems of journal operation, the significance of packing friction losses relative to those of the bearing alone will be of considerable practical interest.

Analyzing the author's paper in the light of the two major disclosures, obviously, much of constructive value to the railroads in the operation of a conventional journal-box assembly would result from a further exploration of this subject through a lower range of speeds and temperatures in combination with various methods of lubrication, lubricants, and bearing construction now available.

The accepted formula for calculating freight-car resistance on straight level track is[10]

$$R = 1.3 + \frac{29}{w} + 0.045V + \frac{0.0005AV^2}{wn} \quad \ldots\ldots\ldots [1]$$

Fig. 21 of this discussion has been superimposed upon the author's Fig. 20 demonstrating what a small portion of total resistance can be charged to journal friction at the load and speeds used in the paper.

The values given by the author for power losses are roughly one tenth of that given by the first two terms of Equation [1] of this discussion.

Journal operating temperatures in this paper are at a level much higher than the generally accepted limit for safe performance in service. This is due in large part to operation in the still

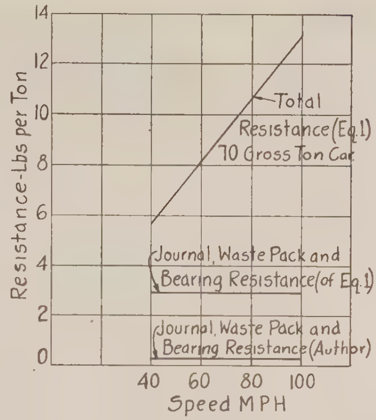

Fig. 21 Relation of Journal Resistance to Total Resistance of a Freight Car

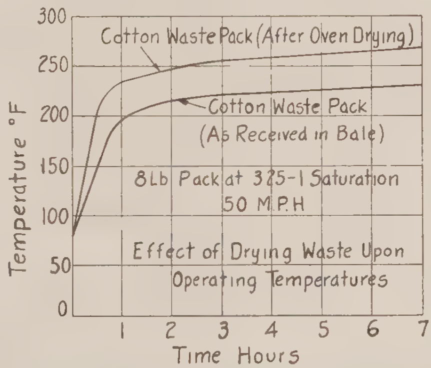

Fig. 22 Effect of Drying Waste Upon Operating Temperatures

air of the laboratory. Pearce[11] shows the magnitude of this difference at lower speeds than covered in this paper.

Another contributing factor to the high temperature obtained with the waste pack was the use of "oven-dried" waste as so designated by the author. In investigations of this kind, in the interest of accurate duplication of results, oven-drying of waste is done to offset the variation in moisture content and the effect on temperature which would otherwise exist between various samples of waste. In preparing the waste for test purposes it is dried at a temperature of 220 F. The effect of this drying upon operating temperatures is shown in Fig. 22 of this discussion.

The contribution of the lubricating medium to the total power loss of the bearing assembly has never been fully appreciated. The placing of a waste pack in a journal box is very similar to the installation of an opposed bearing, as there is an upward pressure of the waste pack against the lower half of the journal. Fig. 23 shows how this contributes to the elevation of the running temperature as the amount of packing at the same oil-waste ratio, is varied in the same journal box.

To verify the power losses of the lubricating medium, as shown in Fig. 14 of the paper, a study was made of the reduction in power input to the driving motor by the momentary lowering of the lubricating medium from contact with the lower half of the

journal. This was accomplished by the use of the bearing described by Pearce[12] as bearing No. 18, this bearing being capable of operation for sustained periods on the stored oil. This time interval was quite adequate to take the necessary instrument readings. The box used was split on its horizontal center line and mounted on a jack so that it could be quickly lowered and again raised. Results are shown in Fig. 24 of this discussion, and comparison with the author's Fig. 14 indicates that the calculated loss of the lubricating medium is in good general agreement with the experimental findings.

R. J. Shoemaker.[13] In connection with the results obtained with pad lubrication reported in this paper, we may state that one of the major trunk-line railroads of this country has been using pad lubrication (Magnus type) very successfully for a number of years past in connection with oil lubrication of driving-box brasses of main passenger and freight power, also on main-line passenger cars, locomotive tender, and locomotive truck and trailer brasses.

By the use of pad lubrication, considerable economy of operation has been accomplished as shown by reduction in the number of hotboxes, increased service life of bearings, and corelated parts, reduction in friction, etc., as compared with results obtained with conventional lubrication formerly used.

With regard to the economy of materials accomplished in the tests of new types of bearings reported in the paper, the author states, "Since there appears to be no satisfactory substitute for babbitt, reduction in quantity is the only open course." The author further states that in redesigning the prewar type of journal bearing, the babbitt metal was reduced 50 per cent in weight, or in other words, reducing the lining metal from $^1/_4$ to $^1/_8$-in. thickness, as was done in the A.A.R. emergency-type bearing used in the early years of the war. However, in view of the unsatisfactory performance in service of this $^1/_8$-in. lining, the babbitt metal was later restored to its original $^1/_4$-in. thickness, as now used by the railroads in the present type of A.A.R. emergency journal bearing.

With regard to a satisfactory substitute for babbitt metal, we may mention that our company developed and put on the market a number of years ago an alkali-earth-hardened lining metal for bearings known as "Satco" metal, which is having widespread and successful use as a substitute for lead- and tin-base babbitts, block tin, etc., in various types of railway and other bearings.

This metal is a lead-base alloy containing from 95 to 98 per cent lead with the balance calcium, tin, and other hardeners. It contains no antimony or copper. During the late war great economies were effected by the use of Satco bearing metal in vital materials such as tin, copper, antimony, etc.

Satco metal has a melting point approximately 150 F higher than that of babbitt metals with a correspondingly greater hardness at elevated temperatures. Tables 5 and 6 of this discussion show comparative physical properties of Satco metal, A.A.R. babbitt, tin-base babbitt and antimonial lead at normal and elevated temperatures.

Table 5 Degrees Brinell Hardness of Various Bearing Metals

(500 kg load)

Deg F	Satco	Tin-base babbitt	A.A.R. babbitt	Antimonial lead
70	23.8	22.2	17.8	15.0
212	17.2	12.9	9.5	6.2
300	12.0	7.6	4.2	*
400	7.7	*	*	*

* Indicates metal too soft to measure hardness using 500-kg load.

Table 6 Compressive Strength of Various Bearing Metals

(Pounds per square inch; 25 per cent deformation)

Deg F	Satco	Tin-base babbitt	A.A.R. babbitt	Antimonial lead
70	16300	17200	15600	13000
212	10200	7500	6100	5000
300	7000	4000	2700	1100
400	3700	2000	1200	*

* Metal too soft to determine compressive strength due to excessive deformation.

Because of its greater heat resistance Satco-lined bearings perform satisfactorily at temperatures which cause failure by melting in babbitt-lined bearings, consequently the alloy is more resistant to "waste grabs" which are a frequent cause of failure in railway bearings.

In addition to the various types of railway-car and locomotive bearings, Satco metal is also used as a lining in main and connecting-rod bearings and motor-support bearings of Diesel engines. The successful performance of the alloy in this service has been reported by L. M. Tichvinsky.[14]

The author further reports that the lining metal in the "magnus special" bearing tested by the committee showed indications of corrosion during the 80-mph schedule. In this connection we wish to state from our experience with Satco-lined bearings, that corrosion is the exception rather than the rule. In the railway field particularly, corrosion of Satco linings is of rare occurrence.

Under certain conditions, however, particularly with lubricating oils which are compounded with free fatty acids, all types of lining metals regardless of their composition will corrode to some extent.

Author's Closure

The discussion has brought to light some additional experimental work on the subject. It is hoped that Mr. Exline plans to publish the results of the railway-car journal bearing studies conducted in the laboratories of the Gulf Research and Development Company.

Data on lubricator power losses furnished by Mr. Pearce are most interesting inasmuch as they check the results given in the paper by an entirely independent method. With waste-pack lubrication, Fig. 24 shows the losses somewhat greater than the author's Fig. 14. Losses with the pad are in close agreement. Mr. Pearce's direct method of obtaining his data is probably somewhat more accurate than the author's indirect approach. The results, however, are in good agreement as has been pointed out, and may be said to verify some of the conclusions reached in the paper. Mr. Jones's comment that journal friction is a relatively small part of the total car resistance is well illustrated in Fig. 21.

Detailed procedure in the calculation of bearing oil-film thickness and friction, referred to by Mr. Hersey, was purposely omitted to reduce the length of the text. Basic data for these calculations will be found in previously published papers by Kingsbury[15] and Needs.[16]

The test results bring out the very interesting fact that despite the relatively large clearances of the railway journal bearing, clearances far beyond those permitted in other machinery, the bearing friction is slightly less than with the more normal clearances obtained by running the fitted bearings at operating temperatures. In other words, it appears that the friction of the bearing itself is about as low as can be expected and improvement can be hoped for only through method of lubrication. In this respect, statements by Mr. Jackson and Mr. Shoemaker that some of the railroads of this country have been using flood and pad lubrication for a number of years are significant.

A comparison of the test results given in the paper with similar data on roller bearings for railroad equipment as suggested by Mr. Jackson would be very interesting indeed and it is hoped that the Committee will be able to release such information in the not too distant future.

Mr. Shoemaker's data on variation of bearing-lining hardness with temperature are particularly interesting. From the fact that bearing 95-B carried a load of 1930 psi at 375 F with "A.A.R. babbitt" there appears to be ample babbitt hardness safety factor when operating at the usual loads and temperatures encountered in service.

That part of the discussion which is critical stresses the fact that a bearing under test in the laboratory is not meeting actual service conditions, and for this reason the test results are not of practical nature. When planning the tests the difference between laboratory and service conditions was realized. For example, it was not expected that the machine in which the tests were run would give any information on the ability of the bearing to withstand collar cracking forces. Such information is readily obtained by placing the bearing in service. The main objects of the laboratory tests were to investigate bearing friction and method of lubrication under steady comparable conditions and to compare these characteristics with those of the fitted bearing on the assumption that the fitted bearing was the best obtainable for the service. Since all successful bearings in actual service operate by virtue of their oil films, comparisons under comparable conditions of various methods of feeding these oil films are entirely valid, hence practical, regardless of whether the data are accumulated in the laboratory or on the railroad. In order to make the tests comparable they had to be run under steady conditions and since there are very few stretches of track where a train can run 80 or 100 mph for eight consecutive hours, the difficulty of obtaining our data from service is apparent. In some respects the conditions of the laboratory tests were more severe than the bearing would meet in service. Proof of this is the fact that every bearing surviving the laboratory test gave a good account of itself in service.

One or two other points raised by Mr. Mitchell can be answered more specifically. It is quite true that in a railroad car the two opposite bearings push the axle and wheels along. The horizontal component of the load which provides this force is essentially small as compared with the vertical component due to the weight of the car and its load. However small the horizontal load may be it does cause the bearing center line to lead the journal center. This, however, has no effect whatever on formation of the oil film. Only the converging portion of the oil film can possibly generate positive load-carrying pressures. In the testing machine the load-carrying area is in the center of the bearing as shown in Figs. 11, 12, and 13. Because the bearing must carry the axle and wheels along in actual service the load-carrying bearing area will be shifted from the center a very slight distance opposite the direction of rotation. Under comparable operating conditions the films will be exactly the same otherwise.

Regarding heat transfer from bearing to wedge, the test results seem to indicate that the smaller contact area of bearing 94 is not a matter of concern. As Mr. Mitchell has pointed out, the operating temperatures of bearing 94 are much the same as the temperatures of the other two bearings under the same operating conditions. This would be expected inasmuch as friction is approximately the same with each of the three bearings. It will be noted from the tables, however, that the temperatures of bearings 93 and 95 are generally several degrees lower than the journal. With bearing 94 this difference is only a degree or so, the smaller difference being due to less contact area between bearing and wedge.

Dimethyl-Silicone-Polymer Fluids and Their Performance Characteristics in Unilaterally Loaded Journal Bearings[1]

By J. E. Brophy,[2] R. O. Militz,[3] and W. A. Zisman[4]

This investigation concerns the practicability of using the dimethyl silicone polymer fluids as lubricants in unilaterally loaded journal-bearing machines. A specially designed bearing machine was used having forced-feed lubrication up to pressures of 26 psi. It was operated at a speed of 1725 rpm, and the oil-sump temperatures varied from 115 to 130 F, while the bearing temperatures varied from 150 to 240 F. Plain or chrome-plated high-carbon-steel shafts were used in conjunction with bearings of copper-lead, bronze, tin-base babbitt, cast iron, commercial brass, aluminum (17S), copper and Alfin metal. Cast-iron or steel bearings used in conjunction with steel journals were entirely unsatisfactory when lubricated with the silicone fluid. All of the nonferrous bearings performed satisfactorily with the silicone fluid. It was found that an organic silicon-containing film was formed during the long, slow, break-in process. The need for such a long break-in could be eliminated by the application of a technique of pretreating or lacquering the bearings with silicone oil before assembling the test machine. The method of pretreatment is described briefly. It was also discovered that such pretreated bearings were able to carry much higher than normal loads when operated in contact with petroleum lubricating oil.

Introduction

This is part of a larger investigation made by the Naval Research Laboratory during the war at the request of the Bureau of Ships. It concerns the physical and chemical properties of the silicone polymer fluids (or polyorganosiloxanes) and their application to, and development for, naval lubrication problems. As the dimethyl silicone polymer fluids have the smallest temperature coefficients of viscosity of any of the available silicones (or of any other known pure liquids in the viscosity range of lubricants), and as they are especially stable to oxidative decomposition, they have been the most thoroughly studied, and they alone are discussed here.

The dimethyl silicone fluids are included among the various new silicones developed and manufactured by both the Dow Corning Corporation and the General Electric Company and are now commercially available from each supplier under his own trade name.[5,6] At the start of this investigation only one manufacturer was in commercial production and able to supply large enough quantities of the desired fluid; hence all the data given here relate to several large batches of a well-reproduced fluid made by the Dow Corning Corporation.

Comparisons with the latest available and comparable grades of dimethyl silicone polymer fluids manufactured by both producers showed them to behave identically as lubricants. The fluid used here was specially stripped of volatiles, making it noninflammable to incendiary fire. It was identified by the producer as Dow Corning fluid, series 500, batch 369–62–69, and its viscosity-temperature characteristics are summarized as follows:

Temperature, deg F	Kinematic viscosity, centipoises
210	29.8
130	55.6
100	73.5
0	275.0
—20	390.0
—40	600.0

Prior to the investigation of this laboratory all of the lubrication tests reported by the producers and by the numerous other laboratories having access to these fluids had led to the conclusion that the silicones were poor lubricants. However, these fluids were considered so promising in other respects and the need for low- and high-temperature lubricants and noninflammable hydraulic fluids was so great that it was deemed unsound to drop them from consideration on the basis of the usual quick tests for load-carrying capacity.

After some search, a simple technique was found suitable for observing quickly some of the lubricating peculiarities of silicones. This is described in another paper.[7] Using this technique to separate the promising metal combinations from those obviously having no promise, it was found that whereas a number of nonferrous metals were suitable for bearings, steel or cast iron were uniquely unpromising. It was therefore decided to study these extreme types of metal combinations in both a bearing machine and a hydraulic pump system. The results obtained in hydraulic systems are described elsewhere,[7] while the first results obtained in bearing machines are reported here.

Since the theoretically best understood and most common type of lubrication occurs in the unilaterally loaded journal-bearing machine, it was considered to be the appropriate machine for studying load-carrying capacity (or seizure load) as affected by the fluid, the break-in procedure, and the bearing composition. By going from light loads with full hydrodynamic conditions

prevailing, to heavy loads with intermittent metallic contact, it was believed that important peculiarities of the fluid could be noted. It was necessary to design a special bearing machine for this work.

Owing to the originally limited availability and high cost of the silicone fluid, this machine was of small capacity. Nevertheless it was desirable to be able to employ commercially available insert bearings and to secure adequate freedom from shaft deflections and bellmouthing of bearings, which meant that good bearing alignment and accurate boring and finishing of bearings were essential. Several models were built, the final one used for this investigation being shown in Figs. 1 to 4, inclusive.

Due to the poor lubricating value of the silicones in steel-on-steel or steel-on-cast-iron sliding loaded surfaces, the forced-feed oil system of the machine had to be operated with a low-pressure low-flow-rate gear pump designed to avoid such loading. The machine used was equipped with a specially designed gear pump having bronze bearings. Later models of the machine were equipped with Pesco 1P-349N aviation gear pumps run at low speeds.

Experimental Equipment and Methods

Fig. 1 shows the bearing machine completely assembled with weights on the pan of the loading arm. Fig. 2 is a partial test assembly of the bearing machine revealing the placement of the bearings, journal, and thermocouple. Fig. 3 is an assembled view of the support bearings, test bearing, journal, and flinger. Fig. 4 is a view of the component parts of the test assembly shown in Fig. 3.

The small motor A beneath the drain pan, Fig. 1, drives a special vertical, bronze, gear pump B. The pump is immersed in its own reservoir C to minimize the volume of fluid needed. The high-pressure feed line extends from the side of the pump to the aircraft-type Skinner filter D. One copper tube from the filter feeds the support bearings. This tube and its end connection to the support block are shown in Figs. 2, 3, and 4. Another copper tube from the filter goes to a needle valve and thence to a rotameter-type flowmeter E. The fluid pressure is measured at the outlet of the flowmeter. A coiled copper tube connects the flowmeter with the test-bearing holder F. The load on the bearing is applied through the long beam G and a secondary lever system that is connected to the test-bearing holder.

The method of supplying the lubricant to the bearings is shown in Figs. 3 and 4. The flare fitting on the block H is connected to both support bearings by drilled holes. The small hole at the top of the test bearing J shown in Fig. 4, is the supply orifice for the lubricant. The test holder is drilled to connect the flare fitting and the bearing. A spring-loaded thermocouple is screwed into the bottom of the test-bearing holder at point K and contacts the outer surface of the test bearing.

Plain bearings with one hole drilled top center (opposite loaded area) were used. The bore was 0.687 in. and the length of the bearing was $^1/_2$ in. The bearing clearance (bore diameter minus journal diameter) was held to 0.0010 in. $\pm$ 0.0001 in. A special boring technique, developed and made available to this laboratory by Russell Dayton of the Battelle Memorial Institute, was used to assure true cylindrical holes in the test bearing and support bearings. The journals were of chromium-plated high-carbon steel with the exception of that used in run N, in which case it was copper-plated steel. The bearings were pressed into the test-bearing holder and the support block. If rough-boring was necessary, it was accomplished before pressing the bearings into the holder and block. Finish-boring was accomplished in the lathe in a special fixture using the boring technique mentioned previously. This fixture was built to isolate the eccentricities of the lathe spindle from the work and

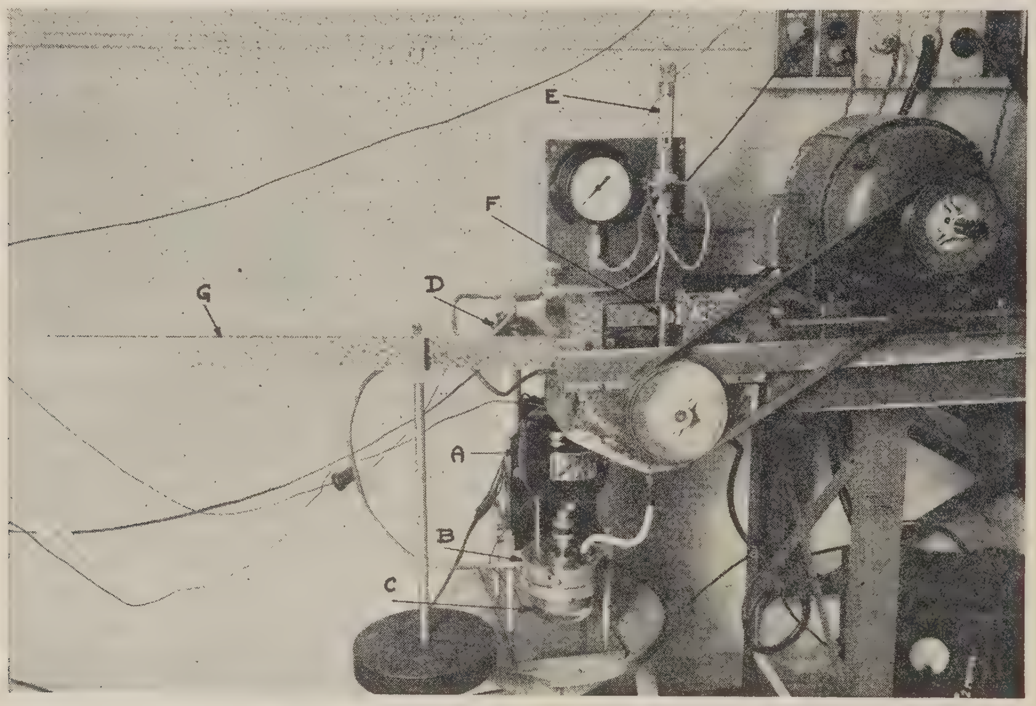

Fig. 1 Bearing-Test Machine, Assembled for Test Run

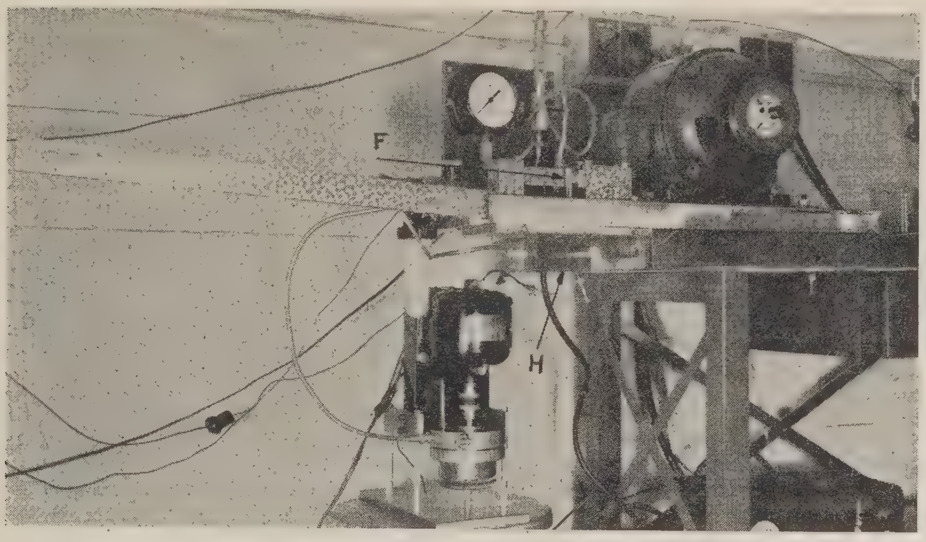

Fig. 2 Bearing-Test Machine With Oil Pan and Drive Pulley Removed

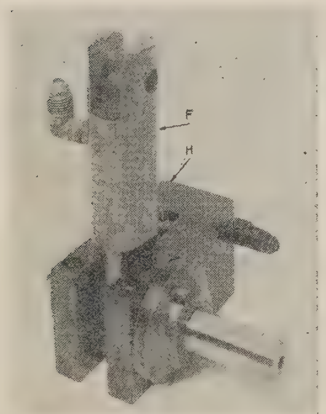

Fig. 3 Assembly of Support and Test Bearings

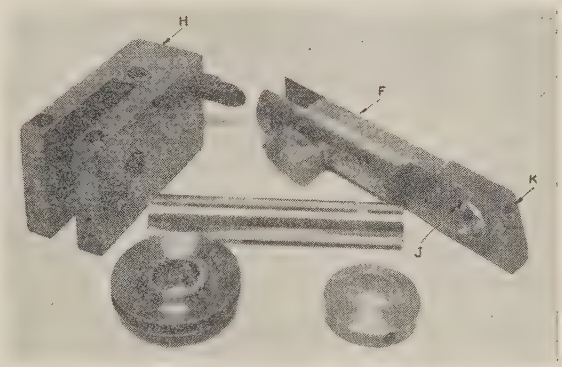

Fig. 4 Component Parts of a Bearing Test

to insure reproducible finishings in the bearing. All parts in the test setup, including the bearings, were washed either in unleaded gasoline or in benzene and blown dry with clean air. All bearing surfaces were wet with the silicone fluid prior to assembly in the machine.

Due to the low surface tension of the silicone fluid, approximately 20 dynes per cm, it was difficult to prevent leakage of the fluid from the system. In the first bearing machine developed for this work it was found that the standard labyrinth-type seal, used so much in modern equipment, was entirely unsatisfactory. Flinger rings were found to work if properly shaped. As for the standard synthetic-rubber seal rings, it was found necessary to change the composition of the rubber to a silicone plasticized Hycar compound, described in the accompanying paper on hydraulics.[7]

The gear pump was operated to deliver the silicone fluid to the test bearing at a pressure of approximately 26 psi. No attempt was made to maintain the same ambient temperature or bearing temperature throughout the various runs. Bearing temperatures ranged from 152 to 240 F, while temperatures of the oil in the sump ranged from 118 to 129 F. The journal speed throughout was 1725 rpm. The load in all the tests was limited to a maximum of approximately 6000 psi. This limit was imposed by the design of the machine, since higher loads would cause excessive shaft deflection and bellmouthing of the bearings.

After some experimentation, several procedures were adopted for breaking in the bearings. A slow break-in consisted of an initial overnight run of 16 hr at 500 psi, and thereafter an increase in the load of 100 psi per hr. This load was continued until failure occurred, or the load limit of the machine was reached (6000 psi). If no seizure occurred the load was cycled between 500 and 6000 psi. One run of 157 hr duration was made. Once broken in, the bearings were run 8 hr per day at 6000 psi after a 15-min warm-up run at 500 psi. The 157-hr run was stopped because of a failure in the power supply to the oil-pump motor. A fast break-in had only 2 hr initial operation at 500 psi, and the load was increased 500 psi every 15 min. A very fast break-in has been used in which the bearing was operated at 500 psi for 2 hr and then loaded to 3000 psi and increased to 6000 psi 15 min after that. The bearing was then cycled between 500 and 6000 psi.

The temperature of the test bearing was taken at the outer

surface of the bearing through the bottom of the holder as previously described. Temperatures were measured and recorded continuously on a Leeds & Northrup potentiometer having a range of 0 to 350 F, and a time of full-scale travel of 27 sec. With this type of instrument it is impossible to follow flash temperatures or temperatures at final seizure, but general operating temperatures were recorded very well. The temperature of the bearing rose slightly after each increase in load, but fell in a few minutes to an equilibrium temperature slightly higher than that for the previous load. This temperature-recording arrangement has proved satisfactory for observing incipient seizure. However, in the runs described in this paper, no difficulties with incipient seizure were found in the silicone-lubricated runs over the load range used.

The bearing metals used included cast iron, babbitt, a high lead and a high-tin bronze, copper-lead alloys containing high, medium, and low amounts of lead, copper-nickel silicide, copper (hard), commercial brass (half-hard temper), aluminum (17S), and Alfin metal. The chemical analyses and sources are given in Table 1. It should be understood that these materials are not the only ones of promise but simply all those investigated to date.

Some Load-Carrying Characteristics of Chemically Untreated Bearings

The first bearing machine built was tried with bearings of cast iron, 80-10-10 bronze, and Delco bushing (copper-lead), and steel-backed babbitt. The nonferrous bearings were satisfactory over the temperature range of 140 to 180 F up to the load-carrying limit of the machine (only 2200 psi). The cast-iron bearings operated under no load but failed promptly at loads of only 250 psi. Therefore a new machine was built permitting loading up to 6000 psi.

Using the break-in procedure already described, copper, Federal Mogul F-16, aluminum (17S), and Alfin alloy bearings were investigated in the journal-bearing machine shown in Figs. 1 to 4, inclusive, using the silicone fluid. The summarized results are given in Table 2, as runs A, B, C, and D. In all cases these metals, once broken in, operated as satisfactory bearings at loads up to the load limit of the test machine (6000 psi). Of course, this conclusion is restricted to the given range of bearing temperatures, oil-flow rates, and ZN/P values (Z, N, and P having the usual meanings, i.e., Z = viscosity; N = rpm of journal; P = bearing load per unit of projected area). The quantity PV (in which P = the load and V = journal velocity in feet per second) used to predict the performance of a bearing with a petroleum oil is given in Table 2. No significance can yet be given to these values for the silicone fluids until more data are collected. In all cases no significant change (± 1 per cent or less) in the viscosity of the fluid resulted.

In each of these runs, as in the earlier bearing tests mentioned, it was found that the slowly broken-in bearings not only developed high load-carrying capacities, but also retained them when the original silicone fluid was replaced by new and unused silicone oil. An obvious inference was that the bearing surface had been chemically or otherwise altered. A careful inspection of each bearing surface following the slow break-in procedure revealed that each loaded surface was coated with a thin transparent film or lacquer roughly 0.0001 in. thick and varying from water-white to pale yellow in color. Such a lacquer had also been found on the bronze bushings of the Pesco high-pressure gear pumps used in the hydraulic pump.[7]

It is now well recognized that bearings carefully run-in on petroleum lubricants slowly develop a dark lacquer coating on the loaded-bearing surface. As it was considered possible that the high load-carrying capacity obtained in a slow break-in with silicone oil was due to the formation of the observed film or

lacquer, it was decided to try to produce artificially such films on bearings and investigate the resulting change in the break-in and load-carrying characteristics of the bearings lubricated with silicone fluids.

Silicone Lacquers and their Use in Silicone-Fluid-Lubricated Systems

Previous research of this laboratory on the oxidation stability of the dimethyl silicone polymer fluids had shown them to be very stable at temperatures up to approximately 300 F. At higher temperatures some formaldehyde and formic acid were evolved, and eventually the oil thickened until it set to form a water-white transparent gel. The rate of oxidation and of viscosity increase was considered negligible for most purposes at temperatures of 300 F, but at higher temperatures they became increasingly more serious. In the temperature range of 300 to 500 F and in the presence of the common metals, Cu, Fe, Al, bronze and babbitt, the rate of oxidation was decreased somewhat. However, pure lead and pure tin were found to be catalysts for accelerating the oxidation and gelation of the oil. From this work and other related research of this laboratory it was concluded that the films on the bearings, as described previously, were silicon-containing organic lacquers or thin films formed during contact of the metal with the products of the silicone-oil oxidation reaction.

The test bearing metals and also the supporting bearings were immersed in beakers of the silicone oil and were heated in the open air for long periods of time at 300 F or higher. The desired lacquers eventually formed, the time required varying with the temperature and metal. Numerous variations of this method of forming lacquers on the bearings have been tried and developed. The method used in preparing the bearings throughout the test discussed in this report involved the use of temperatures of 300 F for as long as 100 hr, or 500 F for only 24 hr. Longer times of exposure were necessary for steel than for nonferrous metals.

With the exception of run F, all of the runs E to N, inclusive, in Table 2 were made with lacquer-coated bearings previously prepared by the chemical method described. After the lacquer treatment the bearings were allowed to cool, were washed with benzene, and were then assembled in the test machine. Following this, the test fluid was added and the bearing test was run according to the loading schedule indicated in Table 3. It will be noted from Table 2 that all these treated bearings carried the maximum load of the machine (6000 psi), while the break-in time was reduced to only 2 hr. Also no significant changes (± 1 per cent or less) in the viscosity of the fluid resulted.

In run F an untreated Delco bearing was used, and it was initially loaded up to and held at 500 psi. After $1^1/_4$ hr operation at that load seizure occurred. This is to be contrasted with the five equally or more rapidly loaded runs, E, G, H, J, and K, on the same bearing metals up to maximum loads of 6000 psi. The low load seizure in run F indicates the need for a slow break-in to obtain load-carrying capacities in excess of 1000 psi. It can now be concluded that a silicone film or lacquer formation on the bearings is necessary for the operation at high unit loads of silicone-fluid-lubricated journal bearings.

In runs L and M on commercial brass and F-1 (high tin-bronze) bearings, respectively, each was chemically treated by the method described, and each could be rapidly and successfully loaded to the maximum load-carrying capacity of the machine. In run N a copper-plated high-carbon-steel journal, rotated in a previously lacquered, cold-rolled steel, test bearing, operated successfully under rapid loading until seizure occurred at 5500 psi. This is to be compared with the very low loads (250 psi) at which seizure occurred with steel-on-cast-iron silicone-lubricated bearings as described in the earlier tests.

Runs V and W were made using lacquer-treated bearings of cast iron and journals of chromium-plated high-carbon steel. Seizures occurred at loads of approximately 2000 and 2500 psi. In another paper,[7] it is shown that Pesco high-pressure gear pumps, fitted with cast-iron bushings, failed in a few minutes at a hydraulic pressure of 600 psi. Therefore, although the silicone-lacquer treatment did not increase the load-carrying capacity of cast-iron bearings to values as high as it did the nonferrous bearings studied, a considerable and perhaps valuable increase did result. This increase in ability to carry loads is especially significant when one considers the very rapid loading schedule followed (see Table 3).

Silicone-Lacquered Bearings and Their Use With Petroleum Oils

The advantages found in silicone-fluid systems in treating bearings with silicone lacquer suggested the investigation of the value of using such treated bearings in petroleum-oil-lubricated systems. In runs P, Q, R, S, and T (see Tables 4 and 5), Navy Symbol 1080 petroleum oil was used for the bearing tests. This is a high V. I. nonadditive aviation-engine lubricant, and the batch used had the following viscosity-temperature characteristics:

15.5 centipoises at 210 F
74.5 centipoises at 130 F
360.0 centipoises at 77 F
2700.0 centipoises at 32 F

The viscosity is identical with that of the silicone fluid used at 148 F, which is not far from a mean of the bearing temperatures encountered.

Before beginning runs P and Q, the bearings were lacquered with a silicone oil by the chemical methods already described. Runs R, S, and T were made without any preliminary chemical treatment of the bearings. It was found that the lacquered

bearings did not seize during a fast break-in until loads were used of 5800 psi with brass and 4300 psi with Delco bearings, respectively. In contrast, the unlacquered Delco bearings seized at from 2100 to 2600 psi, depending upon the loading schedule followed during the break-in. Therefore, with a petroleum-oil-lubricated system, the silicone-lacquer bearing treatment was found to increase considerably the permissible rate of break-in and the seizure load.

Discussion of Experiments

Due to the care used in boring, aligning, and finishing the bearings and journal, reasonably good reproducibility was obtained, and seizure loads did not vary more than approximately 10 per cent from the mean. In this work high enough values of ZN/P were selected to remain usually in the region of hydrodynamic lubrication. It is of immediate interest to learn how much above 6000 psi are the seizure loads for the various nonferrous metals studied. Inasmuch as increases in seizure loads with lacquer formation of from 100 to 200 per cent were found, there is no doubt of the reality of the improvement obtained with lacquering.

Considerable variations were found in the maximum bearing temperatures before seizure. However, this is not unexpected because of the wide range of loading schedules followed during the break-in operations. These temperature variations are not considered as important in silicone-fluid as in petroleum-fluid-lubricated systems, due to both the smaller temperature coefficient of viscosity and the greater oxidation stability of the silicone fluid. As in the hydraulic work,[7] no significant viscosity changes occurred during the bearing runs not accounted for by initial loss of volatiles. This eliminates shear instability of the fluid as a cause of the peculiar lubricating properties of steel-on-steel or cast-iron bearings.

Conclusions

A number of the common bearing metals have been found very promising for use in unilaterally loaded journal bearings, lubricated with the silicone fluid. Among them are copper-lead, bronze, commercial brass, babbitt, copper, aluminum (17S), and Alfin alloy. These were especially effective with chromium-plated high-carbon-steel journals. Cold-rolled steel bearings operated with copper-plated high-carbon-steel journal bearings also showed promise. These nonferrous bearings have been successfully operated at the load limit of the bearing machine used (6000 psi), with load increments of as much as 5500 psi applied during cycling tests.

For the maximum load-carrying capacity the bearings should have either a long gradual break-in or be suitably treated with a silicone lacquer prior to operation. The long, slow break-in process formed a silicon-containing organic film on the bearing. It was found that such film-coated bearings had load-carrying capacities comparable to those of artificially silicone-lacquered bearings.

Bearing systems of steel on steel and steel on cast iron were not satisfactory for operation with silicone fluids. However, a very slow break-in process or a preliminary treatment of the bearings with silicone lacquer enabled them to stand loads of up to approximately 2000 psi. Suitable bearing-lacquer coatings have been formed by completely immersing the bearings in dimethyl silicone polymer fluid (viscosity at room temperature of 50 to 100 centipoises or more may be used) and maintaining them at a temperature of from 300 to 500 F in the presence of air. The time of exposure varied with the metal, being longest for steel and least for copper. Exposures of from 100 hr were needed at 300 F and 24 hr at 500 F.

Acknowledgments

The skillful mechanical and experimental work of John Larson MM 2/c and the able machine work of William Kostowicz MM 2/c were of considerable aid in this work. Their interest and suggestions are much appreciated. Analyses of the test oils before and after the bearing runs were made through the courtesy of Carl Hechmer, Lieutenant, U.S.N.R., and Eleanor Bried, Sp (X) 2/c. Chemical analyses of the bearings listed in Table 1 were made through the co-operation of the Analytical Section of the Metallurgy Division.

Dimethyl-Silicone-Polymer Fluids and Their Performance Characteristics in Hydraulic Systems

By V. G. FITZSIMMONS,[1] D. L. PICKETT,[2] R. O. MILITZ,[3] and W. A. ZISMAN[4]

This investigation concerns research on the polymethyl siloxanes or dimethyl-silicone polymers, and their uses as lubricants and hydraulic fluids. It is shown that these new fluids give excellent results when operated in a standard aircraft-type Pesco gear pump. It was found that the silicones when used in a gear pump fitted with cast-iron bushings caused serious wear and disintegration of the bushings at pump pressures of only 600 psi. It is concluded that the loaded surfaces of steel sliding on cast iron or on steel are not adequately lubricated by the silicone fluid, whereas steel sliding on bronze is effectively lubricated. A simple manually operated slider-and-plate test method was discovered capable of permitting the discrimination between good, bad, and indifferent bearing combinations for use with silicone fluids. Results with 156 combinations of metals are summarized. There is also given a means of relating these observations to the practical problem of selecting suitable metals for use in lubricating the sliding parts of machinery with silicones. The results are related to observations on the choice of suitable metals for gear pumps, piston pumps, and journal bearings. It is shown that the same conclusions relative to steel sliding on steel or on bronze are reached from tests with the Vickers piston pump.

Introduction

EARLY in the war the Naval Research Laboratory was requested by the Bureau of Ordnance to investigate the possibility of using the new silicone-polymer fluids (or polyorganosiloxanes) as recoil and damping fluids. When difficulties due to the inflammability of present aircraft hydraulic fluids became apparent, the Bureau of Aeronautics also became interested in the development of these fluids for use in aircraft hydraulic systems. A description of some of the properties of these fluids by the two producers will be found in the literature.[5,6]

Many of the physical and chemical properties of interest in the evaluation of hydraulic fluids were investigated by this laboratory prior to commencing tests in hydraulic equipment. It was concluded that of the various silicone-polymer fluids, the dimethyl silicones were the most desirable because they had the smallest temperature coefficients of viscosity of any pure fluids known, and also had unusual stability to oxidation. The resistance of the dimethyl-silicone fluids to various fire hazards was studied, and it was concluded that they were adequately resistant to the fire hazards of interest in this investigation. Laboratory tests and M-1 incendiary-bullet firing tests on properly stripped silicones verified that, under such fire hazards, these fluids would not ignite nor would the liquid spray propagate a flame front. This made it of interest to study the operation in hydraulic equipment of a carefully stripped silicone fluid.

Both manufacturers of the silicones were requested to prepare one sample each of the fluid having a viscosity at 210 F of approximately 25 to 30 centistokes. The viscosity-temperature characteristics obtained in each case were within the following narrow ranges:

Temperature, deg F	Viscosity, centistokes
210	26–30
130	52–56
100	68–74
0	259–275
—20	385–390
—40	600–610

The two fluids submitted were used throughout this investigation and no important differences in behavior were found. Other less viscous fluids can be obtained having the advantage of being much less viscous at lower temperatures. Thus a silicone fluid has since been obtained having the advantages that, while the viscosity at 210 F is 18 centistokes at 0 F it is 160 centistokes, and at —40 F it is only 360 centistokes. Such a single hydraulic fluid can at once satisfy all present military requirements in so far as viscosity, volatility, and pour point are concerned. The high viscosity at 100 F of the fluid used here was considered desirable at the commencement of this investigation because the tendency of the silicones to leak out of the hydraulic system and the inflammability were decreased by using the highest possible viscosity consistent with approximating both the low-temperature ordnance and aircraft hydraulic specifications, O.S. 2943 and AN-VV-O-366b.

Experimental Equipment

At the commencement of this investigation the available supply of silicone fluids was very limited and hence the laboratory hydraulic tests were made in systems operated with the small-size high-pressure pumps used in aircraft. These were the 1P-349-N Pesco gear pump and the Vickers model No. PF-2713-10, constant-delivery aircraft piston pump.

The Pesco pump has nitrided gears running in high-lead bronze bushings. The bushings are pressure-loaded against the sides of the gears. Any wear resulting from a test is therefore noticed on the face of the gears and the sliding surface between the thrust face of the bushings and the side of the gears.

The Vickers pump is a 7-piston constant-delivery pump. Several points are observed for wear, one being the hardened-steel

universal link on which are pivoted, on steel pins, four hardened-steel knuckles. Through two steel retainers this assembly serves to connect the drive shaft to the bronze cylinder block. As a result of the angle (10 deg) between the drive shaft and cylinder block, each revolution of the shaft causes the knuckles to rotate 10 deg around the steel pins of the universal link. Bronze bearings at either end of the universal link are lubricated by the fluid pumped being forced through a small hole in the link. The action of the piston in the cylinder block and the sliding of the cylinder block on the valve plate are also observed. Five ball bearings, one thrust loaded, two radial loaded, and two with a combination load, serve to make this pump very desirable as almost every type of wear is represented.

The hydraulic system used is shown in Fig. 1. The reservoir A was designed to produce a long liquid path within the sump from inlet to outlet in order to facilitate deaeration of the fluid. Two sizes of sumps were used, depending upon the amount of the test fluid available. When the smaller was used the total capacity of the hydraulic system was 1.25 gal, while with the larger sump it was 3 gal. Thermometer T was used for reservoir temperature measurements. The line C was $^{5}/_{8}$ in. OD 0.035-in-wall copper tubing. Line D was a standard flexible high-pressure rubber hose with $^{13}/_{32}$-in. ID conforming to the specification AN-863-8-21. All other tubing was $^{1}/_{2}$-in. OD and 0.035-in. wall copper. Standard 24S-T aluminum alloy or equivalent AN-type flare fittings were used throughout. The driving motor used, M, was a General Electric type K, frame 225, 220/440-volts, 3-phase, rated at 5 hp at 3600 rpm. Pressure was controlled by a Vickers No. C-167-E relief valve H. The gage I was used on the high-pressure side of the valve. This was a Lonergan gage with a range up to 3000 psi. Gage J was used to measure the pressure drop across the relief valve, and gage K measured the pressure drop across the filter L. This filter was either a Purolator aircraft-line type, using a paper element impregnated with what is reported to be a phenol-formaldehyde resin, or a Skinner aircraft-instrument-type filter, using a paper-disk element enclosed in a cloth sheath. The hydraulic fluid was cooled in flowing through cooler M_1, which consisted of 20 ft of $^{3}/_{8}$-in. copper tubing inserted in 20 ft of $^{3}/_{4}$-in. copper tubing and then coiled in a helix. The test fluid passed through the space between the inner and outer tubes, and

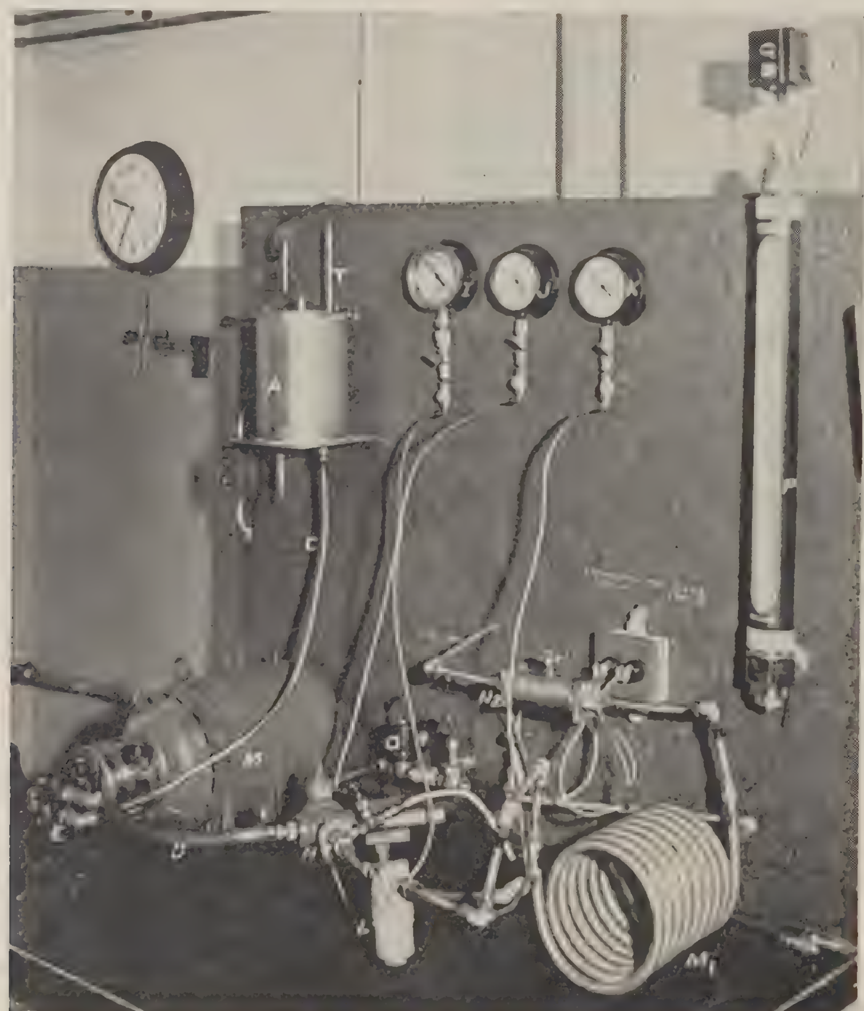

Fig. 1 Hydraulic Test Setup Used

a flow of cooling water passed through the inner $^3/_8$-in. tube. Where necessary the helix was immersed in a cooling bath.

The device N_1 was a Fenwal thermoswitch which was connected with the motor control, the purpose being to shut off the driving motor if the temperature of the hydraulic fluid exceeded the desired test temperature. This device was in the nature of a safety shutoff in case of water failure to the cooler. The device N_2 was also a Fenwal thermoswitch which controlled the sump oil temperature through a solenoid O in the water-supply line to the cooler. The test fluid then passed through P, a Fisher and Porter rotameter Stabl-vis type 12 P7, capable of measuring flow rates from 0 to 5 gpm. On top of the rotameter a Minneapolis-Honeywell Pressuretrol Q was installed. This was a safety device to switch off the power to the drive motor if for any reason the pump failed to deliver fluid. It was caused to operate by the slight pressure in the line from the rotameter to the reservoir which was generally in the neighborhood of 1 or 2 psi. When this pressure was not present the switch moved to the "off" position, thereby breaking the circuit to the drive motor. The fluid left the rotameter through a line which entered the side of the reservoir near the top and then directed the flow against the wall of the container. This caused the test fluid to take a circular path to the pump inlet, thereby allowing any entrapped air bubbles the greatest possible time to escape to the surface of the fluid. The liquid velocity was not sufficient to cause the fluid to vortex in the reservoir.

Operating Technique

Before each test the entire hydraulic system was dismantled and cleaned with suitable solvents. Repeated washing with unleaded gasoline was sufficient to clean the system if previously operated with the silicone fluid. Where polymer-thickened petroleum hydraulic fluids had been used previously, it was necessary to wash all parts in unleaded gasoline to remove the petroleum fluid and to follow that with successive washings with methyl cellosolve and acetone. The cleaning procedure was completed with drying the system with a forced draft of clean air. In using these fluids precautions were necessary owing to the pronounced ability of the dimethyl silicones to creep over surfaces and to leak through mechanical joints. All tubing flares had to be made as nearly perfect and tight as possible, and it was found valuable to use wherever practicable a pipe-thread sealing compound. An available material which was found satisfactory was "Tite-seal," a product of the Radiator Specialty Company of Charlotte, N. C.

Before each run and before a gear pump was placed on the test stand, it was fitted with a new set of bushings and gears. Both the gears and the bushings were thoroughly washed in benzene, dried, and weighed to the nearest tenth of a milligram on an analytical balance. As the pump was assembled, all moving parts and all O-ring seals were wetted with the fluid to be tested. When the system was assembled and secured, it was charged by filling the reservoir and turning the pump slowly until the entire system was filled. The drive motor was then started and the fluid circulated with no restriction offered by the Vickers relief valve until it could be ascertained that the system was operating satisfactorily. The Vickers relief valve was then adjusted to the desired pressure and as the fluid began to heat up, the adjustments on the thermoswitches were made.

Most of the runs were made for 100 hr of continuous operation or until a failure caused discontinuance. Samples of the hydraulic fluid were taken at the end of each run and the viscosity, neutralization number, and precipitation number were measured, the latter two measurements being made only when the reference petroleum fluids were used. The gears and bushings were removed from the pump, washed, and weighed at the end of each run to determine the amount of wear occurring during the test period. The rest of the system was examined for any unusual manifestations such as corrosion, solvent effects, and deposits.

Piston-pump performance was characterized by observations of the flow rate at the beginning and end of each run, appearance of metallic particles in the test fluid or the filter, and condition of the working parts, as evidenced by weight losses, appearance, and fits. Due to the size and mass of the working components as well as to the presence of many crevices impossible to clean perfectly, measurements of weight losses were not considered satisfactory for observing wear.

A new filter core was used for each run and in some cases where a Skinner filter was used, a cloth bag covered the core. After each run the filters were examined for deposits. In some of the runs thermocouple readings were taken to determine temperatures after the fluid had passed through the pump and again after passing through the relief valve. These thermocouple installations were temporary in that the temperature was found to rise 10 deg F passing through the valve. The results were consistent for a number of runs, thus making such observations superfluous and hence they were not made routine observations. The approximate number of cycles which the fluid made per run was calculated by multiplying the time of the run by the flow in gallons per minute and then dividing by the system capacity. The flowmeter readings were not corrected for density or viscosity of the fluid. These readings were all made at running temperature for the purpose of determining losses in volumetric efficiency of the pumps at a determined pump speed. These readings were approximately 4 per cent higher than the actual flow rates.

The reference petroleum hydraulic fluids tested had the following viscosity-temperature characteristics:

Temperature, deg F	Viscosity, centistokes AN-VV-O-366b	O.S. 2943
210	5.16	10.0
130	10.1	...
100	14.1	29.1
0	90.3	223.5
—25	...	556.3
—40	406.4	...

Packings for Systems Operated With Dimethyl-Silicone-Polymer Fluids

If the dimethyl-silicone-polymer fluids are to be used in hydraulic systems, it may be necessary to change the composition of the packings. It was found essential to change the composition of the O-ring seals which are so commonly used especially in aircraft. Whatever the ingredients used as plasticizers for the synthetic rubber of the O-ring seals, these plasticizers gradually were extracted by the silicone fluids, and as a result the rings shrank and became brittle. This shrinkage was of such magnitude as to cause serious leakage from the pumps and other hydraulic components using such rings. As might be expected, the solubility of the plasticizers was increased with time and temperature. It was found that serious leakage occurred after 24 hr of pump operation at 180 F sump temperature. However, it was found possible to run the pump for 500 hr continuously at 140 F without serious leakage, but after that run had been completed the seals had become so brittle that they shattered when an attempt was made to remove them. Even in systems operating at lower temperatures than 140 F, there may be trouble with present O-ring packings after long exposures occurring in peacetime practice or in long storage. There was evidence that the solubility effect was present even at room temperature.

A solution to the problem of the shrinkage of O-ring seals was found. The same solution will probably care for difficulties with

many other types of hydraulic packings. It seems that the most commonly used plasticizers of synthetic rubber are all soluble to some extent in dimethyl-silicone fluids. Therefore the High Polymer Section of this laboratory compounded a new packing with a small amount of the silicone hydraulic fluid under test. The rubber used was basically a Hycar compound having a durometer reading of 60 and a tensile strength of 2000 psi, an elongation of 325 per cent, and a freezing point of —60 F. A small percentage of graphite was also included in the manufacture of this material to reduce the friction of these seals on moving parts. It was found that O-rings made from this stock gave completely satisfactory performance in pumps using silicone fluids for 100 hr continuous running at from 180 to 200 F, the highest temperatures employed in this investigation. It was found later that suitable gaskets necessary for journal-bearing experiments[7] could be made from the same material.

Behavior of Silicone Fluids in Gear Pumps

The results obtained on the reference petroleum oils and on the silicone fluid are given in Tables 1 and 2. The sometimes variable finish and hardness of the gears and bushings furnished by the manufacturers of the pumps caused irregular weight measurements during the break-in of new gears as can be seen when comparing the gear weight losses on all runs, especially runs P-20 and P-21 of Table 2. It can be noticed from runs P-19, P-20, and P-21 that when the same set of gears was re-used the weight losses became less, thus indicating that at least part of the weight loss was not due to the fluid alone but rather to mechanical variables. These three runs are the only ones in which gears were re-used, and so it can be concluded that the weight losses in the other runs represent the highest wear rates to be expected in the history of a given pump operated on clean oil.

It was noticed that when using the petroleum "ordnance hydraulic fluid" O.S. 2943, the weight losses were much greater than when the silicone fluid was used. Values of approximately 0.015 g per gear per 100 hr, using the new gears and bushings with petroleum fluid, should be compared with values of often much less than 0.009 g using the silicone fluid. It was also found that higher rates of bushing wear occurred when petroleum was used than with silicone.

It is believed the cause of the low wear rates on the silicone-lubricated pressure faces of the bronze bushings was the formation of a protective resin consisting of cross-linked polymers developed by oxidation of the fluid. Early research on the oxidation of silicones had shown that gels and eventually cross-linked polysiloxane resins resulted. Similar deposits were obtained by this laboratory when strips of polished metal were immersed in the silicone fluid during the oxidation tests.

Although it was found difficult to detect the presence of gel in the silicone fluid because of the small difference in the refractive indexes of gel and fluid, careful examination under a microscope definitely revealed the presence of particles of gel in the fluid

[7] "Dimethyl-Silicone-Polymer Fluids and Their Performance Characteristics in Unilaterally Loaded Journal Bearings," by J. E. Brophy, R. O. Militz, and W. A. Zisman, published on pages 355–360 of this issue of the Transactions.

which had been run for 100 hr. In every run some soft black gel was found on the filter element. In the 500-hr run, P-25, there was enough gel formed in the fluid so that it could be scraped from the filter walls with a spatula, permitting the recovery of 10 ml. Apparently the only reason for the fluid casting out the gel under normal conditions was that the gel would attach itself to minute particles of more dense material in the fluid and would thereby become heavy enough to be thrown out at points where flow direction changed abruptly such as happened in the filter.

Some attempts were made to concentrate the gel formed by the use of a centrifuge but this method proved unsatisfactory. As a result of the formation of gel in the silicone fluid, it was found that a definite build-up of back pressure occurred on the Skinner filters fitted with bags, accompanied by a gradual clogging of the pores by slime. The rate of clogging, however, was not sufficient to cause trouble in normal operation. Using either the purolator filter or the Skinner filter without a bag, serious clogging of the filter occurred after 500 hr of continuous operation at 140 F and 1500 psi operating pressure.

It will be noticed in Table 2 that there was no significant viscosity change (less than 2 per cent) in the silicone fluid after having been pumped at a pressure of 1500 psi continuously for as long as 500 hr (or 105,000 cycles). For comparison, the petroleum fluid O.S. 2943 decreased in viscosity to less than 50 per cent of its original value after 18,000 cycles.

A set of cast-iron bushings (3.3 per cent carbon content) was made to fit the Pesco 1P-349-N pump to replace the usual bronze bushings. Results with O.S. 1113 petroleum hydraulic oil as well as the silicone fluid are given in Table 3. When operated on

silicone fluid, the pump ran normally at 200 psi for 15 min. Therefore the pressure was increased gradually. At 600 psi the pump began to fail rapidly and the fluid became black with such finely dispersed particles of iron that they were not retained by the filter, while the volumetric efficiency of the pump fell approximately 33 per cent in 5 min, leading to the discontinuance of the entire run. A microscopic examination revealed that much gel had formed in the silicone fluid. Several more runs were made using new cast-iron bushings and pump failures were obtained. The roughened appearance of a set of the cast-iron bushings following such a disastrous run is evident in Fig. 2.

Finally, similar runs were made using the Navy Ordnance petroleum hydraulic fluid O.S. 1113. It was found that the pump operated well at a pressure of 800 psi. When examined after 2 hr of operation, there was only a slightly galled spot on the bushings as evidence of wear.

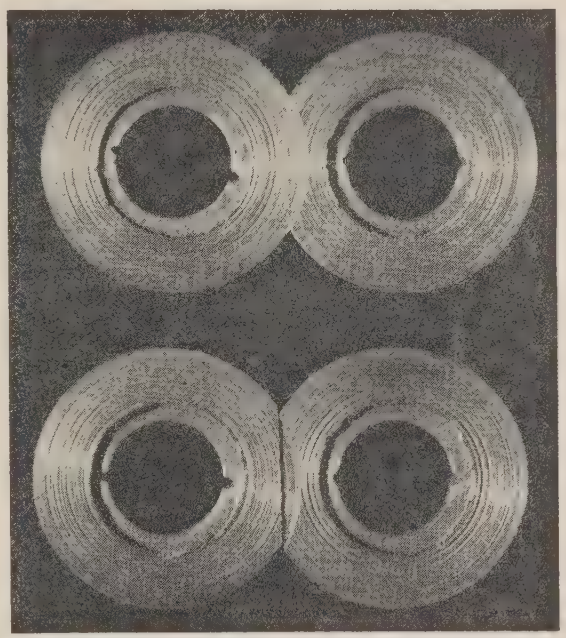

FIG. 2 CAST-IRON BUSHINGS AFTER 0.25 HR IN SILICONE

SELECTION OF BEARING METALS FOR USE WITH SILICONE LUBRICANTS

The contrast in the high rate of wear of silicone-lubricated surfaces of steel rubbing on cast iron, and the negligible rate of wear of steel on bronze in the gear-pump runs described, suggested the possibility that other combinations of rubbing metal surfaces might exist which were also well lubricated by this fluid. It was evident that an undesirably large amount of shop and time-consuming testing machine work would be needed if the large number of metal combinations of interest were tried as pump bushings or test bearings.

In endeavoring to duplicate the serious rate of wear and eventual seizure at low pressures of steel sliding on polished cast iron or on polished steel, a simple technique was found valuable in the rapid sorting out of the good, bad, and indifferent metal combinations lubricated with the silicone fluid. This "slider-and-plate" method consisted in sliding manually a flat cylindrical and polished metal slider having a diameter of 1 in. upon a lubricant-covered, flat, polished metal plate $1^1/_2$ in. wide and 6 in. long while exerting a downward pressure on the slider. The edge of the cylinder was rounded off to make the cylinder operate as a sled and so invite formation of an oil wedge between slider and plate.

In the middle portion of each long back-and-forth stroke of the slider a condition of thick-film lubrication prevailed unless the unit load had become high enough to cause metal-to-metal contact. The maximum load obtainable by exerting pressure manually was approximately 20 psi with the 1-in. slider. Loads of around 40 psi could be obtained using sliders of smaller diameter, although the need for preventing rocking did not permit the use of sliders much smaller than $^5/_8$ in. diam.

The existence of serious wear was determined by the sense of touch, by an inspection of the sliding metal surfaces, by observations of the fluid for deterioration, and especially for the presence of abraded metal. This method may not be equally useful, however, in examining fluids of entirely different chemical compositions.

A series of these simple tests was made, using thirteen different sliders and twelve different plates. The metals used included bronze (80-10-10), brass (commercial), copper, aluminum, magnesium, tin, babbitt (lead-base), cold-rolled steel, stainless steel, and steel plated with nickel, chromium, cadmium, zinc, and silver. This permitted observing 156 combinations of bearing metals. For comparison, a sample of naval specification petroleum oil NS-1047 was used. This high V.I. nonadditive oil had viscosities of 6.3 centistokes at 210 F, 41 centistokes at 100 F, and 2300 centistokes at 0 F.

It was chosen because at the test temperature (68 F), it had the same viscosity as the silicone fluid used. The plated metal surfaces were buffed to a high polish before use in these tests. The other metals were polished, using successively finer grades of emery paper and ending with 4/0 grade paper. All surfaces were previously cleaned with hot c.p. toluene. Although the degree of surface polish somewhat affected the results of this test in so far as doubtful cases were concerned, it was found that the differentiation between the relatively good and bad cases was not changed.

The results of an attempt to classify the observations using the slider-and-plate tests are presented in Tables 4, 5, and 6. In each table the qualitative results are indicated for the silicone oil and for the comparison oil. From the relative performance of all the combinations of lubricated metals tried, three groups were made. The good metal combinations are listed in Table 4. None of these exhibited any adverse characteristics. The bad combinations are listed in Table 5. The doubtful ones, listed in Table 6, had some bad features, such as relatively high friction or the presence of a metallic sludge in the oil after rubbing, but these characteristics were not considered pronounced enough to classify them as definitely bad.

In contradiction to the original conclusion of earlier investigators that silicone fluids were not good lubricants, the results of this study revealed 81 bearing-metal combinations with which they may be found to be useful lubricants. The original reports were based upon the failure of silicone fluids to lubricate steel on steel where petroleum oils behaved very well. It is of interest to point out here that there are cases where the N.S. 1047 petroleum oil behaved poorly, while the silicone fluid produced good lubrication. From Table 4 may be cited such cases as aluminum on brass; copper on magnesium; magnesium on tin, nickel, chromium and cadmium; and cold-rolled steel on nickel and cadmium.

In contrast, the following metal combinations were lubricated well by N.S. 1047 but were not well lubricated with the silicone fluid: Steel, aluminum, copper, and nickel sliding on steel; nickel on brass and on nickel; tin on cadmium, and many others given in Tables 5 and 6.

It is apparent that each particular oil fails to lubricate certain definite metal combinations and that specificity of lubrication is a phenomenon not limited to silicone fluids alone. For example, the difference in the load-carrying capacity between N.S. 1047 oil and white mineral oil or a pure hydrocarbon like dodecylbenzene could be discerned, but in no case was there the serious scratching and seizure encountered with the silicone fluid.

In the case of steel on steel, the N.S. 1047 lubricated specimens were given the maximum manual loading (40 psi with a $^5/_8$-in. slider) and still no tendency toward seizure was noticed. Similar plates when lubricated with silicone oils and placed under loads of only 5 psi could be felt to scratch as though an abrasive were present. Slightly higher loads caused deep scratches or even sudden seizures, and with loads of 30 to 40 psi, movement of the slider almost instantly became an impossibility due to the seizure. In spite of such pronounced differences as this, in individual cases with most of the combinations of metals, the silicone fluid and the N.S. 1047 behaved alike. Thus in Table 4, of every five cases where silicones were found to be good, four were also good with the petroleum oil. From Tables 5 and 6, of every five cases in which silicones were found to be bad or doubtful, petroleum was found to give bad or doubtful results in three.

A qualitative relation can be established between the predictions from these simple tests and the results of tests with other more complex machines such as the journal-bearing machine.[7] In the case of the unilaterally loaded journal-bearing machine, the flat plate of these experiments corresponds to the shaft, and the slider corresponds to the bearing. Thus the slider (like the bearing) will accumulate thermal effects and reaction products which, depending upon the oil, may help or hinder lubrication. In contrast, each element of surface area of the plate (like the journal) will bear the load only periodically, allowing better distribution of the heat and chemical products generated. By similar considerations it is believed that these results can be interpreted for many applications to machinery and mechanisms of a more complex nature.

In trying to relate these slider-and-plate observations to some of the performance characteristics to be expected of more complex machines, another factor must be taken into account. The sliding test does not permit ascertaining the effect of break-in. For example, it has been found in the journal-bearing machine that a steel shaft rotating in a bronze bearing does very well if, and only if, a proper break-in procedure is followed.

In the Pesco pump runs it was found that bronze bushings rubbing against the face of steel gears worked well but developed lacquer coatings. This particular combination of metals belongs to the doubtful class in Table 6 because a slight sludge was noticed. Under careful break-in conditions in a pump or journal bearing,[7] this initial wear is avoided, a protective lacquer is formed, and subsequently the bearing is able to stand higher loads than with petroleum oil under similar conditions. Similar observations apply to the case of a brass slider upon steel, and may apply to other combinations. In agreement with this conclusion, when the slider and plates were coated with silicone lacquer by the method described in the companion paper, reference[7] no difficulties were encountered with seizures or scratching in the slider test.

Behavior of Silicone Fluids in Piston Pumps

Prior to observing the performance of the silicone fluid in the Vickers piston pumps, a 300-hr test run at 1500 psi and 180 F sump temperature was made on the petroleum oil AN-VV-O-366b, to provide reference data. Observations and a thorough inspection were made after 100, 200, and 300 hr of continuous operation, and the results are given in Table 7. The wear rates with this petroleum fluid were negligible. The general pump condition remained excellent throughout the test, while the oil remained clear, although an appreciable darkening in color was observed. The viscosity steadily decreased as usual due to shear breakdown of the polymer thickener. The viscosity decrease in the first 5000 cycles was approximately 24 per cent, and as usual the rate of viscosity breakdown rapidly became less after the first 5000 cycles.

Initial Condition of Pump	100 Hrs. on 366B	New	New

The same pump was thoroughly cleaned with solvents and operated on the silicone fluid. After 65 hr of continuous operation at 1500 psi and 140 F sump temperature, the pump failed through seizure. In another trial, using a new pump and a new batch of silicone fluid, it failed through fracture of the universal link after 80 hr of continuous operation at the same pressure and at 100 F sump temperature. In each trial the oil became dark with dispersed particles of steel before failure occurred. The surfaces of the steel pins and knuckles were so worn where they rubbed each other that their diameters changed by apporximately one half of the original values, see Fig. 3. Enough gel and finely divided metal was created to accumulate in the filters and increase the pressure drop across the filter by 87 psi. Pump failure was directly due to the excessive wear in these members, allowing the piston connecting rods to strike the sides of the cylinders, either causing seizure or breaking of the universal link.

The pump failures in these tests had in each instance been caused by the rapid wearing of the steel universal link and steel knuckle. This was not surprising in view of the results of the slider-and-plate experiments previously described. From that study a number of much more suitable metal combinations than steel on steel suggested themselves for materials to be used in making the link and knuckles. As few would have been available soon enough, 80-10-10 bronze was used instead of the steel knuckles.

Accordingly, a set of four such knuckles was made and installed in a new Vickers pump and tested for 50 hr of continuous operation at 180 F sump temperature and 1500 psi. At the end of this time the system was completely taken down and inspected. No appreciable wear being apparent, the test was con-

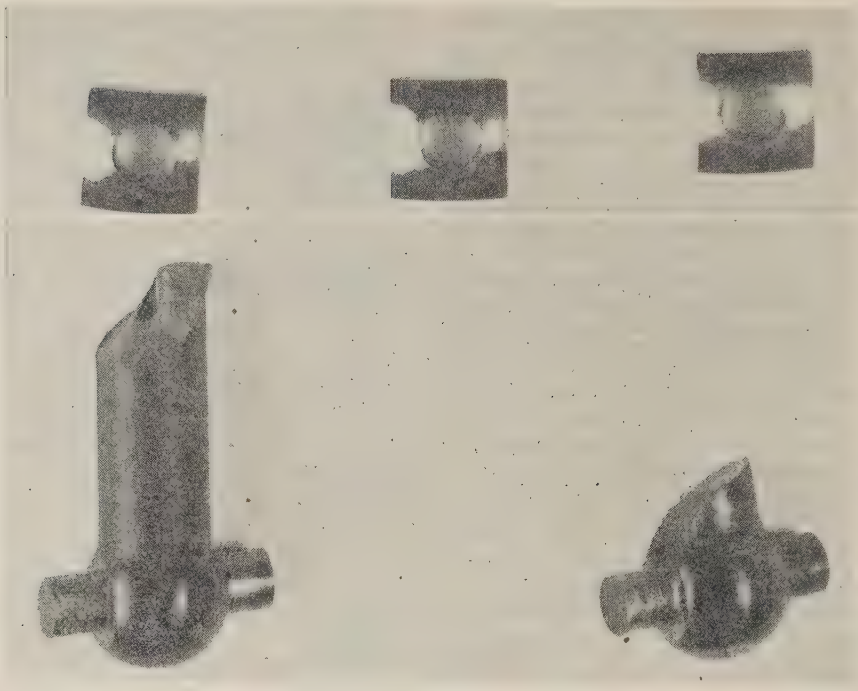

Fig. 3 Universal Link and Steel Knuckles After 80 Hr Operation in Silicone Fluid; Run VPL

tinued for a total of 650 hr of operation, after which it was completely disassembled and inspected. The components of the pump were examined carefully. The universal link pins and knuckles were not unduly worn and the general condition of the pump was considered excellent. The silicone fluid remained clear for the entire test and no significant change was observed in the viscosity. No gel was evident in the fluid and the filter showed freedom from clogging or accumulated slime. However, some gel was found collected around the universal link bearings as it was in all the silicone tests. As the results of the Vickers pump design, these points were exposed to a very small flow of the fluid and any gel accumulated there would have little chance of circulating through the hydraulic system and collecting in the filter.

Hence the use of steel pins and bronze knuckles improved the lubrication characteristics so much as to permit the silicone fluid to be a practicable hydraulic fluid in this type of pump. However, it has not been established here that steel pins and bronze knuckles are the best possible choice of materials. Other combinations of metals deserve consideration by those interested in the necessary changes of design required in pumps to be used with these new fluids.

Conclusions

These experiments make evident the need for discrimination in the use in lubrication and hydraulics of the dimethyl-silicone-polymer fluids. Until a cure is found for the very limited load-carrying capacity of the fluid where both loaded sliding surfaces are ferrous, the application of the fluid to many types of equipment now in use will be limited or impractical. Where one or both of such loaded sliding surfaces are nonferrous or can be replaced by suitable nonferrous metals, much equipment can be adapted to the use of these new fluids. In many cases such changes may require considerable and even undesirable redesign.

The difficulties encountered due to the creeping and leaking tendencies of the silicone fluid will be annoying in some equipment, and the only cure found to date has been in the use of fewer, tighter, and more carefully made mechanical joints. A satisfactory pipe-thread sealant has been found and others probably exist. Its use in tight mechanical joints may be necessary where vibration is severe. The silicone fluids cannot be used where seals are made by metal-to-metal contact without using high sealing pressure or a pipe compound, an example of this difficulty being certain types of aircraft selector valves which require the achievement of a leakproof seal by the use of a steel poppet valve against a steel seat.

The excellent behavior of the silicone fluid in the gear or piston pumps when the proper metal is used for bushings or links and knuckles demonstrates the promise of these new fluids for applications as hydraulic and lubricating fluids. As their peculiarities become better understood, their unusually valuable viscometric, freezing point, and chemical-stability properties will make their adoption increasingly inviting. Therefore, despite the need for redesign, packing changes, tight joints, etc., an increasingly wider use of these remarkable fluids can be expected. The use of the silicone fluid in the composition of the rubber packings instead of the usual plasticizer has shown how readily suitable packings can be prepared.

The protective and durable lacquer formed on the bronze bushings of the gear pump is quite like that found in slowly broken-in journal bearings described elsewhere,[7] and no doubt they are identical in origin and nature. There was no special difficulty with gel formation, for it was significant only after long periods of continuous operation at high sump temperatures. Even then that difficulty appeared adequately cared for by a filter-cartridge change every several hundred hours of continuous operation at high pressure. As the temperature of operation of the pumps rises above 200 F, no doubt the rate of gel formation

will become greater and will necessitate more frequent changes of the filter cartridge.

The results of the simple slider-and-plate tests, although merely qualitative, appear useful. The observed peculiarities of the silicone fluid in lubricating gear and piston pumps, as well as journal bearings,[7] are all in agreement with the predictions made by judicious use of the results of the slider tests, and in fact were used to guide part of the work here described and in the paper on journal bearings.[7] Except for a relatively few combinations, most of the slider-and-plate pairs tried and rated "good" with silicone were also rated "good" with the petroleum oil, and a similar parallelism holds with the combinations rated "bad." Also, many of the metal combinations rated "good" or "bad" for petroleum oil are identical with those experience has shown are useful in bearing systems lubricated with petroleum oils.

The low wear rates found in the gears of the Pesco pumps and the freedom from wear where found in the ball-bearing race of the Vickers pump are considered highly significant with respect to the relation of the behavior of the silicone fluids in rolling and in sliding friction. In both examples of rolling friction encountered here, steel rolled on steel, the unit loads were high, and yet little wear occurred. In contrast, at comparatively very low unit loads in the sliding friction of steel on steel, the failure to lubricate was remarkable. It is well known that sliding friction is less desirable in so far as wear rates are concerned than is rolling friction, but such a contrast as found here requires special explanation. It is suggested that this difference in case of the silicone fluid is due to the fact that, although it has ample chemical stability and adhesiveness to handle high unit loads directed normally to the moving surfaces, it fails under weak loads where sliding occurs as a result of the creation of local hot spots on ferrous and a few other poor-conducting hard metals, causing oxidative breakdown leading to gelling, lacquering, and even local cementing or welding.

ACKNOWLEDGMENTS

It is a pleasure to acknowledge the co-operative efforts of other members of the Lubrication Section, especially Charles M. Murphy, Jr., and Eleanor Bried, Sp(X) 2/c, in making available the necessary viscometric data; Lieut. (jg) G. M. Hain for the careful and useful microscopic examinations; William Kostowicz, MM 2/c, for his skillful machine work; and, in particular, Ensign Harrison Shull, for his experimental and analytical assistance in connection with the slider-and-plate experiments. To Dr. Peter King and Ferdinand Thurman, Sp(X) 3/c of the High Polymer Section, we are indebted for their originality and efforts in the development of the indispensable silicone-oil-resistant packings employed throughout this and related investigations.

Rotary-Pump Theory

By W. E. WILSON,[1] WINNETKA, ILL.

A theory describing the performance of rotary positive-displacement pumps and fluid motors in terms of torque and delivery is presented. From the equations for these two quantities, expressions for power input and power output are developed. The concept of torque efficiency as a complement to the concept of volumetric efficiency is introduced. Equations are developed for the volumetric, torque, and over-all efficiencies. Three operating ranges are identified by outstanding characteristics of the performance in each case. Performance charts in dimensionless form are presented and analyzed. Tests on a conventional gear pump operated as a fluid motor yield data which substantiate the theory in one operating range. Additional tests on a cam-type pump give data confirming the predictions of the theory concerning the performance when pumping oils of high viscosity. Alterations of the physical dimensions of the unit are discussed in terms of effect on the performance characteristics. The possibility of the design of units with optimum dimensions is indicated.

General Theory

The equations which will be developed apply to a rotary positive-displacement unit, acting either as a pump or as a motor. The unit consists of a rotary element, a stationary housing, inlet and outlet passages, and a shaft connected to the rotary element. The definite volume of fluid which is trapped between the rotary element and the housing is positively forced through the unit. Viscous bearing and gear friction as well as other mechanical effects will tend to resist motion of the rotor. These affect the shaft torque by an amount which will be referred to as "torque loss." Flow through the clearances and seals will cause an actual discharge differing from the ideal discharge. These secondary flows are referred to collectively as "slip." A loss in delivery of a pump, not properly designated as slip, is described. This loss is encountered when pumping liquids containing entrained gases, or liquids which vaporize readily.

Three distinct ranges of performance are recognized and defined as follows:

Range 1. All flow of the fluid in the unit in the turbulent range, giving a fluid torque resistance proportional to the square of the angular speed, and slip proportional to the square root of the pressure difference. Slip is independent of the viscosity in this case and torque loss is nearly constant.

Range 2. Laminar flow of the fluid throughout the unit, giving a viscous torque resistance proportional to the first power of the angular speed and first power of the viscosity, and a slip proportional to the first power of the pressure difference and inversely proportional to the viscosity.

Range 3. Laminar flow of the fluid throughout the unit. Slip is negligible due to high viscosity at low speeds. Slip increases as the speed increases due to local heating of the fluid, which in turn is caused by energy dissipated in the shearing action on the viscous liquid. This results in viscous torque loss less than that which would arise from fluid of the original viscosity. Delivery is also reduced by expansion of entrained gases or vapor in the low-pressure region at the pump intake.

In Fig. 1 are shown the characteristics of performance just outlined, in graphical form, in terms of torque and delivery as functions of speed of rotation of rotor shaft at constant pressure differential and constant viscosity at pump intake.

In the development of the theory it is assumed that the rotor shaft is rigid, clearances within the unit remain constant, and the coefficient of friction between unlubricated surfaces is a constant.

Ideal Torque and Delivery

In Fig. 2 is shown a section through a typical rotary pump. Using this sketch for reference, the equations for torque and delivery in general form may be written as follows:

As the rotor of either a pump or a fluid motor rotates, the motion is resisted by a viscous drag which originates in the narrow passages between rotor and housing. In addition there will be resisting torques such as those which originate in the shaft seals which will be nearly constant in magnitude. There are also torques resisting the motion which are proportional to the pressure differential which exists. These torques may originate in the seals if the sealing forces are proportional to the pressure differential, or in the bearings where the resistance is proportional to the bearing load, which in turn depends upon the pressure differential. In the case of the pump the pressure differential causes a torque opposing the motion, and in the case of the fluid motor in the direction of the motion. This torque will be called

Width, perpendicular to sketch, L.

FIG. 2

the ideal torque since it is the torque which would be required to drive the pump or would be developed by the motor if the fluid were frictionless and there were no mechanical friction causing resisting torques.

The torque T required to drive a pump or developed by a fluid motor may be expressed in terms of the torques just discussed as follows

$$\text{Pump:} \quad T = T_i + T_v + T_f + T_c \qquad [1a]$$

$$\text{Motor:} \quad T = T_i - T_v - T_f - T_c \qquad [1b]$$

where

- T_i is ideal torque due to pressure differential and physical dimensions of unit only
- T_v is resisting torque due to viscous shearing of fluid
- T_f is resisting torque, due to mechanical friction, which is directly proportional to pressure differential
- T_c is resisting torque due to mechanical friction which is constant

The delivery of a pump or fluid motor consists of the fluid which is trapped due to the geometrical features of the unit and bodily transported from the inlet to outlet, less that fluid which is returned from the discharge to the intake by the geometrical features of the unit, less that fluid which flows from discharge to intake by reason of the pressure differential (slip) and, in the case of pumped liquids, less the volume of entrained gases or vapor which are expanded at the intake and compressed at the discharge side of the pump. The ideal delivery is that full quantity which is trapped and transported from intake to discharge less that quantity which is returned from discharge to intake by virtue of the geometry of the unit.

The delivery of the pump or fluid motor may therefore be expressed in general terms as follows

$$\text{Pump:} \quad Q = Q_i - Q_s - Q_L \qquad [2a]$$

$$\text{Motor:} \quad Q = Q_i + Q_s \qquad [2b]$$

where

- Q_i is ideal delivery of unit due to its geometrical features only
- Q_s is slip flow caused by pressure differential
- Q_L is delivery loss due to entrained gas or vapor

The ideal torque and ideal delivery of a unit with zero clearance will be distinguished from those of a unit with clearances.

The ideal torque and ideal delivery of a unit with zero clearances may be expressed very simply by considering that the pressure differential acts upon a rotating surface of area A, which by its motion displaces the fluid in a positive manner.

The ideal torque T_i' due to the pressure differential may be expressed in terms of a force $(p_1 - p_2) A$, which acts at the distance r from the axis of rotation thus

$$T_i' = (p_1 - p_2) Ar \qquad [3]$$

where

- p_1 is pressure at intake
- p_2 is pressure at discharge
- A is projected area of moving surface on radial plane
- r is distance from center of pressure to axis of rotation

Similarly, the ideal delivery Q_i' may be expressed as the volume $Ar\omega$ swept out per unit time by the translation of the area A through the distance $r\omega$ thus

$$Q_i' = Ar\omega \qquad [4]$$

where

- ω is angular speed of rotation of rotor shaft
- A is area previously defined
- r is distance from axis of rotation to centroid of area A

It is apparent that the quantity Ar is identical in the two expressions given, when the pressure is constant over the area A. Situations in which the pressure is not constant over the area A will not be considered for the present.

Between the peripheral boundary of the area A and the housing lies a small clearance space through which slip flow occurs. The area of this opening in a radial plane must be considered in some manner in calculating ideal delivery and torque. Definitions to provide for this consideration will be given. Expressions for rate of flow and fluid-resisting torque will be developed on the basis of the assumption that the flow in these small passages is approximated sufficiently closely by the flow between infinite parallel flat plates.

We have defined the ideal delivery as the delivery which would represent the full geometrical delivery of the unit. It is apparent that the fluid which adheres to the moving boundary of the area A in a unit with clearances will result in the transport of fluid through the clearance space. The expression for ideal delivery, Q_i, may then be written

$$Q_i = Ar\omega + ar'\omega$$

or

$$Q_i = \alpha\omega \qquad [5]$$

where

- ar' is volume of fluid carried along by translation of periphery of area A through unit angular distance
- α is equal to $(Ar + ar')$

The quantity α is simply the ideal displacement of the pump or fluid motor per unit rotation of the rotor shaft. This quantity may be most easily determined experimentally by finding the delivery when the pressure differential across the unit is zero. Under these circumstances there can be no slip flow.

One may proceed in a similar manner to write an expression for the ideal torque T_i of a unit with clearance, and for sake of brevity we shall write immediately the expression

$$T_i = (p_1 - p_2)\alpha \qquad [6]$$

where all terms have been defined previously.

The use of the quantity α in the expression for torque as well as delivery may be justified quite rigorously for the case of the ideal pump or fluid motor in a rather simple manner. The mechanical power input to the pump or output of the motor is simply the

product of the torque and angular speed, and the hydraulic power output of the pump or input to the motor is the product of delivery and pressure differential. In an ideal unit the input and output must necessarily be equal. For the case of the ideal unit one may then write

$$T\omega = Q\,\Delta p$$

which in the nomenclature used previously is

$$(p_1 - p_2)\alpha\omega = \alpha\omega(p_1 - p_2)$$

This is obviously an identity as it should be if the quantity α may properly be used in this case. The justification for the use of α in the general case is beyond the scope of the present treatment; however, the case of laminar flow will be considered in detail since the mathematical development is relatively simple.

Slip and Torque Loss

Consider now the flow through a clearance space of the dimensions shown in Fig. 3(*a*). The lower plate moves at the speed $U = r\omega$, where r is the distance from the plate to the axis of rotation. The flow ΔQ_1 through the opening is due to both pressure drop and shear transport of the fluid and is assumed to be in the laminar range.

Referring to Fig. 3(*b*), we consider an element of the fluid at the distance y from the fixed plate, and of the dimensions dx, dy, b. The forces acting on this element are the pressure forces $(p + dp)\,b\,dy$ acting to the right and $p\,b\,dy$ to the left, the shear forces $\tau\,b\,dx$ acting to the left and $(\tau + d\tau)\,b\,dx$ to the right. Assuming steady flow, the acceleration of the element is zero, hence the equation of equilibrium is

$$[(p + dp) - p\,]\,b\,dy + [(\tau + d\tau) - \tau]\,bdx = 0$$

which reduces to

$$\frac{dp}{dx} = -\frac{d\tau}{dy}$$

Since the flow is between parallel plates the pressure gradient dp/dx will be constant. We may therefore integrate the equation just given and obtain

$$\tau = -\frac{dp}{dx}y + \tau_0$$

Newton's viscosity law may now be introduced to relate the shear stress to the velocity gradient

$$\tau = \mu\frac{du}{dy}$$

Substitution of this expression for τ yields the differential equation

$$\mu\frac{du}{dy} = \tau_0 - \frac{dp}{dx}y$$

This may be integrated to yield

$$\mu u = \tau_0 y - \frac{dp}{dx}\frac{y^2}{2} + C_1$$

The boundary conditions are

$$\text{at } y = 0,\quad u = 0$$

$$\text{at } y = c,\quad u = r\omega$$

It follows therefore that

$$C_1 = 0$$

and

$$\tau_0 = \frac{\mu r\omega}{c} + \frac{dp}{dx}\frac{c}{2}$$

The velocity u at any distance y from the fixed plate is then

$$u = \frac{r\omega y}{c} + \frac{1}{\mu}\frac{dp}{dx}\left[\frac{yc}{2} - \frac{y^2}{2}\right]$$

The total quantity of fluid flowing ΔQ_1 is given by

$$\Delta Q_1 = \int_0^c u\cdot b\cdot dy$$

or

$$\Delta Q_1 = \int_0^c \left\{\frac{r\omega y}{c} + \frac{1}{\mu}\frac{dp}{dx}\left[\frac{yc}{2} - \frac{y^2}{2}\right]\right\} bdy$$

and after integration

$$\Delta Q_1 = \left[\frac{r\omega c}{2} + \frac{dp}{dx}\frac{c^3}{12\mu}\right] b$$

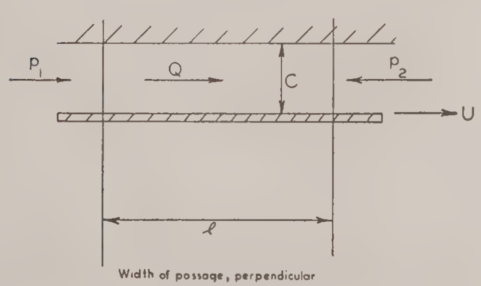
and upon substituting for dp/dx as follows

$$\frac{dp}{dx} = \frac{p_1 - p_2}{l}$$

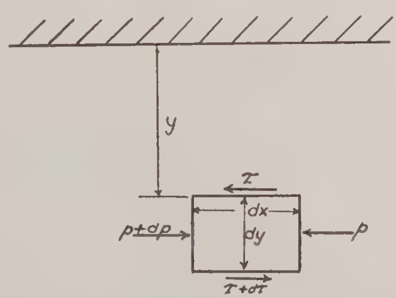
we have finally

$$\Delta Q_1 = \left[\frac{r\omega c}{2} + \frac{(p_1 - p_2)c^3}{12\mu l}\right] b \qquad [7]$$

The unit force τ due to viscous friction which retards the moving plate is given by the value of the shear stress at $y = c$



(*a*)



(*b*)

Fig. 3

$$\tau = -\frac{(p_1 - p_2)}{l}\frac{c}{2} + \frac{\mu r\omega}{c}$$

Since the total force F on the moving plate is

$$F = \tau lb$$

there results a torque ΔT_1 acting on the rotary element of the unit

$$\Delta T_1 = -\left[\frac{(p_1 - p_2)}{l}\frac{c}{2} - \frac{\mu r\omega}{c}\right] lbr \qquad [8]$$

There may be several passages through which the fluid will leak, hence it is necessary to consider the total effect on both torque and delivery. The fact that the torque ΔT_1 and flow ΔQ_1 are linear functions of the pressure difference and angular speed of the shaft permits the equations for net delivery and net torque to be written in the following form

$$Q = Q_i' + \Sigma Q_1$$

$$T = T_i' - \Sigma T_1$$

which upon substitution for ΣQ_1 and ΣT_1 yield

$$Q = Ar\omega + \Sigma\left[\frac{r\omega c}{2} + \frac{(p_1 - p_2)c^3}{12\mu l}\right] b$$

$$T = (p_1 - p_2)Ar + \Sigma\left[\frac{(p_1 - p_2)}{l}\frac{c}{2} - \frac{\mu r\omega}{c}\right] lbr$$

These may be rewritten in the forms

$$Q = \omega\left[Ar + \Sigma\frac{rcb}{2}\right] + \Sigma\frac{(p_1 - p_2)c^3b}{12\mu l} \qquad [9]$$

$$T = (p_1 - p_2)\left(Ar + \Sigma\frac{crb}{2}\right) - \Sigma\frac{\mu\omega lbr^2}{c} \qquad [10]$$

It is apparent that the quantity

$$\left[Ar + \Sigma\frac{rcb}{2}\right]$$

is the factor ω, and $\Sigma\frac{rcb}{2}$ is the quantity ar' previously defined. Also in accordance with previous definitions, the delivery loss due to pressure differential is the slip. It follows therefore that the slip ΔQ_s for a single passage is given by

$$\Delta Q_s = \frac{(p_1 - p_2)c^3b}{12}$$

and the torque loss ΔT_L by

$$\Delta T_L = \frac{\mu\omega lbr^2}{c}$$

Now since in any specific unit (pump or motor) the clearance c, length of path l, width of passage b, and radius to the passage r are different for the various elements of the passages surrounding the rotating element, the expressions for the total torque loss T_L, and total slip Q_s must be written in a more general form. This is done as follows

$$Q_s = \frac{\beta p}{\mu} \qquad [11]$$

$$T_L = k\mu\omega \qquad [12]$$

where

$$p = p_1 - p_2$$

It is readily shown that both k and β have the dimensions length to the third power and may be expressed thus

$$\beta = \Sigma\frac{c^3b}{12l}$$

$$k = \Sigma\frac{lbr^2}{c}$$

In order to simplify the equations and without materially decreasing their significance, the torque loss T_L will be considered to include that loss in torque which is due to entrance and exit losses since in the case of laminar flow, these will be nearly proportional to the product of viscosity and angular speed.

Detailed equations for torque, delivery, power input, power output and efficiencies will now be developed for the three performance ranges defined previously.

Torque and Delivery Range 1

In this range of performance the slip is proportional to the square root of the pressure differential and practically independent of the viscosity. The torque losses are principally mechanical in nature, although the fluid resistance will vary with the square of the speed of rotation and will be practically independent of the viscosity of the fluid. The expressions for torque and delivery may now be written, taking into consideration the nature of the slip and resisting torques, thus

$$\text{Pump:} \quad T = \epsilon p\alpha + k\rho\omega^2R^2 + T_c \qquad [13]$$

$$Q = \alpha\omega - \frac{\beta}{R}\sqrt{\frac{p}{\rho}} - Q_L \qquad [14]$$

$$\text{Motor:} \quad T = \epsilon p\alpha - k\rho\omega^2R^2 - T_c \qquad [15]$$

$$Q = \alpha\omega + \frac{\beta}{R}\sqrt{\frac{p}{\rho}} \qquad [16]$$

where

- T is torque input or output, ft-lb
- p is pressure difference, psf
- T_c is torque due to mechanical friction independent of pressure, ft-lb
- α is ideal displacement, cu ft per radian
- k is a coefficient with dimensions, cu ft
- μ is viscosity of fluid, slugs per ft-sec
- ω is angular speed of shaft, radian per sec
- Q is delivery, cfs
- β is a coefficient with dimensions, cu ft
- ρ is density of fluid, slugs per cu ft
- Q_L is loss in delivery in cu ft per sec due to vaporization of liquid, or liberation of entrained gas at intake
- R is a characteristic radius of the unit, ft
- ϵ is given by the following expression using positive sign for pump and negative sign for motor:

$$\epsilon p\alpha = p\alpha \pm T$$

or

$$\epsilon = 1 \pm \frac{T_f}{\alpha p}$$

T_f is mechanical friction torque which is proportional to pressure differential

Now since T_f is proportional to the pressure differential p, one may write

$$T_f = mp$$

and it follows that

$$\epsilon = 1 \pm \frac{m}{\alpha}$$

which is a constant for any one pump or motor.

Torque and Delivery Ranges 2 and 3

In a similar manner expressions for torque and delivery for both pump and motor in performance ranges 2 and 3 may now be written, using the nomenclature employed previously, as follows

$$\text{Pump:}\quad T = \epsilon p\alpha + k\mu\omega + T_c \quad [17]$$

$$Q = \alpha\omega - \frac{\beta p}{\mu} - Q_L \quad [18]$$

$$\text{Motor:}\quad T = \epsilon p\alpha - k\mu\omega - T_c \quad [19]$$

$$Q = \alpha\omega + \frac{\beta p}{\mu} \quad [20]$$

The distinction between range 2 and range 3 comes in the variation of the viscosity with speed in range 3, and the difference in order of magnitude of the last two terms in the equation for pump delivery. In range 2 the torque shows a straight-line variation with speed, due to the constancy of the viscosity. Also in range 2 the delivery loss Q_L is negligible. In range 3 the torque does not change as rapidly with speed as would be indicated by a constant value of the viscosity, and the slip is either negligible compared with Q_L or shows an increase with the speed corresponding to the decrease in viscosity which is characteristic of this situation.

Power

Equations for power output and power input may be written on the basis of the fundamental expressions

Pump: Power output $= P_0 = Qp$
Power input $= P_i = T\omega$

Motor: Power output $= P_0 = T\omega$
Power input $= P_i = Qp$

Substitution of the previously given expressions for torque and delivery yields the following equations

Range 1

$$\text{Pump:}\quad P_0 = p\alpha\omega\left[1 - \frac{\beta\sqrt{p/\rho}}{R\alpha\omega} - \frac{Q_L}{\alpha\omega}\right] \quad [21]$$

$$P_i = p\alpha\omega\left[\epsilon + \frac{k\omega^2R^2\rho}{p\alpha} + \frac{T_c}{p\alpha}\right] \quad [22]$$

$$\text{Motor:}\quad P_0 = p\alpha\omega\left[\epsilon - \frac{k\omega^2R^2\rho}{p\alpha} - \frac{T_c}{p\alpha}\right] \quad [23]$$

$$P_i = p\alpha\omega\left[1 + \frac{\beta\sqrt{p/\rho}}{\alpha\omega R}\right] \quad [24]$$

Ranges 2 and 3

$$\text{Pump:}\quad P_0 = p\alpha\omega\left[1 - \frac{\beta p}{\mu\alpha\omega} - \frac{Q_L}{\alpha\omega}\right] \quad [25]$$

$$P_i = p\alpha\omega\left[\epsilon + \frac{k\mu\omega}{p\alpha} + \frac{T_c}{p\alpha}\right] \quad [26]$$

$$\text{Motor:}\quad P_0 = p\alpha\omega\left[\epsilon - \frac{k\mu\omega}{p\alpha} - \frac{T_c}{p\alpha}\right] \quad [27]$$

$$P_i = p\alpha\omega\left[1 + \frac{\beta p}{\mu\alpha\omega}\right] \quad [28]$$

Efficiency

In the case of a motor, the ratio of the actual torque to the theoretical torque may be termed the torque efficiency E_T; and the ratio of the theoretical delivery to the actual delivery may be termed the volumetric efficiency E_v. The reciprocals of these quantities are the corresponding efficiencies for the pump. These may be written as follows

Range 1

$$\text{Pump:}\quad E_T = \frac{p\alpha}{T} = \frac{1}{\epsilon + \dfrac{k}{\alpha}\dfrac{\omega^2R^2\rho}{p} + \dfrac{T_c}{p\alpha}} \quad [29]$$

$$E_v = \frac{Q}{\alpha\omega} = 1 - \frac{\beta}{\alpha}\frac{\sqrt{p/\rho}}{\omega R} - \frac{Q_L}{aw} \quad [30]$$

$$\text{Motor:}\quad E_T = \frac{T}{p\alpha} = \epsilon - \frac{k}{\alpha}\frac{\omega^2R^2\rho}{p} - \frac{T_c}{p\alpha} \quad [31]$$

$$E_v = \frac{\alpha\omega}{Q} = \frac{1}{1 + \dfrac{\beta}{\alpha}\dfrac{\sqrt{p/\rho}}{\omega R}} \quad [32]$$

Ranges 2 and 3

$$\text{Pump:}\quad E_T = \frac{p\alpha}{T} = \frac{1}{\epsilon + \dfrac{k}{\alpha}\dfrac{\mu\omega}{p} + \dfrac{T_c}{p\alpha}} \quad [33]$$

$$E_v = \frac{Q}{\alpha\omega} = 1 - \frac{\beta}{\alpha}\frac{p}{\mu\omega} - \frac{Q_L}{aw} \quad [34]$$

$$\text{Motor:}\quad E_T = \frac{T}{p\alpha} = \epsilon - \frac{k}{\alpha}\frac{\mu\omega}{p} - \frac{T_c}{p\alpha} \quad [35]$$

$$E_v = \frac{\alpha\omega}{Q} = \frac{1}{1 + \dfrac{\beta}{\alpha}\dfrac{p}{\mu\omega}} \quad [36]$$

It is convenient to make the following simplification in nomenclature
Let

$$\phi_1 = \frac{\rho\omega^2R^2}{p}$$

in range 1, and

$$\phi = \frac{\mu\omega}{p}$$

in ranges 2 and 3.

The over-all efficiency E is now defined as the power output of the unit divided by the power input; thus

$$E = \frac{P_0}{P_i}$$

The expressions for this over-all efficiency may be written as follows, provided we substitute in each case the appropriate term ϕ or ϕ_1 for the parameters cited previously

RANGE 1

$$\text{Pump:}\quad E = \frac{1 - \dfrac{\beta}{\alpha\sqrt{\phi_1}}}{\epsilon + \dfrac{k\phi_1}{\alpha} + \dfrac{T_c}{p\alpha}} \quad [37]$$

$$\text{Motor:}\quad E = \frac{\epsilon - \dfrac{k\phi_1}{\alpha} - \dfrac{T_c}{p\alpha}}{1 + \dfrac{\beta}{\alpha\sqrt{\phi_1}}} \quad [38]$$

RANGES 2 AND 3

$$\text{Pump:}\quad E = \frac{1 - \dfrac{\beta}{\alpha\phi} - \dfrac{Q_L}{\alpha\omega}}{\epsilon + \dfrac{k\phi}{\alpha} + \dfrac{T_c}{p\alpha}} \quad [39]$$

$$\text{Motor:}\quad E = \frac{\epsilon - \dfrac{k\phi}{\alpha} - \dfrac{T_c}{p\alpha}}{1 + \dfrac{\beta}{\alpha\phi}} \quad [40]$$

It is pertinent to note that significant simplification of the equations for range 2 may be effected by noting the relative order of magnitude of the terms involved in the various equations just given. When operating in this range at fairly high pressures, e.g., over 300 psi, the term $\dfrac{T_c}{p\alpha}$ is frequently found to be negligible in comparison with $k\phi/\alpha$ and ϵ. Also by definition, the term $Q_L/(\alpha\omega)$ is small in this range compared with $\beta/(\alpha\phi)$. The simplified equations in range 2 then reduce to

$$\text{Pump:}\quad E_v = 1 - \frac{\beta}{\alpha\phi} \quad [41]$$

$$E_T = \frac{1}{\epsilon + \dfrac{k\phi}{\alpha}} \quad [42]$$

$$E = \frac{1 - \dfrac{\beta}{\alpha\phi}}{\epsilon + \dfrac{k\phi}{\alpha}} \quad [43]$$

$$\text{Motor:}\quad E_v = \frac{1}{1 + \dfrac{\beta}{\alpha\phi}} \quad [44]$$

$$E_T = \epsilon - \frac{k}{\alpha}\phi \quad [45]$$

$$E = \frac{\epsilon - \dfrac{k\phi}{\alpha}}{1 + \dfrac{\beta}{\alpha\phi}} \quad [46]$$

It is immediately apparent that under these circumstances the performance of the pump or fluid motor may be expressed in terms of dimensionless ratios descriptive of the geometry of the unit, namely, k/α and β/α; and the dimensionless parameter expressed as $\phi = \dfrac{\mu\omega}{p}$, which describes the conditions of operation.

Consideration of the equation for over-all efficiency E in this case leads to the immediate conclusion that there is a particular value of ϕ which corresponds to the maximum efficiency of the unit. The value of ϕ which corresponds to the maximum efficiency may readily be obtained by maximizing the equations for over-all efficiency, considering ϕ as the only variable. The resulting values of ϕ are given by

$$\text{Pump:}\quad \phi_m = \frac{\beta}{\alpha}\left[1 + \sqrt{1 + \frac{\epsilon\alpha^2}{\beta k}}\right] \quad [47]$$

$$\text{Motor:}\quad \phi_m = \frac{\beta}{\alpha}\left[-1 + \sqrt{1 + \frac{\epsilon\alpha^2}{\beta k}}\right] \quad [48]$$

where ϕ_m is the value of ϕ corresponding to E_{max}.

The corresponding values of E_{max} are

$$\text{Pump:}\quad E_m = \frac{1}{\epsilon_1\left[1 + 2\theta + 2\sqrt{\theta(1+\theta)}\right]} \quad [49]$$

$$\text{Motor:}\quad E_m = \epsilon_2\left[1 + 2\theta - 2\sqrt{\theta(1+\theta)}\right] \quad [50]$$

where

$$\theta = \frac{k\beta}{\epsilon\alpha^2}$$

These expressions for efficiency are shown graphically in Fig. 4

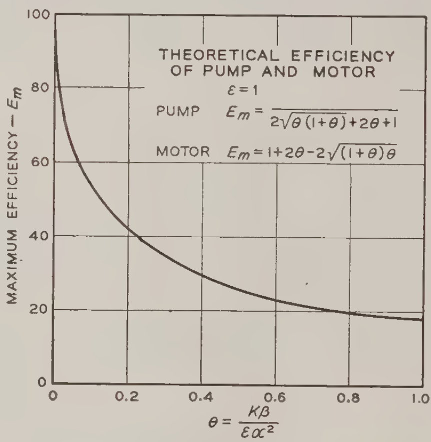


FIG. 4

for the case of $\epsilon_1 = \epsilon_2 = 1$. It is readily shown that motor and pump efficiencies are identical in this case. It is immediately apparent that the maximum efficiency is a function of θ and ϵ only, and that these in turn are determined by the geometry of the unit only.

Since the concept of torque efficiency is somewhat unfamiliar, it is well to point out the relationship which exists between the volumetric efficiency E_v, the torque efficiency E_T, and the over-all efficiency E. By definition the following expressions may be written for a pump

$$E_v = \frac{Q}{Q_i}$$

$$E_T = \frac{T_i}{T}$$

$$E = \frac{Qp}{T\omega}$$

The product of E_v and E_T may then be obtained thus

$$E_vE_T = \frac{QT_i}{Q_iT}$$

Substituting the following quantities for ideal torque and ideal delivery

$$T_i = p\alpha \qquad Q_i = \alpha\omega$$

we obtain

$$E_vE_T = \frac{Qp}{T\omega}$$

from which it may be concluded that the product of the volumetric efficiency and the torque efficiency is equal to the over-all efficiency. A check of the equations given previously for the various cases reveals that they are in agreement with this general conclusion, and a similar demonstration may be made for the case of a motor.

Local Heating of Liquid

It has been pointed out that the reduction in viscosity by the heating developed in the shearing action on the fluid in the narrow passage between rotor and housing is a most important feature of the performance in range 3 (44).[2] An equation describing the important characteristics of this phenomenon will be derived.

The narrow passage, shown schematically in Fig. 3(*a*), will be used as the basis of this development. The work done on the fluid which flows through the passage is equal to the product of the force exerted by the moving plate on the fluid and the speed at which the plate moves. It will be assumed that this energy which is supplied to the fluid is dissipated entirely in raising the temperature of the fluid. The following expressions for work done and heat absorbed may be written

$$\text{Work done on fluid} = \left[\mu\frac{r\omega}{c} + \frac{(p_1 - p_2)c}{2}\right]r\omega bl$$

$$\text{Heat absorbed by fluid} = c_sQw\Delta T$$

where

c_s is heat required to raise temperature of 1 lb of liquid 1 deg F
w is weight of 1 cu ft of liquid
ΔT is rise of temperature in deg F of liquid in distance l
μ is coefficient of viscosity of liquid in slugs per ft-sec
Q is rate of flow of liquid through narrow opening relative to moving plate, cfs

All other terms have been defined previously or are defined in Fig. 3(*a*).

Equating these rates of energy supply and absorption, assuming no heat loss to the surroundings, introducing the mechanical equivalent of heat J and the value of Q from Equation [7], we have

$$J\,c_s\left[\frac{r\omega c}{2} + \frac{(p_1 - p_2)c^3}{12\mu l}\right]bw\Delta T = \left[\frac{\mu r\omega}{c} + \frac{(p_1 - p_2)c}{2l}\right]r\omega bl$$

Suitable algebraic manipulations lead to the following expression for the temperature rise

$$\Delta T = \frac{\mu l r\omega}{c_sc^2wJ}\left[2 + \frac{1}{\frac{1}{4} + \frac{3r\omega\mu l}{2c^2(p_1 - p_2)}}\right] \ldots\ldots [51]$$

It is readily determined that the expression contained within the brackets must have a value between 2 and 6. For purposes of simplification it is assumed that a constant value of 4 for the quantity within the bracket will yield results sufficiently reliable for practical use.

While it is necessary to calculate the temperature rise in the slip passage, it is further required that the change in viscosity be determined. For purposes of calculation the viscosity μ of the liquid is approximated by the expression

$$\mu = \mu_0e^{-\gamma T} \ldots\ldots [52]$$

where

μ_0 is viscosity at $T = 0$
γ is a constant for any particular liquid
e is base of natural logarithms

Considering now the change dT in the temperature along a length dx of the passage, we may rewrite Equation [51] upon using the value 4 for the bracket thus

$$\frac{dT}{\mu_0e^{-\gamma T}} = \frac{4r\omega}{c_swc^2J}dx$$

This may be integrated to yield

$$\mu = \frac{B\mu_1}{\mu_1x + B} \ldots\ldots [53]$$

where

$$B = \frac{c_swc^2J}{4\gamma r\omega}$$

and x is the distance along the passage to the point at which the viscosity is μ. The quantity μ_1 is the viscosity at entrance to the pump or motor.

The average value of the viscosity in the passage is of particular significance. Denoting this average value by μ_{avg}, it may be calculated as follows

Define

$$\mu_{avg} = \frac{\int_0^l \mu dx}{l}$$

then

$$\mu_{avg} = \frac{1}{l}\int_0^l \frac{B\mu_1}{\mu_1x + B}\cdot dx$$

Integration and simplification yield

$$\mu_{avg} = \frac{B}{l}\log_e\left[\frac{\mu_1l}{B} + 1\right] \ldots\ldots [54]$$

This may be put into a more significant form by dividing both sides of the equation by μ_1 the initial viscosity of the liquid

$$\frac{\mu_{avg}}{\mu_1} = \frac{B}{\mu_1l}\log_e\left[\frac{\mu_1l}{B} + 1\right]$$

which may be rewritten in the following form

$$\frac{\mu_{avg}}{\mu_1} = \frac{c_swc^2J}{4\gamma r\omega l\mu_1}\log_e\left[\frac{4\gamma r\omega l\mu_1}{c_swc^2J} + 1\right] \ldots\ldots [55]$$

The variation of μ_{avg} with angular speed ω with constant pressure differential is particularly significant. When the angular

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

speed is zero the ratio $\frac{\mu_{avg}}{\mu_1}$ reduces to the form 0/0 which may be shown mathematically to have the value 1, as would be expected from purely physical considerations. As the angular speed increases the ratio $\frac{\mu_{avg}}{\mu_1}$ approaches zero. The viscous torque may be expressed in terms of the reduced viscosity μ_{avg}

$$T_v = k\mu_{avg}\omega$$

and upon substituting the expression for μ_{avg}

$$T_v = \frac{kc_s wc^2 J}{4\gamma rl} \log_e \left[\frac{4\gamma rl\omega\mu_1}{c_s wc^2 J} + 1\right] \ldots\ldots\ldots [56]$$

which shows a continually increasing value of the torque T_v as the speed increases. However, T_v will, under these circumstances, always be less than $k\mu_1\omega$, the torque which would be encountered if the viscosity remained at its initial value μ_1.

A detailed analysis of the problem of the effect of the reduction in pressure in the neighborhood of a pump inlet on delivery has been given by Pigott (42, 44), for the case of volatile low-viscosity liquids. The effect of viscous resistance in reducing inlet side pressures and thereby causing loss in delivery due to the expansion of entrained air, may be analyzed in the elementary manner to be discussed.

Viscosity and Entrained Gases

When pumping extremely viscous liquids the resistance to flow causes excessive reductions in pressure in the intake passages. Entrained gas will expand in low-pressure regions in the neighborhood of the inlet and fill to a greater or lesser extent the volume intended for the transport of liquid from the intake to the discharge of the pump. When this gas reaches the discharge side of the pump its volume is reduced due to the high pressure encountered (39, 42, 44, 45).

The volume of entrained gas per unit volume of liquid is V_g, at the inlet pressure p_1, and this volume increases to V_g', due to the reduction in pressure as the liquid enters the trapping space in the pump. Then the expanded gas and sufficient oil to fill the displacement volume of the pump are transported to the high-pressure side of the pump where the volume of the gas is reduced to V_g''. If the flow in the intake passages and adjacent to the rotor is considered to be as indicated in Fig. 5, and the flow is treated as

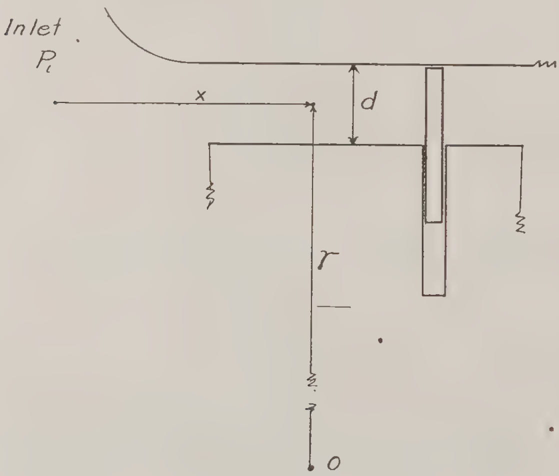

Fig. 5

laminar flow between parallel flat plates, one may state that to fill the space behind the advancing vane a quantity of liquid $bdr\omega$ must be drawn into the space per unit time. Now making use of Equation [7] which describes the flow between parallel flat plates, and setting the rate of flow equal to $bdr\omega$ we have

$$bdr\omega = \left[\frac{r\omega d}{2} + \frac{(p_1 - p)d^3}{12\mu x}\right] b$$

This may be solved for the pressure p and yields

$$p = p_1 - 6\mu\omega \frac{rx}{d^2} \ldots\ldots\ldots\ldots\ldots [57]$$

where

p is pressure at any point within inlet passage, psf
x is distance in feet from intake to point at which p is measured
r is radial distance in feet to point at which p is measured
d is radial distance in feet from rotor to housing

Equation [57] may be put in dimensionless form

$$\frac{p}{p_1} = 1 - \frac{6rx}{d^2}\frac{\mu\omega}{p_1} \ldots\ldots\ldots\ldots\ldots [58]$$

The loss in delivery will be caused by the expansion of the entrained gas of volume V_g. Assuming this expansion takes place isothermally, we have

$$\frac{V_g}{V_g'} = \frac{p}{p_1}$$

where

V_g is volume of entrained gas at intake pressure p_1 per unit volume of liquid
V_g' is expanded volume of entrained air at pressure p per unit volume of liquid

As the liquid and gas progress to the region of high pressure a reduction in volume of the gas to V_g'' is accomplished. Assuming isothermal compression, we may write

$$\frac{V_g''}{V_g} = \frac{p_1}{p_2}$$

where p_2 is the pressure at the discharge of the pump. The loss in volume V_L per unit volume of liquid due to expansion of the gas is simply the difference between V_g' and V_g''. Expressing this as an equation, we have

$$V_L = V_g' - V_g'' = \frac{V_g p_1}{p} - \frac{V_g p_1}{p_2}$$

and upon substituting for p_1/p there results

$$V_L = V_g \left[\frac{1}{1 - \frac{6rx}{d^2}\frac{\mu\omega}{p_1}} - \frac{p_1}{p_2}\right] \ldots\ldots\ldots [59]$$

The quantity V_L represents, therefore, the proportion of the displacement which is lost at a point located x feet from the inlet due to expansion of entrained gas. The quantity V_g is simply the ratio of the volume of entrained gas to the volume of liquid at intake pressure.

It will be noted that the loss in displacement V_L is associated with the distance x. In order to obtain the total loss in displacement it is necessary to sum up the losses V_L, at each point x, over the entire region involved.

Although this equation is based on gross oversimplifications it indicates the nature of the variables which describe the phe-

nomenon, and it is evident that greater refinements will lead to expressions containing the same parameters $\frac{\mu\omega}{p_1}$ and $\frac{p_1}{p_2}$ and differing only in algebraic form. Summation of the losses in displacement will again change only the form of the expression and not the quantities involved. Use will be made of this observation in analyzing experimental data.

Experimental Data for Hydraulic Motor

Data obtained in the test of a conventional gear pump operating as a hydraulic motor are presented in dimensionless form in Figs. 6, 7, 8, and 9. The tests were performed on a pump with a theoretical displacement of 0.283 gal per 100 revolutions. Oils with viscosities ranging from 200 SSU to 6000 SSU were used. Pressures ranged from 180 psi to 600 psi. The speed, torque output, capacity, temperature of oil and pressure differences were observed and the viscosity of the oil determined at various temperatures.

In Fig. 6 the torque efficiency is shown as a function of the dimensionless parameter $\frac{\mu\omega}{p}$. In Fig. 7 the reciprocal of the volumetric efficiency is shown as a function of the dimensionless parameter $\frac{\mu\omega}{p}$. In Fig. 8 the reciprocal of the volumetric efficiency is again shown as a function of $\frac{\mu\omega}{p}$, but the abscissa is in this case $\left(\frac{\mu\omega}{p}\right)^{-1}$. In Fig. 9 the over-all efficiency is shown as a function of $\frac{\mu\omega}{p}$. The quantities β and k are evaluated, assuming the quantity T_f to be negligible, from the data shown in Figs. 6, 7, 8, and 9. The solid line in Fig. 9 is computed on the basis of these values.

In Figs. 11 and 12 are shown the plottings of experimental data on the performance of a cam-type rotary pump operating in range 3. The plotting in Fig. 11 of torque input as a function of speed is with constant pressure differential and approximately constant viscosity at intake. In Fig. 12 is shown a plotting of loss in delivery as a function of the parameter $\frac{\mu\omega}{p_1}$, where ω is the speed of rotation of the shaft, for the same pump operating with a wide range of intake pressures and viscosity.

Evaluation of Theory and Data

The data may be considered to provide a striking confirmation of the predictions of the theory concerning the performance characteristics of a conventional gear pump operating as a motor in performance range 2 and of the effect of high viscosity on a pump operating in range 3. The dimensionless plotting of the torque efficiency as a function of the parameter $\frac{\mu\omega}{p}$, shown in Fig. 6, is characterized by a close grouping of the points about a straight line as predicted by theory. The deviation of a small number of points representing runs at the lowest pressure used, namely, 180 psi, indicating as they do a considerable magnitude of the factor $T_c/(p\alpha)$, might well provide material for an interesting study of the pump mechanism. The volumetric efficiency plotted in reciprocal form in Fig. 8, shows an excellent approach to the straight line predicted by the theory. In Fig. 9 points representing data on the over-all efficiency show excellent agreement with the curve calculated from the values of β, k, and ϵ, which were evaluated by means of the previous plottings.

As predicted by Equation [48], the maximum efficiency occurs very close to $\frac{\mu\omega}{p} = 69 \times 10^{-7}$. The peak efficiency with a few exceptions lies in the range 58 to 67 per cent compared with the

The use of the dimensionless performance curves in evaluating a particular design may now be studied in some detail. In Fig. 10 are illustrated the particular features of these plottings which make them extremely powerful tools in analyzing performance and planning improvements. For simplicity and ease of comparison with the experimental data, the case of a hydraulic motor is considered.

In Fig. 10(a) is shown a graphical representation of the discharge characteristics of the unit on the basis of Equation [36] which may be inverted for this purpose

$$\frac{Q}{\alpha\omega} = 1 + \frac{\beta}{\alpha}\frac{p}{\mu\omega}$$

This plots as a straight line on rectangular co-ordinate paper, with $\dfrac{Q}{\alpha\omega}$ as ordinate and $\dfrac{p}{\mu\omega}$ as abscissa. The intercept on the vertical axis at $\dfrac{p}{\mu\omega} = 0$ is necessarily unity, since $\dfrac{p}{\mu\omega} = 0$ corresponds to either zero pressure difference, infinite speed, or infinite viscosity, each of which obviously necessitates zero slip or $\dfrac{Q}{\alpha\omega} = 1$. The slope of the curve is $\dfrac{\beta}{\alpha}$, a physical characteristic of the unit which is a dimensionless ratio. This ratio would be given, if all slip passages corresponded to the idealized case in Fig. 3(a), by the quantity

$$\frac{\beta}{\alpha} = \Sigma\,\frac{c^3b}{12lcrb} = \Sigma\,\frac{c^2}{12lr}$$

where r is the distance from the moving plate to the axis of rotation. In the case of an actual unit this factor $\dfrac{\beta}{\alpha}$ will depend, as indicated, upon the clearances, lengths of flow paths, and distances to the axis of rotation, for all the passages through which leaks take place.

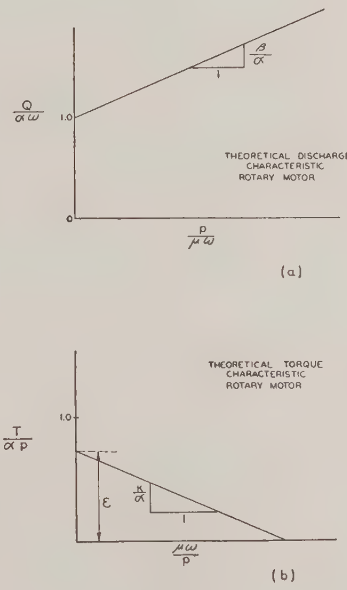

FIG. 10

Similarly in the plotting of torque efficiency $\dfrac{T}{p\alpha}$ versus $\dfrac{\mu\omega}{p}$ a straight line is expected, since the simplified expression obtained from Equation [35] for torque efficiency is

$$\frac{T}{\alpha p} = \epsilon - \frac{k}{\alpha}\frac{\mu\omega}{p}$$

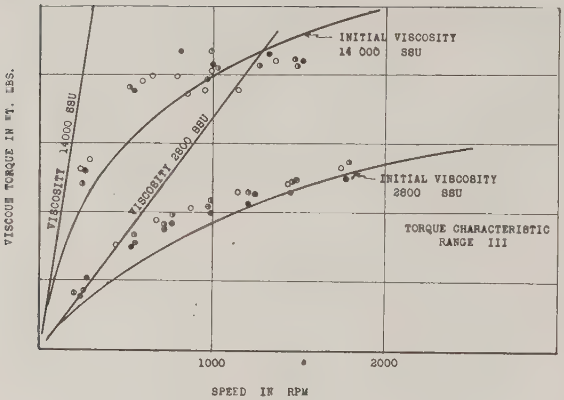

FIG. 11

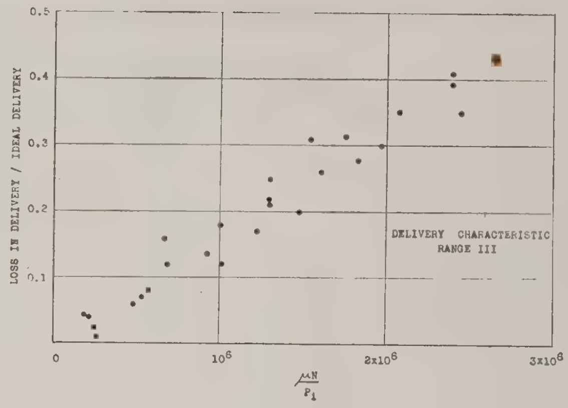

FIG. 12

Deviations of the actual performance from that indicated by the theory will occur if the clearances or alignment of the parts of the unit change, or if the nature of the flow in the unit is different from that assumed, e.g., turbulent rather than laminar. Such changes in clearances and alignment may be caused by pressure increase or decrease or by centrifugal effects due to speed changes.

If in a test the viscosity and pressure difference are held constant at certain values during successive series of runs, one would expect the data to plot as series of points forming straight lines on both types of plottings, shown in Fig. 10. Deviations from the theoretical form of the plots may be of the nature to be indicated and have the significance stated.

If the plotted data give points forming straight lines but the slopes vary from series to series this variation in slope must be caused by changes in the geometrical features of the unit by the pressure, since the viscosity was held constant.

If the curves are not straight lines the reason may be either that the flow is not in the assumed regime, e.g., it is assumed laminar but actually proves to be turbulent, or the geometrical features of the unit change with speed due to centrifugal effects.

If the plottings are parallel straight lines but the intercepts vary from series to series, the cause must be sought in changes in geometry due to pressure resulting in a change in mechanical friction.

The significance of the parameter $\frac{\mu\omega}{p}$ is of note. Since the maximum efficiency occurs at a specific value of the parameter $\frac{\mu\omega}{p}$, it is obvious that this maximum may be attained with various combinations of μ, ω, and p. For example, use of an oil of great viscosity will result in maximum efficiency at very low speed for a given pressure difference. The corresponding speed at a high pressure difference will be proportionately greater. Use of an oil of low viscosity will result in maximum efficiency at higher speeds for the same pressure difference.

A general characteristic of hydraulic units operating with laminar flow is apparent from Equations [49] and [50] in that efficiency of the unit operated as a pump will always be the same as the efficiency of the unit operated as a motor, if $\epsilon = 1$. The difference in efficiency in the two cases will never be very great unless the mechanical friction is greatly different in the two cases.

Specific details of the experimental data will be analyzed, keeping in mind the general principles previously set forth.

The plotting of the data in Fig. 6 makes possible a determination of the coefficient k since $\left(-\frac{k}{\alpha}\right)$ is the slope of the straight line which is taken as a fair representation of the trend of the data. Deviations from the straight line may be due to at least two specific causes, as follows:

1 Local heating of the oil due to energy dissipation causes a local viscosity far different from that measured at the discharge of the unit, thus placing operation in range 3 rather than in range 2 as assumed.

2 Variations in orientation and clearances of the elements of the unit and their lubrication during the runs cause changes in both the mechanical friction and the viscous resistance.

The value of ϵ is given by the value of E_T at $\frac{\mu\omega}{p} = 0$. The plotting of Fig. 7 shows an asymptotic approach of $\frac{Q}{\alpha\omega}$ to the value unity as $\frac{\mu\omega}{p}$ increases as would be expected from the theory. Fig. 8 gives the necessary information to evaluate β since the slope of the solid line is $\frac{\beta}{\alpha}$.

The interpretation of the factor ϵ is important since it represents a major element in the design of hydraulic units. The value of ϵ appears to be essentially a constant for much of the data and its nature as a factor, analogous to a coefficient of kinetic friction describing mechanical friction, appears to be confirmed since the coefficient of kinetic friction is practically independent of speed, pressure, and viscosity. Certain deviations from the expected are evident in the data, especially for runs at 180 psi, which might be interpreted as a change in ϵ but may better be explained on the basis of the neglected term of Equation [35]. The experimentally determined value of 0.80 for ϵ indicates a 20 per cent loss through mechanical friction in this particular pump. A considerable improvement in performance might be effected by a suitable change in design.

It is also pertinent to point out that Equation [50] indicates an efficiency, which might well be termed the hydraulic efficiency, of better than 78 per cent, if $\epsilon = 1$, for all values of θ less than approximately 0.02. It is clear from a consideration of the elements of the pump geometry that a value of θ in excess of 0.02 is a practical impossibility in even a poorly conceived design. The value of θ for the pump studied was approximately 0.013, which corresponds to an efficiency of approximately 79 per cent.

A study of the equations developed reveals the effect of changes in the physical dimensions of the unit which might be made to alter the performance characteristics by changing either clearance or displacement or both.

It is apparent that an increase in clearance results in

1 Decrease in k.
2 Increase in β.

An increase in α results in

1 Increase in torque.
2 Increase in capacity.

However, it is pertinent to point out that a detailed analysis of the performance of a rotary pump as influenced by its geometrical features reveals that for any given value of rotor length and rotor diameter there is an optimum value for the clearance for best performance in range 2. It may be shown also that the performance, solely from a hydraulic standpoint, improves as the ratio of rotor length to rotor diameter is increased. There is of course an obvious limitation on this increase imposed by shaft deflection.

The data for pump performance in range 3 reveals a number of interesting features. The plotting of torque as a function of speed shows the characteristic decrease in slope of the curve as the speed increases. The solid lines indicating the torque which would be expected for the given intake viscosity, if there were no local heating, were obtained from experiments at lower viscosities. The solid curved line for the case of initial viscosity of 2800 SSU was calculated to pass through one of the experimentally determined points thus evaluating the constant $\frac{B}{l}$ of Equation [54] for the pump. The curved solid line for the initial viscosity of 14,000 SSU was then calculated using the same constant. It is apparent that the agreement with the experimental data is as good as could be expected considering the approximate nature of the theory and the oversimplification involved in it.

The relationship between loss in delivery and the parameter $\frac{\mu\omega}{p_1}$ is particularly interesting when it is realized that the plotted points represent a wide variation in viscosity, speed, and intake pressure. The effect of discharge pressure has been neglected in the plotting, hence one may expect that the scattering of points may well be due to some extent to this neglected factor.

A detailed analysis of pump-intake geometry should lead to useful equations predicting the effect on performance in so far as lost delivery with high viscosity is concerned.

Conclusions

On the basis of the experimental data the following conclusions may be derived:

1 Predictions of the theory are borne out.

2 Experimental data may be presented in a compact dimensionless form.

3 Losses in efficiency may be traced readily and the causes determined.

4 Hydraulic and mechanical factors in performance are shown in proper perspective and may be analyzed separately.

5 Performance of units with fluids giving flows in the turbulent range may be expected to be subject to effective study by means of this theory and method of analysis of data.

Air-Gas Ratio Control Applied to Nonatmospheric-Pressure Furnaces

By H. C. McRae,[1] Cleveland, Ohio

For reasons of economy and efficiency, in the burning of fuel gases in industrial furnaces it is essential to maintain the air-gas ratio at approximately the correct point for perfect combustion. Furthermore it is important to control the ratio of air flow to gas flow because of the effect of burned gases or atmosphere upon material being heat-treated. The author discusses in detail the various control processes available, the equipment developed for the purpose, and analyzes the several control circuits, basing the work on the laws of low-pressure gas flow or noncompressible flow.

Introduction

In the process of burning fuel gases in the combustion chamber of an industrial furnace, usually the approximate amount of air required for perfect combustion is introduced along with the gas in some form or another. For the purpose of fuel economy alone, at elevated temperatures, the air-gas ratio must be held close to the proper amount. Aside from this reason, it is important to control the ratio of air flow to gas flow because of the effect of the burned gases or atmosphere upon the material being heat-treated. Sometimes the reaction produced by a small amount of excess air is desirable, while in other applications a deficiency of air may produce the desired result. Of course the air may be introduced as primary air, that is, air which is mixed with the gas before reaching the combustion chamber, or as secondary air which mixes with the gas as it is burning. "Free" air from the atmosphere is often used for a source of secondary air. In this case the air enters directly through ports in the furnace wall because of furnace draft, or this air may be induced by the momentum of the mixture of primary air and gas through a burner port which is discharging into an opening in the furnace wall. The quantity of free secondary air is difficult to control because it is so easily affected by small changes in furnace pressure and therefore that application is excluded from this discussion.

For manual or automatic control of temperature a variable heat input is required. In batch-type furnaces a high heat input is used to heat up a cold furnace or to heat up a cold load. As the desired temperature is reached the heat input is decreased until it just balances the losses of heat through the furnace wall and out of the flue. In continuous furnaces a variable heat input is used to maintain a variable loading at a constant temperature. Variable heat flow means variable gas- and air-flow rates. Maintenance of the correct air-gas ratio with variable demand of heat flow and with variable furnace-pressure conditions, then, is the subject under discussion.

The amount of air required for perfect combustion of natural gases is approximately 10 parts to 1 of gas and for manufactured gases is about 5 parts to 1 of gas. These two gases are the ones most commonly used, although there are others which require more air and some which require less air. Air is therefore considered to be the principal fluid because of its greater quantity. This means that the energy required for the mixing process and delivery of the mixture to the furnace can best be obtained from the air stream rather than from the gas stream. Another reason for considering the air to be the principal fluid is that it may be conveniently compressed to a pound (per square inch) pressure or so by the use of the proper blower while gas is frequently furnished at only a few ounces (per square inch) pressure. Occasionally, high-pressure gas of several pounds pressure is available, in which case the energy from the gas stream may be used to induce free primary air from the atmosphere, but here again as in the use of free secondary air, the air-gas ratio is upset easily by changes in furnace pressure. The use of free air is therefore not considered here. The following discussion assumes that air may be furnished at a pressure of $^1/_4$ to 2 psi, whether it be primary or secondary air.

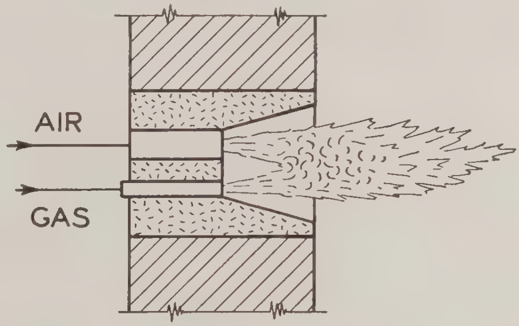

Fig. 1

The gas pressure available will be considered as three distinct cases, low, medium, or high pressure, and may affect the type of control to be used for air-gas ratio control. The low-pressure gas will be reduced to zero pressure or approximately so. Medium-pressure gas will be higher than this, but not as high as the air pressure furnished. High-pressure gas is available at as high a pressure as the air pressure or higher.

The air-and-gas-mixing apparatus or, simply, "mixer" is the unit where the gas and air are brought together and where the mixing process has begun but may not necessarily be completed. In the use of secondary air the mixer is installed in the furnace wall and is usually called the burner, although for purposes of discussion here it shall be considered a mixer. A primary-air mixer discharges the mixture of air and gas to a piping manifold where it is delivered to a single burner or a multiplicity of burners. In either case, there are recognized three distinct classes of mixers. This classification is based upon the effect of the air flow on the gas flow, that is, whether the air tends to help or hinder the flow of gas. This effect may be measured by discharging the mixer into the atmosphere and turning off the gas supply. The resulting pressure obtained at the gas entrance, which is produced by the air flow, is the key to the classification. If the pressure so

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

obtained is zero or very nearly so, as in Fig. 1, this type is defined as a neutral mixer. On the other hand, if a back pressure is obtained on the gas connection this is called a back-pressure mixer as in Fig. 2. Fig. 3 is an ejector-type mixer which produces suction on the gas and tends to help the flow of gas. When either back pressure or suction is produced, these values are, in general, proportional to the air-pressure supply to the mixer and, indeed, must be so in order to function as a part of the air-gas-ratio control.

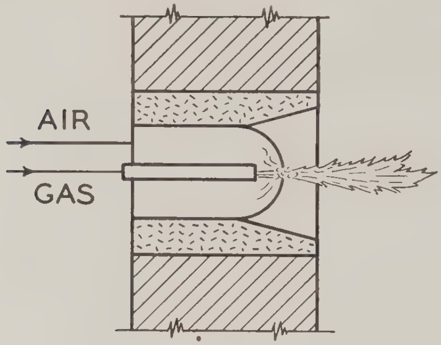

Fig. 2

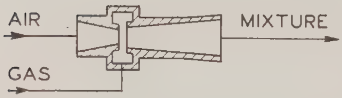

Fig. 3

If, instead of discharging the mixer into atmospheric pressure, it is discharged into a region of back pressure caused by the resistance to flow of a burner or caused by the combustion process itself, the back-pressure effect of a mixer will be increased, or the suction produced by an ejector mixer will be decreased. As long as the back-pressure effect which is downstream from the mixer is constant, it has no detrimental result on the air-gas ratio control, but if this back-pressure effect should become variable, then special allowances must be made in the ratio-control circuit in order to maintain air-gas ratio consistency. In fact, it will be shown how the difference between a constant and a variable back-pressure effect calls for a fundamental difference in the type of air-gas ratio control to be used.

In keeping with the two types of back-pressure effect from the downstream of the mixer, there correspond two classes of furnace-pressure conditions. The first class, a standard-pressure furnace, is defined as one which either has an atmospheric pressure or a back pressure which is in proportion to the mixture pressure being delivered to the furnace by one burner or a group of burners all under the same throttling control. The use of large flue areas and little or no stack effect will maintain zero pressure in the combustion chamber. If a stack is used, an automatic damper control may be installed to maintain zero pressure. Again, in the absence of stack effect, but with limited flue openings, a back pressure is created in the combustion chamber due to the combustion process; however, as long as there is only one throttling control, this back pressure will be in proportion to this throttling-control pressure. With the use of more than one throttling-control on one furnace there is a tendency for interference of one control upon another.

The other type of furnace-pressure condition is called a special pressure furnace and is defined as one which is not standard. This type of pressure is usually variable but may be constant at any value other than zero. The class of special pressures may be produced by the use of a stack, fan, or an extraneous throttling-control system discharging into the combustion chamber of the control group under discussion. Of course the two classes of furnace pressures are relative, not absolute, depending upon the amount of deviation of air-gas ratio that is allowed. In other words, a standard-pressure type of control may be used on an application with a small variation in pressure as long as the corresponding change in air-gas ratio is permissible.

Analysis

At this point it is advisable to review the fundamental gas-flow laws before attempting to analyze the various control circuits. These laws of low-pressure gas flow or noncompressible flow are not exact but are close enough for commercial application. The following terms will be used in the analysis:

Q = volume rate of flow
P = gage pressure
S = specific gravity
R = resistance to flow
A = general bleed constant
K = mixer constant
B, C, D, F, G, H, L, M = general constants

Subscripts:

u refers to upstream
d refers to downstream
1 refers to air stream
2 refers to fuel-gas stream
3 refers to air-gas mixture stream
4 refers to combustion chamber
v refers to bleed valve
o refers to bleed orifice

Any consistent set of units may be used.

The first law of gas flow states that the volume rate of flow of gas (or weight rate of flow if the gas is considered incompressible) is proportional to the square root of the pressure drop or pressure differential across any resistance to flow, such as an orifice plate, Venturi, valve, pipe fitting, etc. This is a common law applied in the metering of gas flow. It is also applied in controlling air-gas ratio. A set of differential pressures indicating air flow and another set of differential pressures indicating gas flow are made to oppose each other through various arrangements of diaphragms.[2] Thus a balance of differential pressures is maintained, which results in a constant air-gas ratio. While it is easily understood how control of the air-gas ratio is obtained using differential pressures, it is much more difficult to understand the control of air-gas ratio by single impulse pressures when used in connection with the various types of mixers and furnace-pressure conditions as heretofore described. If the downstream of an orifice plate is discharged to a known pressure region such as the atmosphere, the upstream pressure tap will indicate flow by itself, since the downstream pressure is known without measurement. In this case the upstream pressure tap becomes the single impulse pressure, by means of which the air-gas ratio must be controlled.

The other gas-flow law is that the volume rate of flow is inversely proportional to the square root of the specific gravity of the gas. Combining the two gas laws

$$Q \sim \sqrt{\frac{P_u - P_d}{S}}$$

[2] "Multiple-Diaphragm Pressure Regulators and Their Application," by H. C. McRae, *Instruments*, vol. 17, September, 1944, pp. 529–531.

It is convenient to express the constant of proportionality as $\sqrt{1/R}$, since the laws have the square-root form and the resistance concept to flow is similar to that used in the electrical, magnetic, thermal, and stress fields. Then, the general law of low-pressure gas flow is

$$Q = \sqrt{\frac{P_u - P_d}{RS}}$$

Any set of units may be used, the resistance unit being defined from the other units. From analogy to the electrical field, resistances may be combined[3] in series and in parallel. Likewise, both of Kirchhoff's laws of electrical networks may be used for gas-flow circuits; namely, (1) the algebraic sum of the gas flows in all the pipes that meet at a point is zero and (2) the total change of pressure around any closed circuit is zero. The resistance form of gas flow and Kirchhoff's first law will be used in the following analysis to prove that the various control circuits do maintain a constant air-gas ratio for variable flow rates. Of course in practice the various control circuits were derived from the analysis.

Although there are several types of control circuits for air-gas ratio control, using single impulse pressures, all of them are derived from the basic form shown in Fig. 4, which is called the

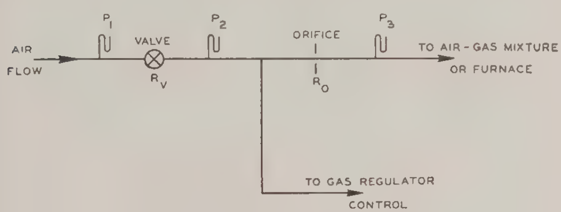

FIG. 4

"general bleed." It must be understood that the bleed mechanism or any of its derivatives is only a small branch of $^1/_4$-in. or $^3/_8$-in. pipe size, going from the main air pipe and usually some point of lesser pressure such as the air-gas mixture pipe, the combustion chamber, or the atmosphere, to the gas-pressure regulator control. Before the complete control circuits can be analyzed it is necessary to develop the following mathematical expressions for the general bleed and other bleed systems.

In Fig. 4 the pipe line going to the gas-regulator control is dead-ended; that is, there is no steady flow of air in this line. Therefore the flow rate through the valve must be equal to the flow rate through the small orifice

$$\sqrt{\frac{P_1 - P_2}{R_v S_1}} = \sqrt{\frac{P_2 - P_3}{R_0 S_1}}$$

Solving this equation

$$P_2 = \left(\frac{R_0}{R_v + R_0}\right) P_1 + \left(\frac{R_v}{R_v + R_0}\right) P_3$$

Let

$$\frac{R_0}{R_v + R_0} = A$$

and, therefore

$$\frac{R_v}{R_v + R_0} = 1 - A$$

[3] "Low Pressure Gas Flow Analyzing by a Resistance Theory," by H. C. McRae, *Industrial Gas*, vol. 19, March, 1941, pp. 17–20.

Rewriting the value of the gas controlling pressure

$$P_2 = AP_1 + (1 - A)P_3 \ldots\ldots\ldots\ldots\ldots [1]$$

where $0 \leq A \leq 1$

Equation [1] is the mathematical expression for the general bleed, stating that P_2 is always a fixed ratio difference between P_1 and P_3, regardless of the rate of flow or how P_1 and P_3 may vary during the control cycle. Since the bleed valve is set once and for all at the beginning of an installation to conform to the particular requirements of the application, R_v and therefore A are constant in the control cycle.

The various types of control are derived from Equation [1] by fixing definite values for A and P_3. For the conditions

$$P_2 = AP_1 + (1 - A)P_3 \ldots\ldots\ldots\ldots\ldots [2]$$

$$0 < A < 1 \quad \text{and } P_3 \neq 0$$

a double connection is required to control the gas (both to P_1 and P_3) and hence the name, "double bleed." If

$$A = 0 \quad \text{and} \quad P_3 \neq 0$$

$$P_2 = P_3 \ldots\ldots\ldots\ldots\ldots\ldots\ldots [3]$$

For this case the bleed valve is closed or $R_v = \infty$. In practice the bleed valve and orifice are not used, since it is necessary to use only a single pipe to connect the air-gas mixture pressure, P_3, to the gas-regulator pressure, P_2. This class of control is called the "reduced cross connection."

The gas-control pressure may also be connected to the combustion chamber, in which case

$$P_2 = P_4 \ldots\ldots\ldots\ldots\ldots\ldots\ldots [4]$$

This type of control is called "cross connection to furnace." In fact, if the mixer is mounted directly on the furnace and the air is used as secondary air, the mixture pressure, P_3, becomes the furnace pressure, P_4. In other words, this case is derived from the previous case.

Again, for the condition

$$P_2 = AP_1, P_3 = 0, 0 < A < 1 \ldots\ldots\ldots\ldots [5]$$

the bleed orifice is discharged directly into the atmosphere. This case is called "single bleed" or abbreviated to simply "bleed."

In addition, if $A = 0$ and $P_3 = 0$

$$P_2 = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots [6]$$

This "zero gas" is the most commonly used type of control; the gas-control regulator need only be vented to the atmosphere and no pipe interconnections between the air and gas are necessary.

The last type of control is derived either from the single or the double bleed, since P_3 may or may not be zero, because $A = 1$

$$P_2 = P_1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots [7]$$

This is called "straight cross connection." For this case the bleed valve is open wide with no resistance; $R_v = 0$. Again, in practice, this is equivalent to a single pipe connection between the air pressure and the gas-control pressure.

The foregoing control classifications give all the necessary combinations in air-gas ratio control by single impulse pressures to cope with the various types of mixers, gas pressures available, and furnace-pressure conditions. There are a few other miscellaneous control types, such as connection of the gas-control pressure to the air and to a gas-pressure point just upstream from the mixer, but these controls only duplicate, in need, what has already been derived. Table 1 is constructed for convenience to summarize the various controls and show their relationship. It will

be shown later how the branch on the right side is used for standard-pressure furnaces, while the left branch is used for special pressure furnaces.

Fig. 5 shows the general arrangement of the air and gas piping with the exception of the bleed control itself. As previously mentioned, the mixer and the burner may be only one unit instead of two separate units as shown. It is important to notice the function of the gas-pressure-regulator control. This device is sometimes called a "zero governor" or "atmospheric regulator." It is nothing more than a diaphragm-operated pressure regulator[4] which controls the gas-discharge pressure to be equal to the impulse pressure imposed from the bleed control, providing of course that the gas-supply pressure is high enough. The control valve is adjusted according to heat-input demand. Thus the air pressure, P_1, and air-flow rate are being adjusted continuously, while likewise the gas-flow rate must remain in step with the air flow through the application of the proper bleed control and the gas regulator.

[4] "Simple Pressure Regulators—Principal Types and Their Characteristics," by H. C. McRae, *Instruments*, vol. 15, February, 1942, pp. 44–45 and 59.

Fig. 6 shows the diagrammatic layout of the circuit in Fig. 5; R_1 represents the resistance to flow of air in the mixer and R_2 is the resistance to gas flow in the mixer, including a gas valve for air-gas ratio adjustment. Term R_3 is the resistance of the burner. The expression, $K_2\ (P_1 - P_3)$, is the suction or back-pressure effect of the air on the gas flow as discussed under the subject of mixer classification. The corresponding effect of the gas on the air flow is $K_1(P_2 - P_3)$. The value of K_2 determines the mixer classification: For $K_2 = 0$, a neutral mixer; for $K_2 < 0$, a back-pressure mixer; and for $K_2 > 0$, the mixer is the ejector type.

The air flow through the resistance, R_1, is

$$Q_1 = \sqrt{\frac{P_1 + K_1(P_2 - P_3) - P_3}{R_1S_1}}$$

The gas flow rate is

$$Q_2 = \sqrt{\frac{P_2 + K_2(P_1 - P_3) - P_3}{R_2S_2}}$$

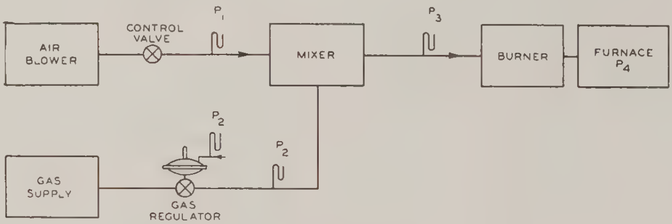

FIG. 5

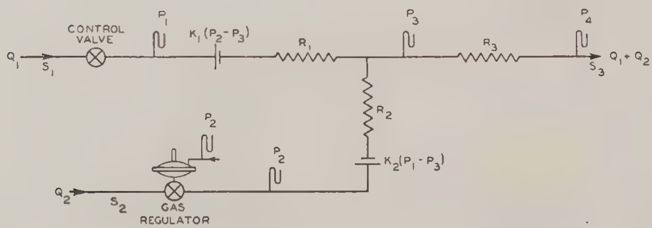

FIG. 6

For the experimental determination of K_2, the gas flow is cut off. Then $Q_2 = 0$ and

$$P_2 + K_2(P_1 - P_3) - P_3 = 0$$

$$K_2 = -\frac{P_2 - P_3}{P_1 - P_3} \text{ (no gas flowing)}$$

In a similar manner, with the air cut off

$$K_1 = -\frac{P_1 - P_3}{P_2 - P_3} \text{ (no air flowing)}$$

In the case that the mixer and the burner become one unit, combustion may affect the K values. For this case the K values will have to be determined under actual combustion and by metering the air- and gas-flow rates; however, P_3 is replaced by P_4.

From the foregoing air- and gas-flow rates the air-gas ratio is

$$\frac{Q_1}{Q_2} = \sqrt{\left(\frac{R_2S_2}{R_1S_1}\right)\left[\frac{P_1 + K_1(P_2 - P_3) - P_3}{P_2 + K_2(P_1 - P_3) - P_3}\right]} \quad \ldots\ldots [8]$$

Since R_1, R_2, S_1, S_2, K_1, and K_2 are constants, it is only necessary to eliminate the pressure terms, which vary in the control cycle, to prove that the air-gas ratio is constant.

Taking a simple case to illustrate the method of proving air-gas-ratio constant, consider a neutral-type mixer discharging into a zero-pressure furnace. In this case, $K_1 = K_2 = P_3 = 0$. Equation [8] becomes

$$\frac{Q_1}{Q_2} = \sqrt{\left(\frac{R_2S_2}{R_1S_1}\right)\left(\frac{P_1}{P_2}\right)}$$

Let $P_2 = AP_1$ be the control chosen, which is a single bleed or straight cross-connection for $A = 1$. After substituting this value for P_2

$$\frac{Q_1}{Q_2} = \sqrt{\left(\frac{R_2S_2}{R_1S_1}\right)\left(\frac{1}{A}\right)} \text{ const}$$

Consider a standard-pressure furnace for which $P_4 = 0$ or in the case that P_4 is proportional to P_3, the furnace resistance to flow may be included in the burner resistance and the flue gases are discharged from the furnace to the atmosphere or zero pressure anyway. In other words, for standard-pressure furnaces the downstream resistance from the mixer is constant. Then, for this case: $P_4 = 0$ and R_1, R_2, R_3, S_1, S_2, S_3 are constant. The control chosen is $P_2 = AP_1$ which is the single-bleed, straight cross connection for $A = 1$, or zero gas for $A = 0$. The pressure, P_3, must be proved to be proportional to P_1, before Equation [8] may be used. Equating the sum of the air and gas flow to be equal to the mixture flow

$$\sqrt{\frac{P_1 + K_1(P_2 - P_3) - P_3}{R_1S_1}} + \sqrt{\frac{P_2 + K_2(P_1 - P_3) - P_3}{R_2S_2}} = \sqrt{\frac{P_3 - P_4}{R_3S_3}}$$

Using the values just given for P_2 and P_4

$$\sqrt{\frac{P_1 - P_3 + AK_1P_1 - K_1P_3}{R_1S_1}} + \sqrt{\frac{AP_1 - P_3 + K_2P_1 - K_2P_3}{R_2S_2}} = \sqrt{\frac{P_3}{R_3S_3}}$$

This equation may be written in more simple form by the use of general constants, since the actual value of P_3 is not needed

$$\sqrt{FP_1 + GP_3} + \sqrt{BP_1 + DP_3} = \sqrt{HP_3}$$

After squaring this equation twice and combining the proper terms in order to eliminate the radicals

$$[(F + B)P_1 + (G + D - H)P_3]^2 = 4[BFP_1^2 + (DF + BG)P_1P_3 + DGP_3^2]$$

Again, simplifying by using general constants

$$P_3^2 + LP_1P_3 + MP_1^2 = 0$$

or

$$P_3 = \frac{-LP_1 \pm \sqrt{L^2P_1^2 - 4MP_1^2}}{2} = \left[-\frac{L}{2} \pm \frac{\sqrt{L^2 - 4M}}{2}\right]P_1$$

and finally

$$P_3 = CP_1$$

Now Equation [8] becomes

$$\frac{Q_1}{Q_2} = \sqrt{\left(\frac{R_2S_2}{R_1S_1}\right)\left[\frac{1 + AK_1 - CK_1 - C}{A + K_2 - CK_2 - C}\right]}$$

which is constant and independent of the control pressure P_1.

Since it is proved that zero gas produces constant air-gas ratio for standard-pressure furnaces or zero-pressure furnaces, this case may be easily extended to prove that cross connection to furnace holds constant air-gas ratio for special pressure furnaces. These two cases become equivalent when all the pressures in the latter case are referred to P_4, the furnace pressure, as a base instead of the atmosphere or gage pressure. In other words, since $P_2 = P_4$, P_2 will always be zero if referred to its value exceeding P_4. Likewise, P_1 and P_3 take on new values that differ from their old gage values by the same amount that P_4 differs from zero gage pressure.

Now consider the general case of special-pressure furnaces. Both P_4 and R_3 become variable for this case, although R_3, the burner resistance, is not usually varied purposely but may vary slightly with temperature change. P_3 is no longer proportional to P_1 and therefore the single-bleed will not hold constant air-gas ratio. Choose

$$P_2 = AP_1 + (1 - A)P_3$$

the double bleed control, the reduced cross connection for $A = 0$, or the straight cross connection for $A = 1$. Equation [8] becomes

TABLE 2 TYPE OF CONTROL FOR GIVEN APPLICATION

Mixer classification	Gas pressure available	Standard pressure furnaces	Special pressure furnaces
Ejector type	Low	Zero gas	Cross connection to furnace
	Medium	Zero gas	Cross connection to furnace
		Single bleed	Reduced cross connection
			Double bleed
	High	Zero gas	Straight cross connection
		Straight cross connection	
Neutral or back-pressure type	Low	No method available	No method available
	Medium	Single bleed	Double bleed
	High	Straight cross connection	Straight cross connection

$$\frac{Q_1}{Q_2} = \sqrt{\left(\frac{R_2S_2}{R_1S_1}\right)\left[\frac{(P_1 - P_3) + K_1(AP_1 + P_3 - AP_3 - P_3)}{AP_1 + P_3 - AP_3 - P_3 + K_2(P_1 - P_3)}\right]}$$

$$= \sqrt{\left(\frac{R_2S_2}{R_1S_1}\right)\left[\frac{(P_1 - P_3) + AK_1(P_1 - P_3)}{A(P_1 - P_3) + K_2(P_1 - P_3)}\right]}$$

$$= \sqrt{\left(\frac{R_2S_2}{R_1S_1}\right)\left[\frac{1 + AK_1}{A + K_2}\right]} \text{ const}$$

Table 2 shows the type of control to use on any given application. The use of the single bleed and the double bleed have been avoided when possible, although these types of control sometimes have to be used to obtain a sufficient quantity of gas. The reason for avoiding these controls is because of the necessity of adjusting the bleed valve properly to get just the sufficient amount of gas pressure without exceeding the gas-supply pressure minus the pressure drop through the gas regulator. All of the other controls require only a single pipe connection to the gas regulator without any adjustments. The zero gas system is the most popular, because in this case no connection need be made to the gas regulator, and there is always a sufficient supply pressure for this control.

Figs. 7 to 11, inclusive, show the complete circuit for some of the most frequent applications.

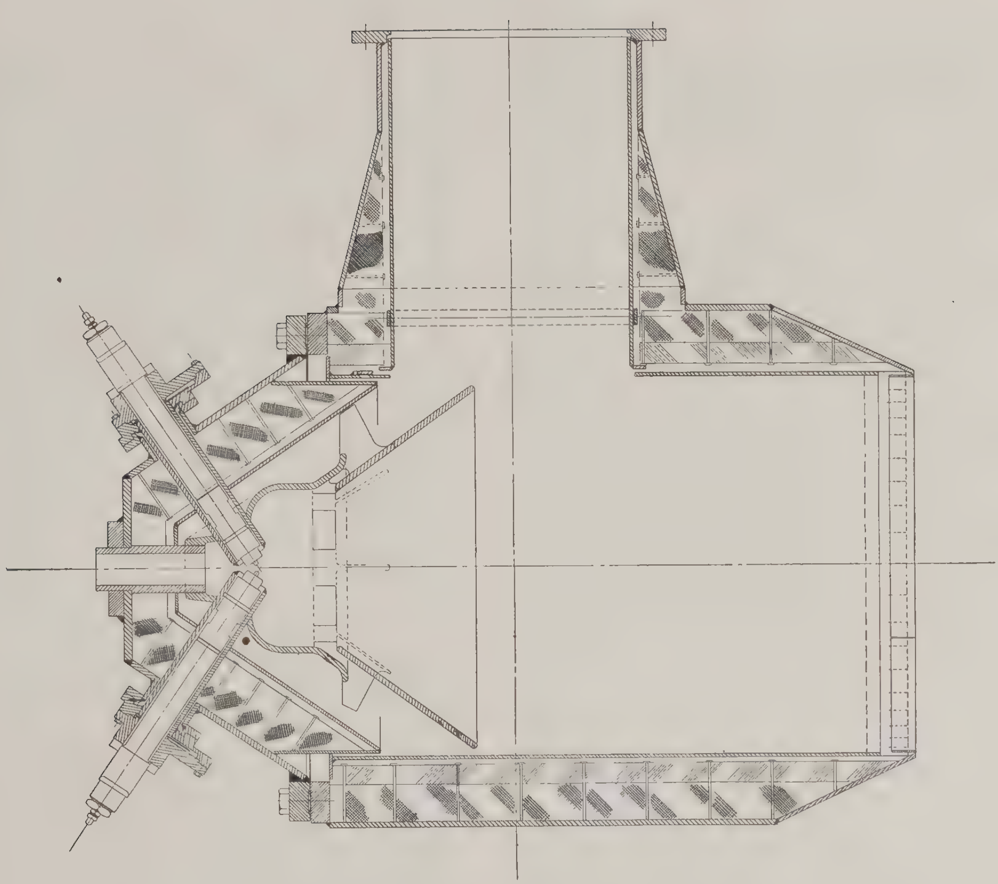

Fig. 1 Elbow Combustion Chamber

The Elbow Combustion Chamber

By M. A. Mayers[1] and W. W. Carter,[2] Jeannette, Pa.

A description is given of the "elbow" combustion chamber, developed for use in the gas-turbine power plant designed and built for the United States Navy by the Elliott Company. This type provides extremely high heat-release rates which is an essential characteristic for gas-turbine applications. The fuel-oil-burning system which utilizes standard Diesel fuel-injection equipment has been developed to a high point of efficiency, and may be varied over a range from full load to 1/10 full load without material change in quality of atomization. The paper discusses in detail the air-flow characteristics, fuel supply, ignition and control devices, and analyzes the combustion-chamber performance-test data.

THE "elbow" combustion chamber was developed for use in the gas-turbine power plant designed and built for the U. S. Navy by the Elliott Company during the period 1942–1944. It has turned out to be exceptionally adapted to gas-turbine use in that it permits heat-release rates of 2.5×10^6 Btu per cu ft per hr, with air supplied at 95 psia, and 650 F, when it requires a pressure drop of only 16 in. water column; it permits a "turndown" to $^1/_{20}$ of full load; and is extremely insensitive to fuel-air ratio. As shown in Fig. 1, it consists of a right-angle elbow in a duct, of which the upstream arm is smaller in diameter than the downstream one. The upstream end of the large arm which forms the combustion chamber proper, is closed by a head which carries an "ignition cone," the fuel-oil burners, an igniter burner, and the "flame-rod" or contact member of the flame-sensitive controller. The chamber contains no inner shell separating combustion air from tempering air, and all the air in the gas-turbine circuit is supplied to the chamber without the

Contributed by the Oil and Gas Power Division and presented at the Annual Meeting, New York, N. Y., November 26–29, 1945, of The American Society of Mechanical Engineers.

necessity for separate control of combustion air. Fuel is supplied to the chamber through standard Diesel fuel-injection equipment, producing a pulsating fuel flow which on a single burner may be varied over the range from full load down to $^1/_{10}$ full load without material change in the quality of the atomization. The rate of fuel flow is controlled by adjusting the position of the control rod of the Diesel injection pump.

Gas-Turbine Combustion-Chamber Requirements

The Elliott gas turbine was designed from the basic premise that such an engine, to be a successful prime mover, must have an efficiency comparable with those of others with which it would compete. To accomplish this aim, it was necessary to provide heating of the working medium in two stages, one before the first stage of expansion and a reheat after this; and to reduce the parasitic losses associated with the combustion chambers to a minimum. The thermodynamic advantages to be gained by reheating have been treated elsewhere (1)[3] and need not be repeated; the process does, however, entail the necessity of supplying heat to a flue gas, resulting from the combustion in the initial, or high-pressure combustion chamber, which may contain 2.7 per cent carbon dioxide, 2.6 per cent water vapor, and whose oxygen concentration may be reduced to about 16.5 per cent.

It may not at first be apparent why the pressure drop in the combustion chambers, as well as in the ducts and heat exchangers, must be so severely limited. The loss in gross turbine work is proportional to the ratio of the pressure drop to the absolute pressure at which it occurs and thus does not appear to be serious. Only a portion of the gross turbine work appears as useful output, this fraction being represented by the work ratio, α (1). The proportional loss of net turbine output due to parasitic losses is inversely proportional to α and may be therefore from 2.5 to 4 times as great as the loss in gross turbine work.

Since this machine was designed for naval ship propulsion, it was necessary for it to operate over a wide range of loads. The cubic relation between speed and power in ship propulsion, coupled with the fact that the gas turbine is governed directly by the rate of heat input, demands a high degree of flexibility in the fuel-burning system. Fig. 2 shows how the fuel-burning rate, and the power output depend upon the propeller-shaft speed. For maneuvering at speeds down to 45 per cent of full-power speed the high-pressure chamber must operate stably over a range of burning rates of 10 to 1; while for the design conditions of speeds down to $^1/_3$ of full the turndown must approach 20:1. Conventional marine practice of changing the tips or spray plates of fuel burners is not acceptable for this application, since burner removal from chambers operating under pressures greatly exceeding atmospheric could hardly be made rapid enough.

Associated with the need for wide-range characteristics of the fuel-burning equipment is the necessity that it be insensitive to over-all excess air. It is evident from Fig. 2 that the air-to-fuel ratio covers an extreme range from 600:1 in the low-pressure chamber to about 120:1 in the high-pressure chamber. In addition, variations in operating conditions such as weather, draft of vessel, etc., might impose variations about the curve of air-to-fuel ratio, at any value of speed, of 10–25 per cent. Previous chambers (2) had used separate control of combustion air to meet this type of difficulty. In the present instance this solution was unsuitable because air was supplied to the chambers at such high temperatures that valves or dampers could hardly be expected to operate reliably, and because of the stringency of pressure-drop restrictions.

It is desirable that the combustion chambers for gas-turbine plants permit very high heat-release rates; in fact, the possibility that this may be secured is one of the main attractions of the internal-combustion gas turbine. It was, moreover, believed to be essential that these combustion chambers operate with a perfectly clean discharge, as the effect of soot, smoke, or gaseous products of incomplete combustion on the turbines and heat-transfer surfaces could not be predicted. The requirement of clean discharge also made it undesirable to leave exposed surfaces of nonmetallic refractories in the combustion chamber, since spalling or dusting of such material would foul the gas stream. Of course, safety, reliability, and convenience in operation, as well as ease and accessibility for necessary repairs are also desirable characteristics.

[3] Numbers in parentheses refer to the Bibliography at the end of the paper.

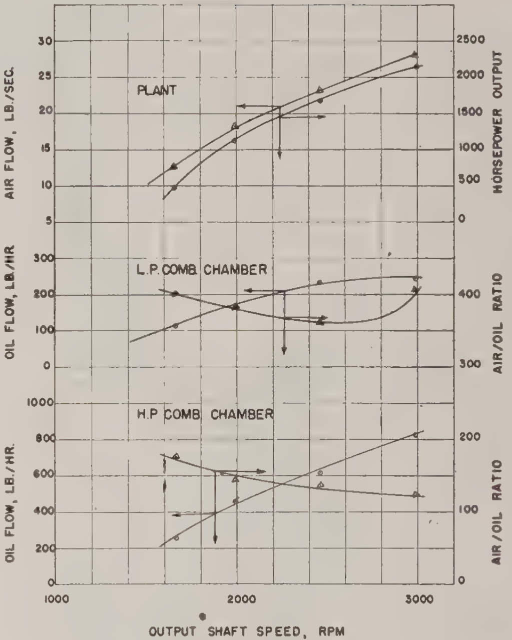

Fig. 2 Dependence of Combustion-Chamber Performance on Output Shaft Speed

Characteristics of Elbow-Type Combustion Chamber

Air Flow. The air, on entering the main combustion chamber through the side inlet, follows the flow pattern characteristic of flow through an elbow in a pipe line (3), producing a double-vortex system. The two vortexes lie on either side of the center line of the inlet duct and have opposite senses of rotation. When the chamber is in operation the centers of these vortices appear as two bright spots to an observer looking upstream from the outlet of the chamber.

The strength of the vortex system is enhanced by making the diameter of the inlet duct less than that of the main chamber. While exact limits of this ratio have not yet been established, it has been found by model tests that the vortexes become less stable and show more tendency to break down into a single vortex having relatively undisturbed laminar flow, when the ratio of the diameters becomes greater than 0.6. The same kind of breakdown is produced by eccentricity of the inlet, or departure of the inlet center line from an extension of a radius of the combustion chamber proper.

A portion of the air entering the chamber is trapped behind the edge of the ignition cone which projects across the inlet air stream. Some of this air flows into the cylindrical part of the ignition cone through the slots shown in Fig. 1, producing a ring

vortex which has been shown to stabilize the ignition of fuel sprays (4), by some such mechanism as the following: Air from the slots in the ignition cone, on meeting the back wall of the ignition cone, turns radially outward, causing the formation of a vortex ring whose sense of rotation is such that the flow through the center of the ring is upstream. This causes the ring to take up a fixed position in relation to the back wall into and out of which air passes without affecting the stability of the vortex system as a whole (5). Thus the vortex ring is similar to a smoke ring, except that it is fixed in position and is continuously replenished. The entering air which has swept over the fuel spray injected into the chamber, carries with it a portion of finely atomized oil and oil vapor which serves as fuel for a continuously regenerated pilot flame established in the vortex ring.

The pilot flame formed by the vortex ring probably serves as a source of heat and of "active centers" to initiate the combustion of the main oil spray with the remainder of the air flowing through the ignition cone. Under conditions of very low oil-air ratio this small amount of air may be sufficient to burn the oil completely within the ignition cone, itself; but at higher loads, this protected region serves only as a space within which the whole mass of fuel may be vaporized and ignited. It should be noted that no rotation about the axis of the chamber is imparted to the flow through this cone. In every instance in which such rotation was produced, drops of burning oil were thrown against the walls of the cone, which eventually produced coke deposits.

The mass of ignited fuel issuing from the ignition cone appears to flow into the centers of the two vortexes formed by the main air flow, in which their combustion is completed. Observation of the bright spots formed by the double-vortex system shows that their size depends on the load, or rate of burning oil. At medium loads, large enough so combustion is not complete within the ignition cone, the spots are quite small and are clearly separated. As the load increases they increase in size until the two spots nearly touch. One might imagine that the flow out of the cone is directed into the centers of the vortices and that the burning fluid diffuses radially out from these centers to an extent determined by the amount of air required to complete its combustion. It has been suggested (6) that the reduction in static pressure at the center of a vortex (7) may be the agency which produces such a directed flow.

That some mechanism, such as that just suggested, governs the operation of the chamber can scarcely be doubted. At no time has there been evidence of incomplete combustion such as would result from the quenching of the burning by too great an amount of excess air, even though the chambers have been operated at air-to-oil ratios as great as 600:1. Moreover, the temperature of the flame, estimated from visual observation of its color, must be of the order of 3000 F, a value associated with combustion with only a small excess of air. Another observation, which helps to show that only the portion of the air that penetrates nearly to the center of the vortexes takes part in the combustion of the fuel, is that the air in the outer filaments of the vortex flow, which sweeps the walls of the combustion chambers, remains cool in the sections of the chamber in which rapid combustion occurs and serves to cool the metallic walls. This portion of the air rises in temperature some distance downstream and is eventually mixed by the residual vortex motion with the combustion air proper.

This characteristic of the elbow combustion chamber makes it almost unique among high-duty chambers; other types, which depend upon partial admission of air into the combustion space vented through liner walls, thereby make the liner wall behave like a ported gas burner except that in this case flames of air in a fuel-rich atmosphere are set up. The proximity of these flames to the chamber wall leads, of course, to overheating of the liner. In the elbow chamber no such overheating or warping of the chamber liner has ever been observed; tests, described below, indicate that no point on the inner shell rises more than 300 deg F above the outlet gas temperature even though it is exposed to direct radiation from a dense flame.

Fuel Supply. Fuel is supplied to these combustion chambers by means of commercial types of Diesel injection equipment. Number 2 Diesel oil is pumped through wound cartridge filters made by Commercial Filter Corporation under the trade name "Fulflo," to the inlet of 8-cylinder pumps made by the American Bosch Corporation. The discharges of all eight cylinders of each pump are led through $^1/_8$-in. $\times$ $^1/_4$-in. hydraulic tubing to a high-pressure manifold in which the lines are brought together. From here they pass through $^1/_4$-in. $\times$ $^1/_2$-in. hydraulic tubing, to a single water-cooled fuel injector, of a standard design produced by Aircraft and Diesel Equipment Corporation. Thus each pump, header, and injector combination forms a single burner unit.

The injection pumps have cylinder bores of 10 mm and actual plunger strokes of 10 mm. The plungers are cam-actuated so as to have essentially constant velocity over the effective or delivery part of the stroke, which can be varied by changing the point at which a relief port is uncovered by the plunger. Thus fuel is delivered at a constant rate during a short variable time interval. The volume of fuel per injection is directly proportional to the length of the time interval during which injection of fuel occurs and is controlled by the position of a pushrod which simultaneously fixes the effective stroke of each plunger. Since the maximum duration of injection from each pump cylinder is 26 deg of camshaft rotation, while the interval between the start of each succeeding injection is 45 deg, it is evident that the discharges do not overlap. The pumps are driven at a constant speed of 1200 rpm, producing a frequency of injection through each burner of 9600 per min, or 160 per sec. Thus the time interval between the start of each injection is 6 milliseconds, which is short enough to assure stable flame, without pulsations, when the fuel is discharged into the ignition cone previously described.

The Adeco injector mentioned previously, contains a spring-loaded differential-area valve which opens when the fuel-oil line pressure reaches 3300 psi. This valve insures clean sharp dis-

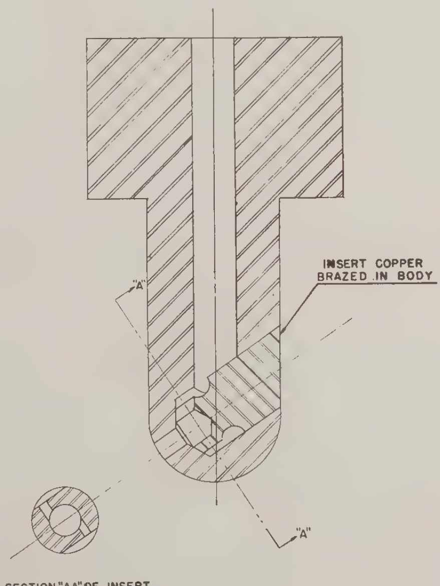

Fig. 3 Diesel Injector-Nozzle Tip

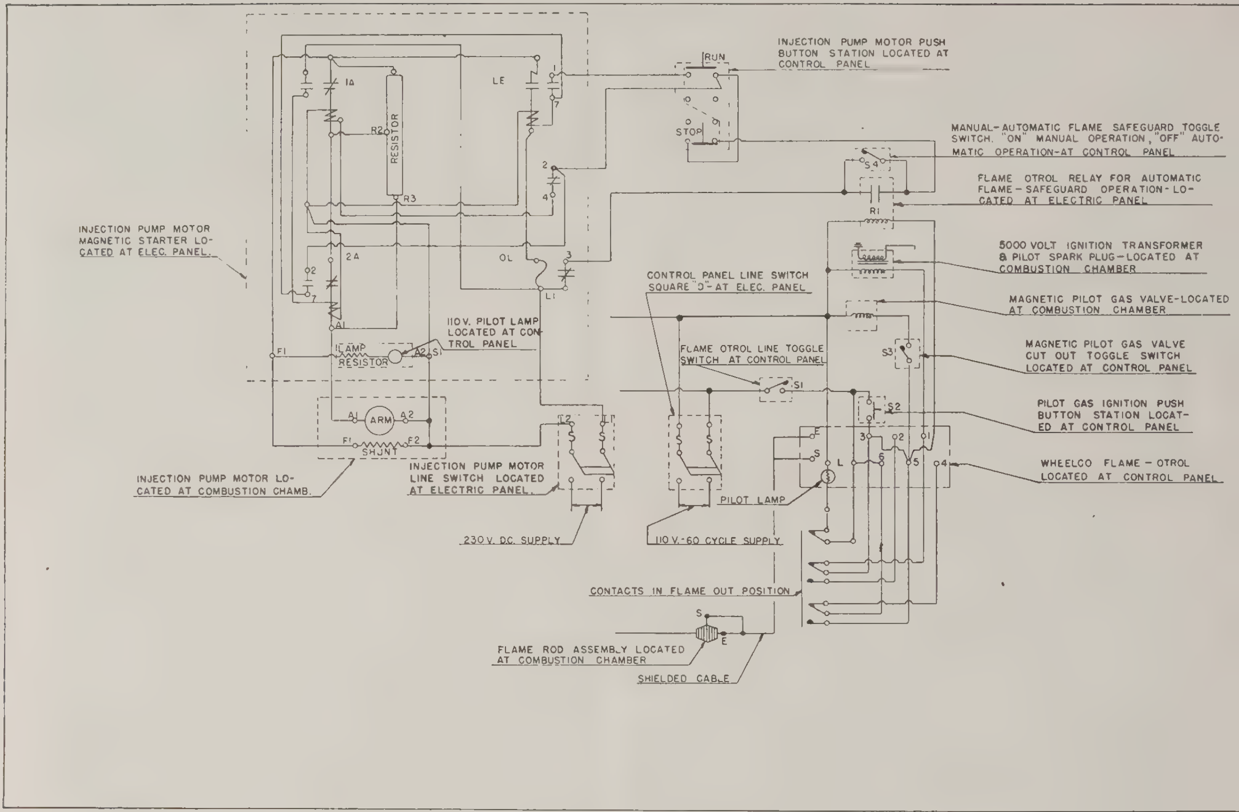

Fig. 4 Flame-Control Circuit

charges and prevents "dribbling" between pulses. The injector is equipped with nozzle tips whose construction is shown in Fig. 3. By this means the advantages of the fine atomization and uniform distribution produced by a whirling cone spray, used conventionally in large mechanical-atomizing oil-burner nozzles, were secured for the spray from a Diesel injector. The discharge orifice is set at an angle to the axis of the tip to permit inserting two injectors in the same ignition cone with their tips not more than 1 in. apart, and having them discharge axially down through the same cone. The tips are installed in the injector by means of a jig which insures the correctness of their orientation, while the injectors are held in the chamber by a fixture built into the burner support. Since fuel is delivered to the injector at a constant instantaneous rate during the injection interval, the atomizing energy is constant from maximum to minimum capacity and good atomization is obtained over the full range.

Ignition and Control Devices. The head of the chamber also carries a spark-ignited gas-fired igniter burner, and the support for the "Flame-rod" or sensing element of the controller, made by Wheelco Instrument Company, which insures that fuel will not be supplied to the chamber in the absence of a source of ignition. This device uses the electrical conductivity of the flame to balance a bridge circuit, allowing a relay to close. This relay may be connected, as shown in Fig. 4, to hold open a valve for gas supply or to close contactors supplying power to the injection pumps. If the conductivity of the circuit including the Flame-rod is either above or below that of the flame the relay opens, cutting off power from these operations, and lighting a signal lamp. The Flame-o-trol, or measuring and control element of this device, which is mounted on the main operating panel board of the gas-turbine unit, is by-passed at starting by depressing a push button which simultaneously opens the gas-supply valve to the igniter burner and applies a sparking voltage to the electrodes of the igniter.

The igniter burners are supplied with a propane-and-air mixture formed in a Venturi mixer; propane is supplied from commercial tanks. Air to the mixer, and cooling air to the Flame-rod holders is supplied by the high-pressure compressor of the gas-turbine set. A small portion of the discharge of this compressor is drawn off from the main discharge duct ahead of the regenerator, passed through a small aftercooler, and is supplied to these auxiliaries. The air- and gas-piping diagram of these devices is shown in Fig. 5.

Sight glasses are mounted on the combustion chambers at convenient points to permit observation of the flame. Those installed in these chambers do not, unfortunately, permit removal of the glass while the chamber is under pressure, but the sight glasses designed for the future will. To date, no glass has ever broken in service.

Materials and Construction. The inner shell of the chamber, which acts merely as a shield to prevent abrasion of the internal insulation by the gas stream and takes no pressure load, is of 25 per cent Cr, 20 per cent Ni, type No. 310 steel. The inner shell is supported centrally in the chamber by means of two "spoked" supports which permit radial expansion of the shell without altering the center-line position. The shells are fixed axially near the air-inlet position and are free to expand in both directions from this point. Flexible seals to prevent pieces of insu-

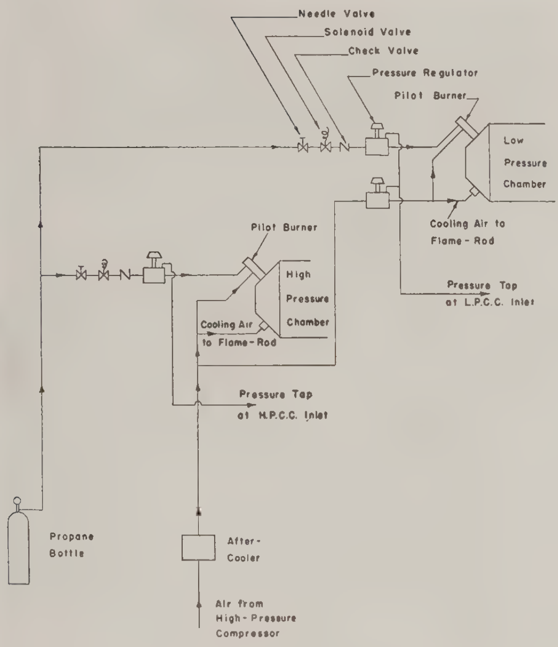

FIG. 5 AIR AND GAS PIPING TO IGNITERS AND FLAME RODS

lation getting into the gas stream are installed at either end of the inner shell.

The ignition cone is cast of chrome iron containing a minimum of 28 per cent Cr. The burner holders are of No. 302 stainless steel. Except for the insulation, which occupies the space between the inner and outer shells, these are the only parts exposed to extreme temperatures.

The internal insulation consists of two layers; the inside, which is exposed to the highest temperature, being of a lightweight brick $1^1/_2$ in. thick. The outer layer is a slag-wool block, wired and cemented to the outer shell. In the high-pressure chamber it was desired to minimize the thermal expansion of the structural member of the combustion chamber, so the block insulation is 2 in. thick and the outer pressure-retaining shell is of mild steel. In the low-pressure chamber some thermal expansion was desired, intermediate between the amount that would be caused by exposure of the shell to gas temperature and that of a "cold" shell. One inch of block insulation was therefore placed inside the shell and $1^1/_2$ in. outside, and the outer shell was made of 18 Cr, 8 Ni, type No. 302 stainless steel.

The heads for both chambers have outer shells of mild steel, inner shells of type No. 310 and are insulated between the shells. They are bolted to the combustion chamber proper by studs tapped into the combustion-chamber flange. The joint is sealed by a double-ring copper-wire gasket. Since the head of the chamber carries all the internal elements, these are immediately accessible for repair or replacement on its removal.

COMBUSTION-CHAMBER PERFORMANCE

An extensive series of tests was made on an experimental combustion chamber, a duplicate in its principal dimensions to the high-pressure combustion chamber. The chamber could be supplied at a maximum pressure of 8 psig, with 5600 cfm of air which could be heated to temperatures up to 1000 F, by burning natural gas in it in a special furnace. The maximum weight flow of air was only about one fifth of that in the gas-turbine set, and only one burner-injection pump unit was installed. It was anticipated, however, that these tests would permit determining if the performance of the combustion chambers would limit the plant operation, as a wider range of air-oil ratios could be tested than would be used in the plant, and shorter burning times could be obtained, since larger volume flows and higher velocities could be produced by lowering the pressure. It was expected that the fourfold increase in pressure in the prototype would permit increasing the heat-release rate by more than the factor of 3 between that of the prototype and that reached in the tests.

These tests were aimed at the determination of the operating efficiency of the combustion chamber. For a system in which the flue-gas discharge temperature is far above the air inlet temperature, it is not immediately obvious how the thermal efficiency should be defined. One possibility is to compare the higher heating value of the fuel with the difference between the enthalpy of all of the products of combustion and that of the air and fuel supplied. The first term in this difference is subject to some error because of uncertainty in the actual amount of moisture in the flue gas, but the results calculated in this manner have been presented in Table 1, under the column heading "Efficiency by Heat-Balance Method." Another method of expressing the efficiency, derivable from the same heat-balance equation, results in a comparison of the change in enthalpy of the air supplied to the chamber with a quantity defined by chemists (8) as the "heating value at the temperature" of the combustion-chamber discharge. The combustion-chamber efficiency thus defined may be expressed

$$\eta = \frac{A}{F}\,\frac{i_2 - i_1}{H_2} \qquad [1]$$

where η is combustion-chamber efficiency

$\frac{A}{F}$ is air-fuel ratio at which chamber is operated

i_2, i_1 are enthalpies of air at discharge and inlet conditions, respectively

H_2 is heating value of fuel at temperature of combustion-chamber discharge and is defined by

$$H_2 = H_0 - [w_c(i_{C_2} - i_{C_0}) + w_H(i_{H_2} - i_{H_0}) - w_0(i_{0_2} - i_{0_0})] \quad [2]$$

where H_0 is heating value of fuel determined under standard conditions

w_C, w_H, w_0 are weights of carbon dioxide, water, and oxygen entering the reaction per unit weight of fuel

i_{C_2}, i_{C_0}, etc., are enthalpies of constituents indicated by letter subscripts at the condition of discharge from the chamber and standard condition, respectively.

This efficiency is entered in Table 1, under the column heading "Efficiency by Bureau of Ships Method" (9), and is plotted in Fig. 6.

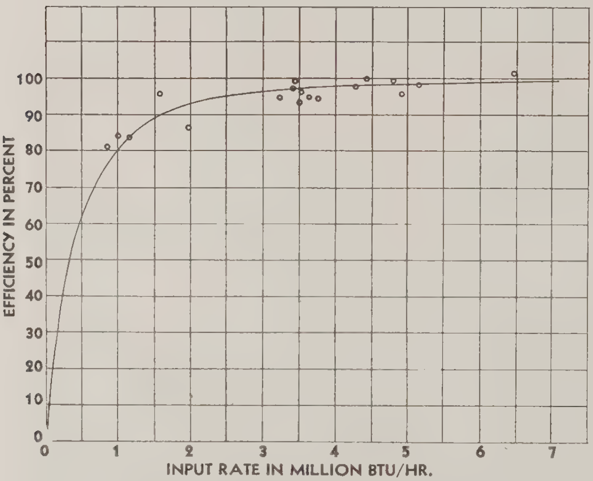

Fig. 6 Combustion-Chamber Efficiencies at Various Loads

Instrumentation. Both methods of determining efficiency require accurate measurement of the temperature of the discharge from the combustion chamber. Two methods of measuring this temperature were used. One was similar to that used by King (10) in determining a reference temperature for the calibration of shielded thermocouples, while the other, which also permitted estimating the degree of stratification in the discharge temperature, was based on the average of the indications of three shielded thermocouples (11) placed in the combustion-chamber discharge. The average of the three thermocouples was always higher than the indication of the single reference couple, which could be accounted for by heat loss between the two temperature-measuring stations. Because stratification in the outlet duct cast some doubt on the validity of the average, and since there was a possibility that the temperatures of the shielded couples were influenced by catalytic combustion on the metallic surfaces of the shields, the reference couple was always used for efficiency estimates.

The pressure measurements used for estimation of the pressure drop across the chamber were the subject of rather intensive study. This characteristic of the chamber was of special importance, but was very small in magnitude so that great care was needed in its measurement. The static-pressure measurements in both the inlet and outlet ducts were checked, during cold-air runs, against the indications of a Fecheimer tube (12) to assure freedom from errors due to impact pressures.

Gas samples were drawn from both inlet and outlet ducts and were analyzed on an Ellison three-chamber gas analyzer of the Orsat type. This instrument could not be expected to indicate small concentrations of the products of incomplete combustion, which might, however, have a relatively large effect on the chamber efficiency. In order to permit the diagnosis of losses from this source, a combustible-gas analyzer, having a full-scale range equivalent to 1 per cent of carbon monoxide, was kindly lent us by the Mine Safety Appliances Company, Pittsburgh, Pa., and a series of tests (runs Nos. 40–44 inclusive) were run, covering the range of air-oil ratios, in which gas samples from the regular taps were conducted to the analyzer. As shown in Table 2, the maximum indication of combustible gas during the run was about 0.02 per cent, equivalent to about 0.6 per cent heat loss to incomplete combustion. For the first 10 to 15 min of operation of the chamber after lighting off, a decreasing indication, starting at a peak of about 0.06 per cent equivalent carbon monoxide, was observed. As this analyzer, by producing catalytic combustion of combustible components of the gas stream on the surface of the platinum wire whose temperature affects the balance of a resistance bridge, indicates the presence of all products of incomplete combustion, these tests were considered conclusive proof that the fuel was completely burned out at the discharge of the chamber.

Test Results. The detailed results of the combustion-chamber tests are presented in Tables 1 and 2, while the efficiency measurements are summarized in Fig. 6. Above fuel-supply rates of 2.5 $\times$ 10^6 Btu per hr, the combustion-chamber efficiency remains above 99 per cent, up to the maximum load carried in these tests, 6.5 $\times$ 10^6 Btu per hr. The limitation on the maximum load was imposed, not by oil-supply capacity or combustion conditions, but by the necessity of limiting the temperature of the discharge, which was vented to the atmosphere through mild-steel ducts.

This maximum represents about 35 per cent of the full-load heat input of the high-pressure chamber in the gas-turbine set. Tests on the chambers installed in the gas-turbine set, in which rates up to the design full-load condition have been carried, indicate no decrease in combustion efficiency as the load is further increased. Of course, these tests are not of as high precision as those on the experimental combustion chamber because of the impracticability of accurate measurement of air flow, and the lack of checks on temperature measurements. A significant result is that neither the stability of operation, nor the combustion efficiency is affected by the presence of products of combustion in

the inlet air, or by the reduction of the oxygen content of the inlet air to 16.3 per cent on the dry basis, corresponding to about 15.6 per cent before condensation of moisture.

As the combustion rate is decreased the efficiency of the chamber appears to fall off to about 81 per cent at a heat-liberation rate of 0.7×10^4 Btu per hr, the lowest stable combustion rate that could be maintained. At the lowest rate the radiation from the outside shell of the chamber accounts for approximately 5 per cent of the heat supplied by fuel, while incomplete combustion accounts for only 1 per cent or so more. The remainder of the apparent loss, amounting to about 14 per cent of the heat in the fuel at the lowest rate, is unaccounted for and must be ascribed to inaccuracies in the measurements.

Preliminary tests had shown that the pressure loss of the air passing through the chamber amounted to approximately one velocity head of the fluid at the entrance to the chamber. These tests were made in a chamber lacking the transition and elbow at the discharge of both the experimental chamber and those in the gas-turbine plant and were not of a high order of precision. The tests reported in Table 1 confirmed this result, however; they also permitted the formulation of a relatively precise expression for the loss in pressure. Study of the data by the methods of correlation analysis (13) showed that the pressure drop was dependent upon the velocity head of the gas leaving the combustion chamber, as well as that at the entrance. Since the quantity of fluid is essentially the same at entrance and exit, these velocity heads are simply related through the ratio of the absolute temperatures at the two sections, designated here as β. Using this convention, the results of these tests may be expressed

$$p = (0.360\beta - 0.077)h_1 \quad \text{[3]}$$

where

p is static pressure drop in any convenient units

h_1 is velocity head at combustion-chamber inlet in same units

$\beta = \dfrac{T_2}{T_1}$ is ratio of absolute temperature of air leaving to that entering the chamber

This expression represents the data of Table 1 to within about 9 per cent and was used to predict the performance of the chambers for the gas-turbine plant.

Stratification of the gas stream with respect to temperature has been the most troublesome characteristic of the combustion chamber. The difference in temperature across the gas stream may amount to 50 per cent or more of the average temperature rise. Temperature traverses have shown that the hot spot is always displaced from the center line toward the inlet of the chamber. It is curious that the chamber may operate consistently with low stratification at one speed of the turbine and just as consistently with high stratification just a few hundred revolutions higher or lower. Further investigation of this characteristic is being made.

The highest metal temperatures occurring in the chamber are those of the ignition cone. Temperatures of the inner shell were also measured during the early runs on the experimental chamber, but the couples at these positions were broken, before the tests reported here were run, by the axial movement of the inner shell relative to the outer shell accompanying heating up and cooling down. They remained in place long enough, however, to show that the shell at no point exceeded the temperature of the ignition cone. Immediately in front of the cone, at the inlet side, the shell temperature usually approached the maximum cone temperature. The variation of the average ignition-cone temperature with the load on the chamber is quite regular, as shown in

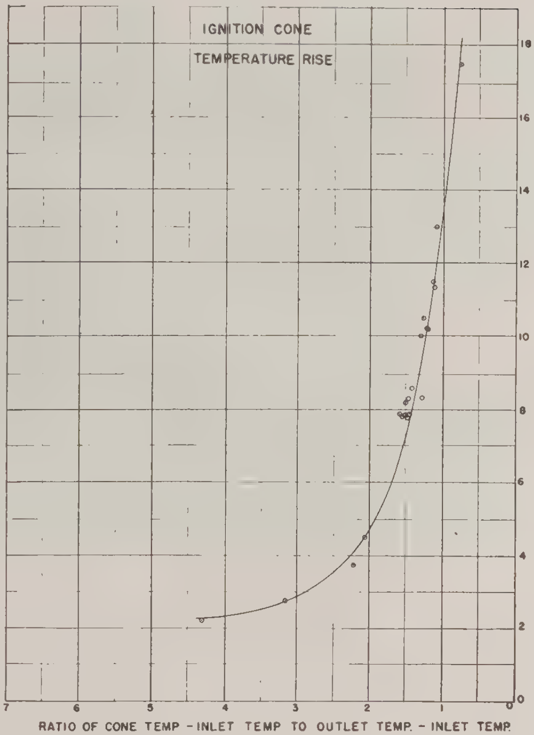

Fig. 7 Ignition-Cone Temperature Rise

Fig. 7. The results shown here may be generalized by the conclusion that at no point in the chamber does the metal temperature exceed the chamber discharge temperature by more than 300 deg F, under any condition of operation.

Notes on the Development

Work on this project started late in 1942, with an attempt to design a combustion chamber that would fit the space requirements of the proposed plant layout. Several designs following more or less conventional practice were completed and chambers of mild steel were built for testing in an outdoor test stand.

In these conventional chambers combustion air was separated from tempering air by a metal shell (2) since it was thought that the large amount of excess air would quench the burning of the fuel. The largest part of the air passed around this shell while combustion air was admitted to the burner end of the shell through a variety of registers, most of which were equipped with adjustable vanes, as in boiler practice. A "spinless" register was also built, in which the primary air was admitted between two coaxial cones, which produced much more stable ignition in a smaller volume of the chamber than did any of the others. It was also found that such stable ignition was essential, with either continuous or intermittent injection of the fuel, to reduction of the flame length. This register was the elementary form of the ignition cone now in use.

Of the chambers proper, those having circumferential slots which admitted air axially along the walls of the inner shell were found to produce very long flames, while those having round holes producing radial jets gave short flames but required relatively larger pressure drop. The "elbow" form of chamber was produced fortuitously by the removal of all inner shells in an attempt to reduce pressure drop.

Acknowledgments

The authors wish to acknowledge the assistance and encouragement supplied throughout this development by Commodore R. V. Kleinschmidt and his staff in the Research Section of the Bureau of Ships; and to thank the Chief of the Bureau of Ships for permission to publish this material. We wish also to thank Mr. R. B. Smith, vice-president Engineering, and the rest of the management of the Elliott Company for their support of this work; and to express our gratitude to William Schoenfelt, formerly a member of the Engineering Research and Development Department of the company, and especially to George Schertzinger, for their devoted work on this problem.

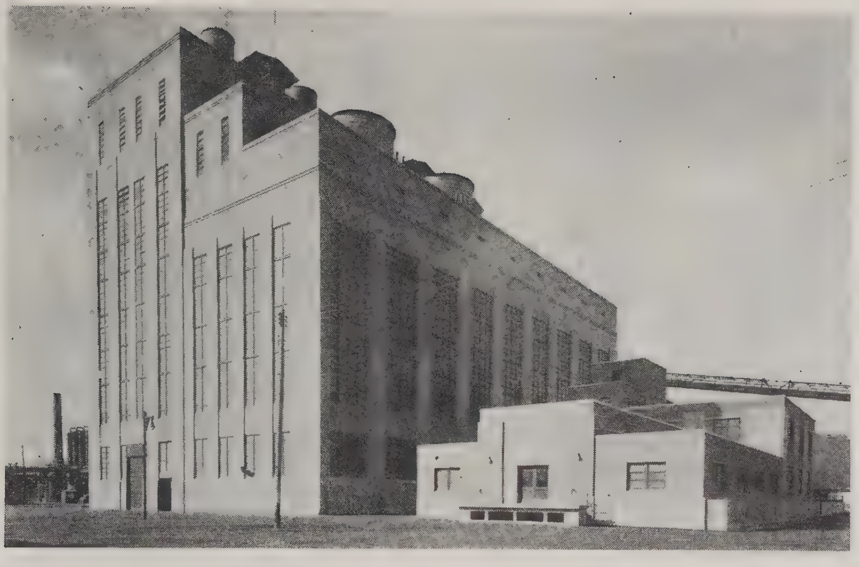

FIG. 1 GENERAL VIEW OF POWER PLANT

A Comparison of Operation of Forced- and Natural-Circulation Boilers

BY G. F. ROSS[1] AND LEONARD WILKINS,[2] KOBUTA, PA.

Steam-generating facilities at the Koppers Company, Incorporated, Butadiene Division, Butadiene-Styrene Chemical Plant, at Kobuta, Pa., include two types of units; natural-circulation boilers and the first forced-circulation boiler to be installed in the United States for industrial-plant processes. Since plant operation began in the summer of 1943, this installation has afforded boiler operators an opportunity to compare the operating characteristics of the two types. This paper describes briefly the design and operating features of these steam generators, together with some of the difficulties encountered and how they were overcome.

THE installation of a controlled forced-circulation boiler unit adjacent to three natural-circulation boiler units of identical rating at the Koppers Company, Incorporated, Butadiene Division, Butadiene-Styrene Chemical Plant[3] has afforded boiler operators an opportunity to compare the operating characteristics of these two types of steam-generating units. Boiler designers and operators are naturally interested in the first application in this country of a forced-circulation boiler unit to supply steam for industrial-plant processes. The steam-generating facilities at Kobuta were built at a time when the steel demand for other urgent war needs was at its peak; the Government directed that a forced-circulation boiler unit should be installed. Plant operations began in June, 1943, with one natural-circulation boiler; in August, 1943, the forced-circulation unit was placed in service.

It will be the endeavor of this paper to describe briefly the design features and compare the major operating differences between the two types of steam-generating units and to outline a few of the operational difficulties that accompany boiler generators of this type. Problems attendant to starting up the units for the first time are intentionally omitted, as boiler designers and operators are well aware that initial operating difficulties rarely recur after the difficulty is once remedied. All boilers installed at this plant met the manufacturers' expected-performance specifications and this paper will deal only with problems arising after acceptance.

It is well to point out that operating personnel was obtained several months prior to operations, in order that start-up of the boiler units could proceed without delay. Operators observed the complete erection of each boiler unit with its auxiliaries, and supervisors conducted short classes with operators to familiarize them with the operating characteristics of each boiler. The wisdom of such a procedure was illustrated by the ability of the operators to start up each unit as it was completed and maintain it on the line as a reliable steam source for plant process. The start-up of the forced-circulation unit was no more of an event than that of the natural-circulation units, as operators had become accustomed to its unconventional design.

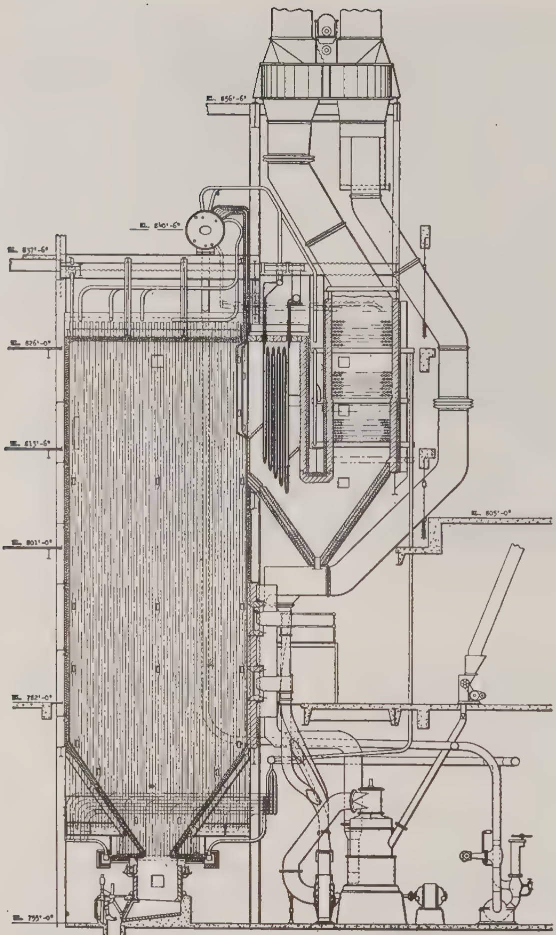

FIG. 2 CROSS-SECTIONAL VIEW, FORCED-CIRCULATION BOILER

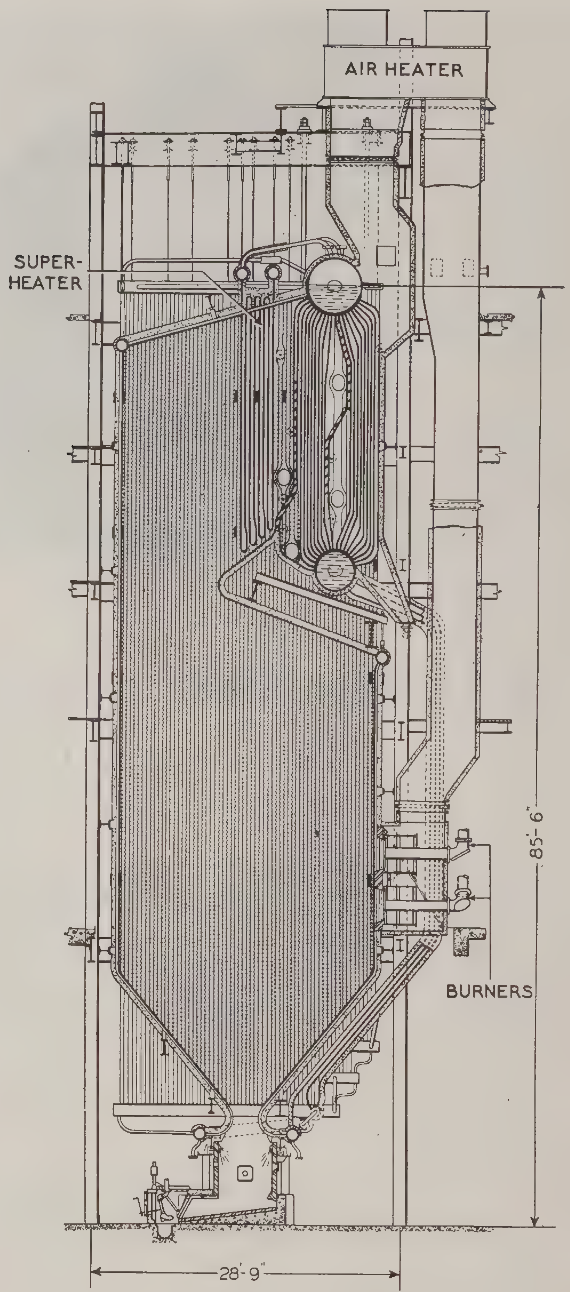

FIG. 3 CROSS-SECTIONAL VIEW, NATURAL-CIRCULATION BOILER

It is beyond the scope of this paper to present in detail the design data of these boiler units. Aside from a secondary interest in these data, boiler operators are primarily interested in the operating characteristics, availability, water control, and maintenance of their steam-generating units. A description of the physical layout of the steam plant is included to better acquaint the reader with its size, design features, and operating conditions. It must be remembered that war regulations prohibited extensive refinements in this steam plant, and these limitations were met remarkably well.

The time limit of construction and operating date prohibited exhaustive studies in layout and operating equipment. That the plant has produced steam consistent with high demand attests to the ability of the designers and operators to meet the wartime limitations. Most boiler operators will agree that boiler auxiliaries present more operating difficulties than the actual furnace, and it is well to note that in this case the boiler auxiliaries are not as a whole duplicated in each of the types of boilers. No attempt will be made to compare these auxiliaries, but the inclusion of the operation of the forced-circulation pumps is made, since it is considered an integral part of the forced-circulation boiler unit.

It is not the intention here to present data to influence the selection of any particular type of boiler unit. Boiler operators pride themselves on being able to fire any type of steam-generating equipment and to secure from it the maximum possible efficiency and reliability. After two years of experience with each of these types of boilers, it is possible to make a comparison of their operation and to present to those interested a summary of our experience at Kobuta.

DESCRIPTION OF PLANT AND BOILER AUXILIARIES

The original steam plant consists of four 350,000-lb per hr

boilers, designed for superheater-outlet conditions of 725 psi pressure and 750 F temperature. The first is a Combustion Engineering Company single-drum controlled forced-circulation boiler, Fig. 2, and the other three are Babcock & Wilcox Company two-drum, radiant-type, natural-circulation units, Fig. 3. Operating experience indicated that the capacity of three boilers was not sufficient to supply all the steam demanded by the chemical-process units with one boiler off the line for inspection and maintenance. Accordingly, a fifth boiler of 180,000 lb per hr capacity at 450 psi pressure without superheat was installed. This latest addition is a Combustion Engineering Company four-drum natural-circulation unit. Total steam-generating capacity available from the five boilers is 1,580,000 lb per hr. The four high-pressure units are housed in a reinforced-concrete boilerhouse, approximately 130 ft high, while the low-pressure unit is installed in a separate annex at the south end of the original concrete boiler room. No further reference will be made to the smaller natural-circulation unit and its auxiliaries.

Draft equipment for each of the high-pressure units is identical, consisting of one induced- and one forced-draft fan per boiler, with turbine drives. An important factor in selecting boiler capacity was the limitation of draft equipment to single fans per boiler so as to require a minimum number of reduction-geared-turbine drives, an extremely critical item during the construction period. Fly-ash collection equipment is within the induced-fan housings, thus minimizing the use of steel. Each boiler is equipped with a Ljungström air preheater. A combination of two coal-and-gas, and two coal-and-oil burners fire the forced-circulation boiler. Natural-circulation-boiler furnaces are equipped with six combination coal-and-oil, and two separate gas burners. All furnaces are dry-bottom, with intermittent ash-sluicing facilities, and continuous ash sprays. The forced-circulation unit is equipped with two Raymond bowl mills, with integral exhausters, and the natural-circulation units are fired with two Hardinge-type ball mills, with remote exhausters located on the operating floor. Suitable feed pumps are installed in the pump bay on the ground-floor elevation. These consist of five units, i.e., three turbine-driven, one motor-driven, and one combination turbine-and-motor dual-drive unit.

Steam at 700 psi and 750 F goes to a 35,000-kw turbogenerator which exhausts at 165 psi back pressure for chemical-plant-process requirements. Total plant electrical load approximates 14,000 kw, the excess electrical energy going into the local utility system. Exhaust steam leaves the turbine discharge and passes into two 24-in. lines at 165 psi and 460 F, which maintains slight superheat to the farthest end of the process-plant distribution lines. Part of this steam is reduced to 75 psi for process, as needed. In order to furnish 165-psi steam with a turbine or utility tie-line outage, desuperheating and pressure-reducing stations are installed between the boiler headers and exhaust lines. Any sudden interruption to exhaust-steam supply operates these stations through master controllers. Desuperheating water is supplied from the condensate system through special pumps installed at the feed-pump bay.

Main high-pressure boiler-plant piping is so arranged that boilers may be isolated into two separate generating systems, each

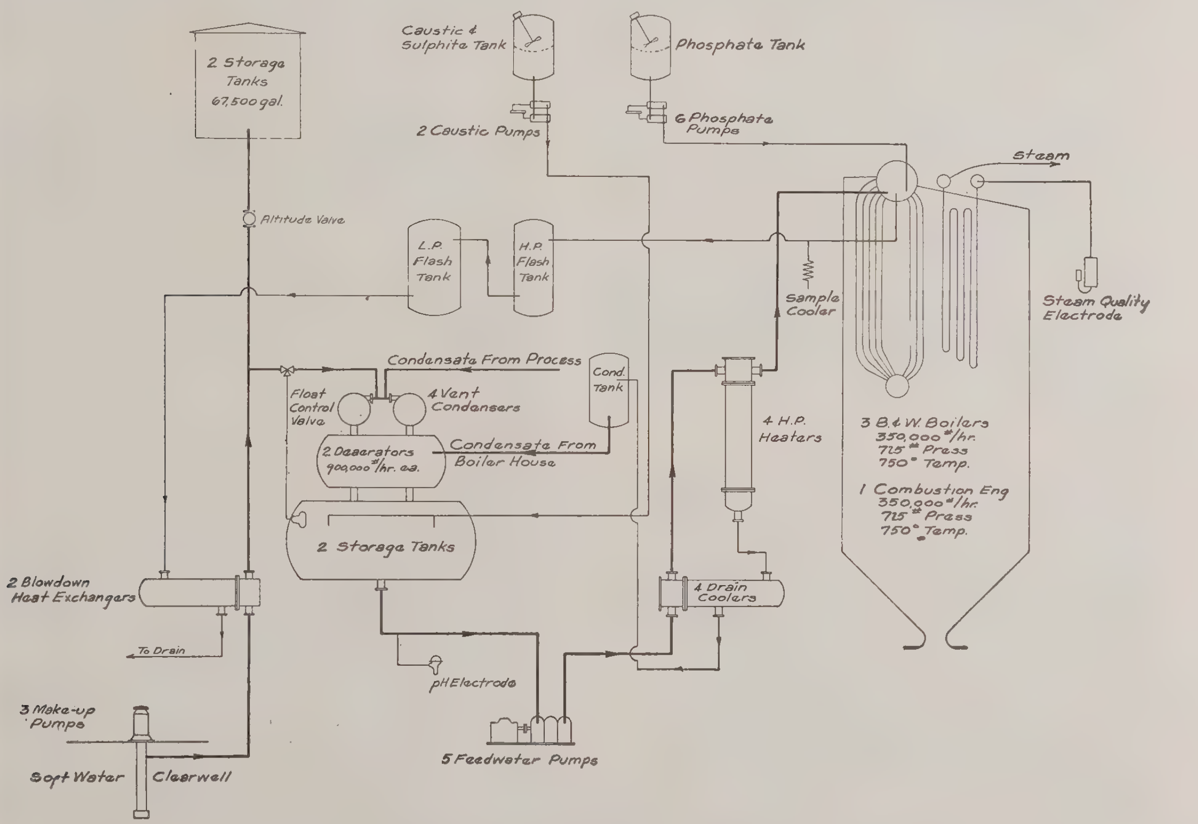

FIG. 4 BOILER-FEEDWATER FLOW DIAGRAM

containing its own feedwater, steam-generating, and blowdown facilities. The forced-circulation main steam lead and one of the natural-circulation units are tied to a common header with the remaining two high-pressure units discharging into a similar header. The turbogenerator is fitted with double inlet valves, one from each main boiler header.

The blowdown system consists of two separate series of high- and low-pressure flash tanks, from which 165-psi and 10-psi steam is supplied to the high-pressure heaters and to the deaerators, the effluent being sewered through the blowdown heat exchangers. It has been noted that during peak loads and high rate of blowdown, approximately 50 per cent of the 165-psi steam requirements for the high-pressure heaters is met by the high-pressure flash steam. The feedwater flow is illustrated in Fig. 4.

Coal comes to the plant by rail, truck, or barge. Belt conveyers transport it from unloading points to storage or directly into the crushers where it is sized to $^3/_4$ in. or less, before entering the bunker house. A feeder tripper distributes coal into eight 250-ton hoppers from which it drops by gravity, through automatic scales to mill feeders and pulverizers at each boiler. Furnace volumes permit carrying full boiler load on coal alone, consuming 1500 to 1700 tons per 24 hr for the four large boilers. All-electric combustion control is duplicated on all boiler units, regulating air and coal feed according to steam demands. Hand preadjustment of the control mechanism assures sufficient combustion air for oil and gas.

Feedwater-pump- and draft-fan-turbine exhaust goes to two deaerating feedwater heaters that handle both return condensate and raw make-up. A reducing valve from the main-turbine exhaust supplies any deficiency. The high-pressure closed heaters receive steam directly from the main-turbine exhaust, supplemented by flash from the blowdown system.

Water-Treating Facilities

Treating-plant equipment and basins are located adjacent to the powerhouse in a separate building and connected to the station by a pipe tunnel. Ohio River water is fed into three Spaulding precipitators in the water-treating plant through a 20-in. line. The raw-water flowmeter controls the rate of chemical input. Lime, soda-ash, and copperas solutions are fed by individual pumps into the inlet flume of the precipitators. At the maximum rate of flow through the precipitators, the detention time is 90 min. The water, having been clarified and partially softened in its passage through the precipitators, flows by gravity to six Anthrafilt filters. The filtering capacity is 3900 gpm and

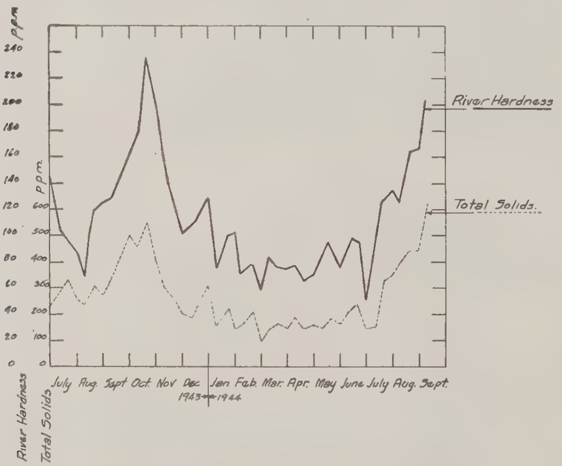

Fig. 5 Ohio River Water Characteristics

the flow of water through the filters is regulated by rate-of-flow controllers. In leaving the filters, the water is discharged into an acid-mixing chamber before passing into a filter clearwell, and a pH value of 8.3 is maintained to prevent deterioration of the zeolite in the final softeners.

After the water is clarified, partially softened, filtered, and acidified to the correct pH, it is pumped to six gravity-flow zeolite softeners. The design of the equipment was based on a hardness of 55 ppm from the filter clearwell. With this capacity setting, each unit is capable of softening about 770,000 gal of water in each regeneration. The zeolite operates in the sodium cycle with rock salt for preparation of the solution. The treating process is capable of delivering the required boiler make-up water to the boilerhouse with a residual hardness rarely exceeding 2 ppm even during periods of peak hardness of the raw water.

Make-up water is pumped from the soft clearwell to two deaerators located in the boiler plant. Each deaerator is designed to operate at a pressure of 10 psi with a guarantee to remove the oxygen from 900,000 lb of feedwater per hr. To protect the equipment from corrosion attack, sodium sulphite is fed into the deaerator storage tank. Caustic soda is also added at this point to maintain a safe pH value in the feedwater, as it passes through the feed pumps and high-pressure heaters. Caustic-soda feed is also used to maintain the specified alkalinity range in the boiler water. Sodium-metaphosphate solution is fed directly into the upper drums of the four boilers to satisfy demands of residual hardness of the boiler feedwater and acts as a sludge-forming accelerator. Each boiler is equipped with a boiler-water-sample cooling coil located at the upper drum, and two Straub condensers with conductivity cells and recorders are provided to obtain a continuous check on the quality of steam leaving the boiler drum.

Controlled Forced-Circulation Unit

The sectional view of the forced-circulation unit shows no lower or mud drum. Forced circulation eliminates the need for the lower drum with its interconnecting generating surface necessary to set up circulation between the lower and upper drums. Boiler feedwater enters the single drum after passing through the economizer which is located in the upper section of the convection zone, immediately below the air preheater. The feedwater is introduced into the drum through a submerged pipe which extends the entire length of the drum, discharging the water through perforations. Two 10-in. downcomer pipes, located about 6 ft from each end of the drum, carry the water down to the circulating pumps. These downcomer openings are protected by wire screens as mechanical protection for the circulation-pump impellers and are also fitted with downtake spiders to eliminate vortex formation.

The circulating pumps are 10 × 10 Allis-Chalmers horizontal single-stage type, Fig. 6, rated at 4500 gpm, 151 ft head, 517 F, and suction pressure of 800 psi. They have an end suction and a side discharge and are driven by horizontal steam turbines through a Fast "spacer" coupling. Ball-thrust bearings absorb all the thrust load of the pump. Through close co-operation between the representatives of the boiler and pump manufacturers, the pumps are so designed to maintain a constant and unfailing flow of water through the boiler and to operate continuously and without interruption, in order to protect the boiler tubes. To facilitate removal of the rotating element, there has been incorporated in the design of the pump a casing cover, or end head, through which all the internal parts of the pump can be removed. A close-clearance bushing directly behind the pump impeller is used with "bleed-in" and "bleed-off" connections to reduce the temperature and pressure on the stuffing box. The bleed-in connection permits a water flow of 20 gpm at 240 F and 900 psi from the boiler feed pump discharge main to enter the inner end

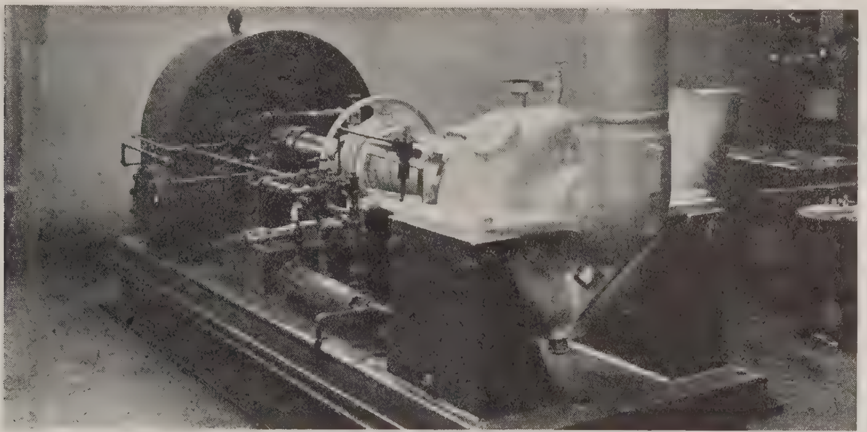

FIG. 6 FORCED-CIRCULATION-BOILER PUMP
(Rated at 4500 gpm, 151-ft head, 1500 rpm, 517 deg F; suction pressure 800 psi.)

of the reducing bushing. This flow of water at a pressure higher than pressure in the pump maintains a water flow at 240 F out of the bushing into the pump, instead of the hot boiler water in the pump flowing back toward the packing. About 2 gpm of 240 F water flows into the pump, and the remaining 18 gpm is bled off through the bleed-off connection. By this arrangement it is possible to pack against a low pressure and low temperature, rather than against the normal boiler pressure and temperature. Further reference is made to this feature later in the text.

The circulating pumps located on the ground floor withdraw water from the drum and discharge into a loop which supplies water to wall-distributing headers. Two of these headers supply the burner and rear-wall tubes, two supply the central section of the side walls, four others supply the outside sections of the side walls, and the remaining one supplies water to the secondary generating section.

Flow of water from the headers to the wall and secondary-generator tubes is controlled by a series of combination orifice strainers, consisting of a nipple approximately 6 in. long perforated by $^3/_{16}$-in. holes and drilled with a control orifice. The arrangement is such as to permit removal of the orifice strainers from the headers for inspection and cleaning. One orifice strainer serves a tube nozzle which is trifurcated for the three wall tubes which arise from it. A total of 276 strainer orifices are provided to supply 183 tubes on each of the burner and rear walls, 198 tubes on each of the side walls, and 32 tubes in each section of the secondary generator located immediately below the economizer. Front- and rear-wall tubes lead directly into the top of the drum above water level, while the side-wall and secondary-generator elements collect into headers and pass into the drum through 4-in. risers entering the drum above the water level.

The 54-in-drum internals are so arranged that the water-steam mixture is first directed downward by a deflector baffle at the tube entrances. The flow is then reversed in direction permitting the water to separate from the steam. This reversal permits the steam part of the mixture to continue directly to the screen driers, while the remainder of the mixture bubbles through a submerged screen below the water level. Steam at relatively low velocity passes through three sets of screen driers for the complete removal of any entrapped moisture. In leaving the drum, the steam passes around deflector plates located directly under the tubes leading to the superheater.

The superheater element hangs directly in the gas stream at the entrance to the convection section and is protected by a slag screen of staggered front-wall tubes, three rows deep. Combustion gases pass out of the furnace through the front-wall screen, across the superheater bank, through the convection bank containing two sections of generating tubes, and through the economizer. The last banks are supported on water-cooled beams which are part of the secondary-generator circuit. Soot is removed below the superheater, and by the dust collector in the induced-draft-fan housing.

It will be noted that in the forced-circulation unit there is no need for generating tubes to be suspended in the gas passes and baffles for routing gas flow are not required. The forced-circulation unit thus approaches a favorable design of gas passes and tube arrangement to overcome any fly-ash erosion difficulties.

Boiler dimensions of the forced-circulation unit are given in Table 1.

TABLE 1 FORCED-CIRCULATION-UNIT DATA

Furnace volume, cu ft gross	25,400
Boiler heating surface, sq ft	4,510
Waterwall surface, sq ft	8,470
Superheater surface, sq ft	4,430
Economizer surface, sq ft	9,830
Air preheater surface, sq ft	38,900
Operating water volume, lb	36,643
Steam drum	54″ diam × 28′–9½″ long
Upper wall tubes	$1^1/_4$″ OD × 0.120″ wall thickness
Lower wall tubes	$1^1/_4$″ OD × 0.150″ wall thickness

NATURAL-CIRCULATION UNITS

As noted by the sectional side view, Fig. 3, the natural-circulation boilers have two drums with pendant superheater. Feedwater enters the upper drum through a perforated pipe below the water level and passes down to the mud drum through interconnecting generating and heating tubes. Water is then distributed to the waterwalls through eight headers located at the bottom of the furnace. Two of these supply front and rear walls, two supply the center and rear section of the side walls, and the other four supply the front sections of the side walls. Rear- and front-wall tubes terminate directly in the steam drum entering below water level. The side-wall tubes terminate in headers at the top of the furnace and continue to the drum by risers entering the drum above water level, but inside the internal baffle compartment.

The 60-in-drum internals cause the water and steam mixture in the wall and generator tubes to enter a baffled compartment from which the mixture passes tangentially into 44 cyclone steam separators. As a result of the whirling action of the cyclones, the

water is directed downward while the steam passes upward through the corrugated scrubber elements for further removal of moisture. In leaving the drum the steam passes through a twin-type steam scrubber where the last trace of moisture is removed. The natural-circulation boilers are not equipped with economizers. The convection bank and superheater elements are protected from direct radiation by a water-cooled arch extending approximately halfway into the furnace, immediately below the mud drum.

Attention is called to the baffle arrangement as shown in the sectional view, Fig. 3. The baffle between the first and second pass is of tile construction. The upper section of the baffle separating the second and last pass was originally as shown in Fig. 3 and is also of tile construction, the sloping portion being of the poured type, and the lower section again of tile construction. In recent months two generating-tube failures have occurred on two of these natural-circulation units due to fly-ash erosion of the tube metal. In the first case, leakage of dust-laden gas through the baffle, separating the second and last pass, seriously eroded the generating tubes directly behind this baffle, a short distance below the top drum. In the other case, concentration of fly ash sweeping down the slope of this same baffle eroded tubes in the row just ahead of this baffle at a point just below the baffle slope. Baffle changes have been completed on all three of the natural-circulation units by making the entire baffle vertical from the drum downward. This arrangement should overcome both difficulties as well as afford convenient access to the furnace for inspection of the baffle for leakage. Soot is removed at the second pass of the convection bank at mud-drum level, as well as by collection in the induced-draft fan similar to the forced-circulation unit.

Boiler dimensions of the natural-circulation units are given in Table 2.

TABLE 2 NATURAL-CIRCULATION-UNIT DATA

Boiler heating surface, sq ft	20,640
Waterwall surface, sq ft	6,367
Superheater surface, sq ft	4,030
Total steam-generating surface, sq ft	31,007
Air-heater surface, sq ft	38,600
Volume of combustion space, cu ft	29,900
Operating water volume, lb	150,680
Front-wall tubes	3¼″ OD × 0.203″ wall thickness
Steaming drum	60″ diam. × 30′ long
Mud drum	42″ diam. × 29′ long
Rear-wall tubes	2½″ OD × 0.170″ wall thickness
Side-wall tubes	2½″ OD × 0.170″ wall thickness
Roof tubes	4 ″ OD × 0.213″ wall thickness
Generating tubes	2½″ OD × 0.148″ wall thickness

Operating Conditions

During the latter part of 1943, the entire year of 1944, and the first quarter of 1945, the directed rate of chemical production demanded a peak steam load of 1,300,000 lb per hr, with an installed capacity of 1,400,000 lb per hr at that time. It was the responsibility of the boiler operators to maintain maximum steam generation under extreme varying conditions. Boiler outages were purposely kept to an absolute minimum by maintenance forces on a 24-hr schedule to keep the boiler units in operating service. Initial planning called for scheduled outages of boiler units each 6 months, but revisions were made on first inspections and subsequent tube failures to remove the forced-circulation boiler from the line each 60 days for inspection, and the natural-circulation units each 180 days. This schedule was adhered to during the entire period of peak steam demands.

The complexity of the butadiene-styrene chemical process, with its large number of stills, compressors, and heat exchangers, imposed on the boilers the requirement of maintaining correct pressure and temperature at all times. The chemical process is extremely sensitive to variations in steam conditions and slight steam upsets curtail chemical production. During boiler difficulties, when generating capacity could not maintain proper steam conditions, operators were reluctant to drop steam delivery to process because subsequent readjustment to normal production rate would require 24 to 48 hr, in addition to entailing large losses of raw materials. The boilers were called upon to recover from adverse conditions promptly and in most cases, boiler operators were able to maintain a continuity of steam flow to the process units.

In contrast to the operation and performance of a boiler under central-power-station conditions where make-up water rarely exceeds 2 per cent, and where even this amount is supplied by evaporation, boiler make-up here at Kobuta has been of the order of 60 to 70 per cent due to process-steam requirements. These steam requirements necessitate discarding two thirds of the steam condensate in process wastes.

Ohio River water, which is the raw-water source, contains principally sulphate salts and is generally slightly acid in nature, with a pH of 6.5. Total hardness for the major portion of the year ranges between 70 and 90 ppm expressed as calcium carbonate.

In Table 3 the analysis given for Ohio River water may be considered as being the average.

TABLE 3 TYPICAL ANALYSIS OF OHIO RIVER WATER

	Ppm
Bicarbonate (HCO_3)	7
Sulphate (SO_4)	96
Chloride (Cl)	15
Silica (SiO_2)	5
Iron (Fe)	4
Calcium (Ca)	23
Magnesium (Mg)	5
Sodium (calc.) (Na)	23
Suspended solids	17
Total dissolved solids	195
Soap hardness as $CaCO_3$	78

Composition of the water is subject to wide variations in hardness and dissolved solids, as shown in Fig. 4. During the 2 years that the plant has been in operation, control of water conditioning and continuity of operation have been maintained under conditions where hardness of the water has fluctuated from a low of 60 ppm during the winter and early spring seasons, to a high exceeding 250 ppm during periods of low river flow. Similarly, dissolved solids fluctuated from a low of 100 ppm to a high exceeding 600 ppm. Obviously with boiler make-up exceeding 60 per cent, and with solids concentrating in the boilers in a very short time during periods of peak dissolved solids, conditions exist which tax a conventional natural-circulation boiler to the limit and impose on the operation of a forced-circulation unit the additional measures necessary to prevent an accumulation of suspended matter at its control orifice strainers great enough to cause tube failures. Blowdown equipment is adjusted to maintain a dissolved-solids content of 2000 ppm in the boiler water.

On the basis of the average analysis of raw water in which dissolved solids were 178 ppm a blowdown of 10 per cent was expected. As most of the heat-recovery equipment was designed to handle this quantity, the blowdown facilities were vastly overloaded when it became necessary to blow down 30 per cent of the feedwater in order to maintain the desirable boiler-water conditions when the dissolved solids in the raw water exceeded 600 ppm. After installing larger blowdown valves and pipes, and with the continuous-blowdown equipment operating at maximum, it is still necessary to supplement this with continuous blowing of the mud drums. With the installation of the fifth boiler, blowdown-equipment arrangements can be made to modify the blowdown lines in such a manner as to recover the heat normally lost in the use of the mud-drum blows.

Residue oil and gas furnished from the process units is delivered to the boilerhouse for burning in combination with the

coal obtained from the local bituminous mines. Normally, moisture content of the coal does not exceed 4 per cent, but there have been periods during transportation difficulties, when 10 to 15 per cent moisture coal has been delivered to the pulverized-fuel equipment; such periods occurring when steaming capacity was at a premium. While the ability to satisfy steam demand under these moisture conditions is a function of the fuel-burning and handling auxiliaries, boiler operators were called upon to adjust boiler ratings continuously to maintain proper pressure and loading. These periods made it possible to observe the individual boiler response to the demands for steam to process. That no particular difference between the boiler units was found might be surprising to those who believe that the forced-circulation unit responds and recovers load in less time than the natural-circulation units of the same capacity. With the units equipped with different types of mills, any indication of such conditions might be attributed to the mill performance rather than to that of the boiler.

Local strip-mined coal, ranging in quantities of 25 to 50 per cent of the total fuel, has been fired in all boilers. Two generating-tube failures and severe erosion of generating tubes in the natural-circulation boilers have led several consultants to consider these conditions to be the result of the high silica content of the ash of this strip-mined coal.

Operating Characteristics

The forced-circulation boiler, with $1^1/_4$-in-OD wall tubes and only one drum, has considerably less water in it than the natural-circulation unit has, with two or more drums and larger-diameter wall and generating tubes. The forced-circulation boiler holds approximately 37,000 lb of water at steaming level, compared to the natural-circulation boiler which holds 155,000 lb, or nearly $4^1/_4$ times as much. This causes a greater sensitivity in the forced-circulation boiler to changes in feedwater conditions or changes in controls.

With the natural-circulation boiler operated at 350,000 lb of steam per hr for a period of 2 hr with the blowdown completely shut off and with 400 ppm dissolved solids in the feedwater, an increase of 1800 ppm in the solids concentration of the boiler water would result. This added to the normal 2000 ppm carried would mean a total concentration of the boiler water of 3800 ppm. Actual operating data indicate that these boilers can be operated at 400,000 lb per hr with 4000 ppm dissolved solids. Should the continuous blowdown be completely shut off on these natural-circulation boilers, no serious results would be experienced before the boiler operators could remedy the condition.

In the case of the forced-circulation unit under the same conditions, the concentrating effect of evaporation would result in a total dissolved solids content of 9600 ppm. At a steam rate of 350,000 lb per hr, solids carry-over would probably begin with a concentration of 5000 ppm and would doubtless be experienced if the blowdown were stopped for only $^1/_2$ hr.

To be reasonably free from upsets of the nature described, analyses of the boiler waters are made every 2 hr, total solids being checked by the conductivity method. In so far as the natural-circulation boiler is concerned, this 2-hr frequency is adequate to detect any major change in conditions before the results become serious. Such is not the case in the forced-circulation unit. Carry-over has been experienced on several occasions with the forced-circulation unit as a result of rapid increase in solids concentration, the carry-over being detected by means of the steam-temperature recorder.

Arrangements are being made to install a conductivity recorder on all the boilers, recording total solids in the continuous blowdown. Especially in the case of the forced-circulation boiler, where the quantity of water at steaming level is relatively small and where the percentage make-up is relatively high, a conductivity apparatus recording total solids should be installed as standard equipment with the boiler.

Natural-circulation units depend on differences in specific gravity to set up circulation; and as a result, circulation rates vary with changes in rating or changes in heat input. In the forced-circulation boiler the rate of circulation is fixed and controlled by means of centrifugal pumps which take the water from the main drum and discharge it to distribution headers where it enters the tubes through control orifices. These orifices are so sized that a reasonable pressure drop is experienced across them and good control of distribution is the result.

It is natural to expect that a centrifugal pump installed in the boiler-water circuit would be regarded as an outstanding weak point in the entire system. In actual practice, this has not proved to be the case at Kobuta. To date there has been no instance of circulation failure due to the pumps. The forced-circulation unit is equipped with two pumps, one operating at rated speed and load, the other idling at approximately 400 rpm. The original installation required manual operation to place the idling pump in service should the loaded pump fail. This arrangement made it mandatory to station an operator at the pumps at all times. Physical layout has placed the pumps remote from the boiler feed pump bay, and in the future, boiler-installation designers might consider locating a forced-circulation boiler in such a manner that the circulation pumps can be attended by the normal boiler feed pump operator or water attendant. The usual interlocks for tripping the coal-pulverizing mills when the pump differential reaches the low limit were provided, but this feature was removed shortly after the unit went into service, because of the feeling that the pump attendant was sufficient protection.

The stationing of the pump attendant was regarded as a stopgap measure for emergency protection of the boiler, and at present quick-opening steam valves have been installed to bring the idling pump to full speed and rating automatically. The control for these valves is taken directly from a differential-pressure controller. On occasions when upsets resulted in low steam pressure to the pumps, and pump differential reached the low safe limit, the idling pump was automatically put in service in a very satisfactory manner. It is now believed that with this feature added, and based on the performance of the pumps to date, the reliability of the circulation system is assured.

Efficiency and performance tests have indicated no outstand-

TABLE 4 PERFORMANCE DATA OF FORCED-CIRCULATION AND NATURAL-CIRCULATION STEAM GENERATORS

	Forced-circulation unit	Natural-circulation unit
Steam output, lb per hr	352500	345000
Temperature of air for combustion, deg F	90	106.3
Temperature of feedwater to boiler, deg F	472	364
Exit gas—CO_2 content, per cent	14.9	15.2
Heat content of coal (as fired), Btu per lb	13695	13095
Steam pressure, psi	720	722
Air pressure at burners, in. water	1.92	2.8
Draft in furnace, in. water	0.139	0.22
Draft at boiler outlet, in. water	1.9	2.98
Draft at economizer outlet, in. water	4.31	....
Draft at air-heater outlet, in. water	6.81	10.65
Steam temperature, deg F	726	690
Temperature of air leaving air heater, deg F	574	554
Temperature of gases leaving boiler, deg F	1038	658
Temperature of gases leaving economizer, deg F	697	....
Temperature of gases leaving air heater, deg F	379	376
Temperature of feedwater entering economizer, deg F	350	....
Combustion space per lb of coal per hr, cu ft	0.78	0.92
Heat absorbed by water in economizer, Btu per lb	133	....
Heat absorbed by water and steam in boiler, Btu per lb	742.3	864
Refuse, per cent of fuel (as fired), per cent	11.82	15
Rate of heat absorption per lb of fuel, KB	11.54	10.95
Rate of heat absorption per sq ft of steam-generating-unit surface per hour, KB	13.75	11.47
Efficiency of steam-generating unit, per cent	84.3	84.0
Average draft loss, in. water	6.67	10.43
Average air-pressure loss, in. water	5.93	9.65
Steam purity, ppm	0.6	0.7

ing differences in the two types of boiler units. Table 4 gives comparative test data taken from each of the boilers. These data are presented for general information and do not indicate performance under stable conditions. The forced-circulation and the natural-circulation units have been and are consistently operated at 85 per cent efficiency. Steam requirements for normal operation of the pumps of the forced-circulation unit amount to 10,000 lb per hr, or 3 per cent of the boiler capacity. This power requirement imposes an additional loss of over-all steam output, resulting in a lower inherent over-all efficiency of the forced-circulation type of boiler unit.

With the high make-up previously mentioned, and with the boilers being of necessity maintained on the line for considerable periods, it has been observed that the natural-circulation units form considerable sludge in the vicinity of the downcomer tubes at the top drum. In the forced-circulation unit, this sludge with additional scale particles collects on the orifice strainers tending to plug the control orifices. On two occasions this plugging of orifice strainers has resulted in tube starvation and failure. It has been particularly observed that at no time have scale particles been encountered on the natural-circulation units receiving the same feedwater and treatment. The exact location of the origin of these scale particles has not yet been determined, but they appear to form in the region of the distributing headers ahead of the orifice strainers. Chemical composition of these scale particles is identical with that of the soft sludge which is formed in the natural-circulation boilers.

Removal of the sludge is accomplished in the natural-circulation boiler by the conventional tube turbining of the downcomers with final removal at the mud drum. Build-up of this sludge indicates that a scheduled outage once each 6 months is sufficient for its removal with little danger of serious difficulty for longer periods. In the forced-circulation unit, sludge and scale removal is accomplished by removing and cleaning all the orifice strainers. Past operating data indicate that sludge and scale particles in the forced-circulation unit require a boiler outage each 60 days for inspection, thus reducing its availability, as compared to the natural-circulation boilers.

During internal inspections of the circulating pumps for the forced-circulation unit, it has been revealed that at times considerable build-up of scale takes place on the pump impellers with indications of scale breaking off and entering the orifice headers. As previously described, the circulating pumps have an arrangement of bleed-in and bleed-out connections which permit a small amount of boiler feedwater to enter the pump. Water consultants agree that under pH conditions existent in the feedwater, a reaction between the soluble phosphate present in the boiler water and the hardness present in the incoming feedwater results in a precipitation of calcium phosphate which forms a scale rather than the normal soft sludge precipitated in conditioned boiler water. It has been deemed advisable to maintain this "in" leakage to the pump at a minimum, and differential-pressure regulating valves have been installed to maintain a constant differential pressure automatically in the bleed-in line to the pump over the circulating pump discharge pressure. Prior to this installation, manual adjustments were made with probable erratic results.

In an effort to improve the availability of the forced-circulation unit, and to minimize the work required for sludge and scale-particle removal, two external strainer drums have been installed in each of the pump discharge lines as near as possible to the orifice headers. These strainers have openings of exactly the same size as those in the header orifice strainers, and each strainer has a free area more than twice that of the total for all the orifice strainers. These strainers were installed at a time when it was believed the scale particles were being formed between the steam drum and the distribution headers, including the pump impellers. It was hoped these strainers would thus effectively remove all of the scale particles and cause scheduled boiler outages only to clean the external strainers. Results observed on two occasions, since installation, reveal conditions in general to be no better than prior to their installation. It is apparent that scale is formed on the distribution headers ahead of the orifice strainers, a region of non-heat-absorbing surface, a condition which is contrary to that found in the conventional boilers. No definite conclusion concerning scale formation at this location has been advanced, although suspicion has been pointed to velocities, to mechanical agitation due to the pumps, and to minimum chemical-reaction time in the drum.

The apparent failure to remove the scale particles by mechanical means in the forced-circulation unit and the desirability of preventing sludge accumulation in both types of boilers has led all concerned to an attitude that the problem is one of chemical treatment and elimination of the formation of the sludge and scale rather than removal of scale particles after they have formed. A modified chemical treatment is now being used to overcome this condition and so far the results appear favorable.

The forced-circulation type of boiler has proved to be much more stable than the natural-circulation boilers from the standpoint of water level with varying operating conditions. The fact that the forced-circulation boiler is equipped with an economizer which furnishes the feedwater to the drum at 480 F, as compared with 340 F feedwater entering the natural-circulation drum, is given as one factor for such stability. Another factor is that the rate of circulation is relatively constant for forced circulation at either maximum or minimum rating. This pumping rate is 5100 gpm, or 1,900,000 lb per hr which gives a ratio of circulated water to steam of $5^1/_2$ to 1 at rated load.

In a natural-circulation boiler the rate of water circulation increases with rating, probably resulting in considerable turbulence in the steam drum at higher load conditions. With a slight lowering in drum pressure due to suddenly increased steam demand, the volume of steam bubbles in the generating tubes will increase sufficiently to cause a rise in water level in the drum, since the generating tubes enter the drum below water level. Such a rise, often called "swell," tends to upset feedwater regulation. This condition can only occur in the natural-circulation type of boiler unit. Consequently, the forced-circulation boiler-water level will be upset to a lesser degree by rapid and large load changes regardless of feedwater control than with the natural-circulation boiler. However, the natural-circulation units have, on a number of occasions, experienced load changes from 200,000 to 400,000 lb per hr without seriously upsetting water level and with no sign of carry-over. The ability of the operators and of the feedwater control to handle these conditions indicates that natural-circulation units can take rapid load swings without serious water-level upsets.

The expectation that the forced-circulation boiler with its closely spaced $1^1/_4$-in. tubes would present a nearly solid water-cooled metal surface to the furnace and that slag would not so readily adhere to this surface, has not been realized. Wall soot blowers were installed slightly above burner level to aid in removing this slag deposit. It appears that the greater number of spaces between the tubes for a given width of wall in the forced-circulation unit offers a larger number of points for slag to adhere, thus making it possible for the slag to bridge over more readily in this type of boiler than in the natural-circulation unit with larger wall tubes and greater spacing. With coals of the quality now burned, with an ash-fusion temperature between 2300 F and 2400 F, wall blowers or lancing will not be required for the natural-circulation units.

Tube ruptures at different times on both types of units afforded

the opportunity for boiler operators to compare urgency of removing the boiler from service. With chemical operating units unable to reduce steam demand safely at a moment's notice, the forced-circulation boiler, in one case, was kept on the line at full rating in excess of 3 hr, despite a complete wall-tube rupture. This type of boiler, with its relatively smaller-diameter tubes and small control orifice in the water inlet, in addition to the fact that the generating tubes terminate above the water level in the drum, can suffer a complete tube rupture without the necessity of immediate removal from the line. This is an extremely vital factor in chemical processes where shutdowns must be made in an orderly and safe manner. In the two instances when rupture occurred in a wall tube or generating tube on the natural-circulation units, it was necessary to take the boiler off the line immediately, resulting in pressure upsets to chemical process. A natural-circulation boiler, upon loss of any tube, immediately becomes inoperable.

Conclusion

In summarizing and outlining the characteristics found in these two types of boiler units at the Koppers plant, it is not the intent to suggest advantages or disadvantages of any particular type of unit. That the forced- and natural-circulation principles are radically different would of necessity present different operating characteristics.

The forced-circulation unit has demonstrated particular operating assets as follows:

1 The ability to suffer loss of a tube and continue to operate until other apparatus is brought on the line to take its place, or until load can be sufficiently reduced so that boiler capacity is not required.

2 Water-level stability under conditions of rapid and large load changes.

The natural-circulation units have particular operating assets as follows:

1 Greater availability in comparison with forced-circulation type.

2 Less sensitivity to changes in feedwater conditions, rendering it more suitable for high make-up with high solids in the feedwater.

3 Lower susceptibility to scale formation under equivalent feedwater conditions.

The operating record of both of these types of steam generators reveals their ability to supply process-steam requirements under many adverse conditions. Chemical production of butadiene and styrene has been maintained at high rates throughout the operating period to date, and over-all operation should compare favorably with that of any other steam plant of its size and operating conditions.

Discussion

J. M. Harvey.[4] The character of the water in the Ohio River and its tributaries is such that many problems must be met which do not exist where water of more stable quality, such as water from the Great Lakes, is utilized for boiler-feed purposes. Acid mine drainage and extensive use of these streams for disposal of industrial waste and sewage from the heavily populated surroundings make for extreme variation in the character of the river water.

Characteristic is the trend from a bicarbonate condition, with low dissolved solids and increased suspended material during the heavy run-off in the spring and early summer to a highly acid condition, with high dissolved solids and low suspended material during the low flow in late Summer and Fall. Localized pollution and the presence of river pools may further influence the character of the river water at a particular plant intake.

Generally, the periodic variations in dissolved solids will follow a somewhat fixed pattern with minimum and maximum concentrations reaching about the same value each year, and with the average concentration varying not more than a few ppm over a period of several years. However, combination of conditions may produce considerable deviation from the normal pattern as shown by Fig. 5 in the paper, charting variations during a period when industrial activity was at an unprecedented high.

The wide flexibility of the water-conditioning facilities installed at Kobuta made it possible to cope with the variations imposed and maintain boiler-water conditions within closely defined limits. Even so, characteristics of the river water exert their influence and have been productive of adherent sludge deposits in the boilers. Specific measures were adopted several months ago which we believe, and which are proved in part, will solve this problem.

In January, 1945, silicate treatment was introduced to one of the natural-circulation boilers. At this time the routine water-testing program was expanded to include determination of the silica concentration in the boiler water and saturated steam. These tests soon established the fact that there was no significant difference between the silica present in the steam generated by the boiler receiving silica treatment and the boilers not receiving this treatment.

Since all the natural-circulation boilers had been mechanically cleaned just prior to the introduction of silicate treatment, inspection of these boilers in June, 1945, after a 6-months' run, afforded the opportunity to compare the appearance of the internal surfaces of the boilers. The boiler subjected to silicate treatment was decidedly cleaner than the other natural-circulation boilers.

On the basis of these observed conditions, silicate treatment was extended to all the natural-circulation boilers as well as the forced-circulation boiler. Inspection of the forced-circulation boiler in October, 1945, after a run of approximately 60 days on silicate treatment, revealed accumulation of scale particles in the orifice headers to about the same extent as noted during previous inspections. However, finely divided sludge, which had been found intermingled with the scale particles on previous occasions, was almost entirely absent. The scale particles are identical in chemical composition to the finely divided sludge formerly found along with the scale particles. This is indicative possibly that the scale particles originate at some point in the circulating system where the finely divided sludge adhered and attained more coherent and compact form under conditions existing at that point. Thus we believe there is some possibility that the scale particles will be eliminated with continued operation on the silicate treatment.

In connection with the silicate treatment, it is also worthy of mention that inspection of the 35,000-kw back-pressure turbogenerator in October, 1945, showed the complete absence of any deposits. This inspection was made after approximately 2 years of operation, and silicate treatment was in effect during the last 9 months of operation.

H. J. Klotz.[5] The authors of this paper are to be commended for the unprejudiced presentation of the comparison of the operating characteristics of forced- and natural-circulation boilers of the same capacity installed side by side in an industrial plant and performing under identical conditions as regards load and

[4] Engineering Service, Hall Laboratories, Inc. Pittsburgh, Pa.

[5] Chief Power Engineer, Stone & Webster Engineering Corporation, Boston, Mass. Mem. A.S.M.E.

feedwater. The writer's connection, as consultant to the Office of Rubber Reserve, with the operation of the Koppers plant, has afforded an opportunity to observe that the plant-operating organization has been equally unprejudiced in its handling of the boilers. There has been not the slightest tendency to favor either type of boiler, but a conscientious effort has always been evident to meet any special requirements imposed by the two types of boilers. The fairness of their comparison has thus been assured.

It is, of course, too much to expect that a comparison in one plant only could form the basis to permit final and definite conclusions as to whether one or the other type of boiler should be installed. The principal offsetting features would appear to be the ability of the forced-circulation unit to continue in operation following the loss of a tube, an important item in many processes, compared with the greater availability of the natural-circulation boilers. Corrective measures adopted at the Koppers plant will probably obviate the importance of this comparison as it is believed the causes of the tube ruptures in the natural-circulation boilers have been greatly minimized, and the lower availability of the forced-circulation boiler should eventually be overcome by further progress in chemical treatment of the feedwater plus possible additional mechanical features to prevent sludge accumulation on the orifice strainers.

The extremely variable nature of the make-up water at this plant makes the latter an important consideration and one which, until it is overcome, points to the desirability of the natural-circulation boiler for comparable water conditions.

It is important to note that the pumps required for circulating water with the forced-circulation boiler have imposed no operating problem.

Experience at the Koppers plant indicates that the practicability of the forced-circulation boilers for industrial plants has been sufficiently proved to warrant additional installations, and that any plant considering the choice between the two types would be safe in basing its decision on the relative investments and space requirements after assuring itself that any possible feedwater limitations would be satisfactorily met.

W. S. Patterson.[6] The authors have refrained from comparing differences in design in the two boiler types unless these differences have, up to the present time, resulted in operating assets in favor of one type or the other. However, since forced circulation, applied to large steam generators, is new in this country, it will be of interest to point out some of the reasons for the difference which will be noted from a study of the paper, and some of the potential assets.

Small-diameter tubes are used in forced-circulation boilers because a high flow resistance and velocity in the tubes are desirable, and because a high fluid velocity in the tubes can be realized with a minimum quantity of circulating water handled by the pumps. Small-diameter tubes can have very thin walls, resulting in low hot face skin temperatures and low temperature stress in the tube metal even with very high rates of heat absorption. There is also a saving in weight of tube metal and weight of water in the tubes; but the advantages of small tube diameter are most apparent in high-pressure boilers as will be seen from Fig. 7 of this discussion.

Although bifurcated tubes have been used in natural-circulation-boiler furnaces, this is the first application of trifurcated furnace tubes. Such an arrangement decreases the number of header connections, orifices, and access openings. Before this boiler was placed in operation Pitot tubes were installed in each tube of several of the trifurcated furnace elements to check relative water distribution. The results are presented in Table 5 of this discussion.

[a] Denotes tube in corner of furnace.

The convection boiler, called the "secondary generator," also employs $1^1/_4$-in-OD tubes, but they are fitted with $1^3/_4$-in-high fins and disposed horizontally in a bank below the economizer. These tubes are bifurcated at the end adjacent to the control orifice so that each orifice serves two circuits which are intermeshed, with forged return bends and long-radius bends alternating through the length of each circuit. The tubes are arranged in staggered relationship with $2^1/_2$-in. horizontal and $3^1/_2$-in. vertical spacing, and because of their small diameter and transverse flow of the gases, a very high heat-transfer rate is obtained without the use of baffles and without resorting to a high gas velocity. The surface installed per cubic foot of space in the secondary generator is about twice that of a conventional boiler and each element is independently removable through a large door at one end.

The "water-cooled beams" mentioned in the paper, support the secondary generator and both economizer sections. They are shown at three elevations in Fig. 2 of the paper, and consist of two parallel sets of three headers each, with series flow through each set. The tubes supplying the outer end of the uppermost headers are shown coming off the main distributing header. The water passes through the uppermost headers, thence by external connections to the inner end of the lowest headers, through the latter to the outer end, and thence through external connections to the single secondary-generator inlet header containing the control orifices. The two intermeshed circuits of each secondary-generator element terminate in separate discharge headers which support the lower economizer section. From these headers the steam-water mixture is discharged to the boiler drum.

Since the steam drum is not required to support a bank of steam-generating tubes, it is located entirely outside the setting as shown in Fig. 2 of the paper, which is sometimes possible but

rarely convenient in designing a natural-circulation boiler. In the case of thick drum shells exposed to hot gases, drum protection must be provided, which introduces a maintenance item for the operator; also, where a boiler baffle abuts the drum shell, a positive and tight seal must be maintained to prevent fly-ash erosion of the drum due to baffle leakage. These problems are absent when the drum is outside the setting and therefore represent potential operating assets. It will also be noted that all the drum-tube connections in Fig. 2 of the paper are in one quadrant of the shell, thus reducing to a minimum the amount of thick shell plate required.

The authors point out an operating disadvantage of a high-capacity boiler containing a very small quantity of water, when the rate of blowdown is high due to high make-up of water having high total solids. However, the low weight of water is also associated with low weight of tube metal and this combination results in a lower fuel requirement to place a forced-circulation boiler in service and less heat loss on cooling down. This would be a distinct asset in the case of a boiler subject to week-end shutdowns in many industrial plants. In combination with forced circulation, it also permits entry to the furnace for maintenance within 8 hr of the time the boiler is taken off the line, even in the case of a large high-pressure unit with a wet-bottom furnace. Also, with the increasing popularity of acid cleaning of boilers it is an operating asset to require only one quarter of the amount of acid, flushing water, and neutralizing solution, to say nothing of the time saved in filling draining, etc.; and 2 min operation of the pumps at hourly or half-hourly intervals will completely mix the solvent, re-establishing a uniform concentration and uniform temperature, both of which are important.

Fig. 2 of the paper shows that each pump is equipped with a shutoff valve at suction and discharge. It was originally intended that only one pump would be in operation and the other held as a spare with suction and discharge valves closed. With the method of operation used at this plant the spare pump idles at 400 rpm and with all suction and discharge valves open. The check valve located at each pump discharge has a bypass which permits operating the spare pump in this manner but limits recirculation through the idle pump. The shutoff valves have never been used during operation because the availability of both pumps has been 100 per cent.

The authors give a figure of 10,000 lb per hr steam consumption for circulating-pump drives but the heat extracted in the turbine is only about 200 Btu per lb or 2,000,000 Btu per hr. The fuel equivalent of this is about 0.50 per cent of the fuel fired at maximum rated capacity and part of this energy is returned to the boiler water in passing through the pump.

The occurrence of scale chips in the orifice headers has not been uniform in all headers, and this was originally explained by the fact that the first supply tubes coming off the main distributing header go to the front or burner wall; the next group at each end go to the side-wall headers and the center group go to the rear-wall header. When the sludge and/or scale chips have been present in serious quantities, the front-wall header has generally contained the most and the rear-wall header the least. In fact, the strainers were not removed from the rear wall during one entire year of operation, and beginning in April, 1944, and ending July, 1944, there was one operating period of 30 days, followed by another of 60 days, during which no significant deposits occurred in any of the orifice headers.

The differential-pressure regulating valves on the bleed-in lines to the pumps were recommended by both the pump and the boiler manufacturer during the design stages but were not installed until the spring of 1945.

The authors mention "minimum chemical-reaction time in the drum," as a possible reason for scale in the orifice headers of the forced-circulation boiler. However, it has been noted that a ring of sludge forms even in the perforations of the submerged feed pipe, which is an indication of very quick reaction.

The furnace-wall soot blowers on the forced-circulation boiler were furnished by the boiler manufacturer in 1943 in lieu of removing superheater elements, because during early operation the steam temperature exceeded the guarantee and it was found that removing ash from a band of the furnace walls just above the burners would give 50 deg F steam-temperature control.

One reason for keeping the steam temperature down on the forced-circulation boiler has been because the natural-circulation boilers do not deliver steam at the predicted temperature (see authors' Table 4), and this results in different steam temperatures in the two turbine leads, which is objectionable. Predicted performance of the forced-circulation boiler was deliberately based upon moderately dirty furnace conditions. At maximum load the contract average gas temperature leaving the furnace was 2110 F. A test in January, 1945, at maximum load using an 18-point traverse with a high-velocity shielded platinum thermocouple at three elevations at the superheater entrance gave the following averages:

Upper 1870 F; middle 2015 F; lower 2025 F; during the test the CO_2 entering superheater was 16.3 per cent, the average steam temperature 760 F; the furnace-wall blowers had not yet been placed in service and the walls were moderately dirty. In reference to the authors' conclusion on availability, it might be added that the boiler manufacturer definitely recommended that the forced-circulation boiler be taken out of service every 60 days for inspection, because this boiler was a new development and frequent inspections would avoid the possibility of any major damage to the unit, as well as decrease the possibility of a forced outage. Nevertheless, the availability of the forced-circulation boiler averaged close to 95 per cent from December 1, 1943, to April 1, 1945, and it would be of interest to learn how much greater availability was realized on each of the natural-circulation boilers to justify the conclusion drawn.

S. T. Powell,[7] H. E. Bacon,[8] and L. G. von Lossberg.[9] Personal inspections of these boilers and studies of the feedwater treatment by the writers confirm the authors' observations. In particular, chemical and x-ray analyses of deposits removed from the forced-circulation boiler at the last inspection, representing the conditions during the feeding of sodium silicate to control magnesium in the sludge, show that the desired precipitate, magnesium silicate, is now being produced. However, our recent inspection indicates that troublesome deposits are still occurring in the orifice strainers.

Our experience with water conditioning for the forced-circulation type of unit has also shown that feedwater of high quality is required to prevent deposits in the control-orifice strainers. Also, the relatively small volume of water contained in this type of boiler limits the concentration of constituents that may be tolerated in the feedwater.

The favorable comparison with regard to the operating characteristics of the forced- and natural-circulation boilers for the production of process steam is noted with interest.

It is our opinion that the operators of the plant are to be complimented upon maintaining continuous operation of the steam-generating facilities and related equipment under the rigorous conditions imposed throughout the 2-year war-production period.

[9] Engineering Assistant to Sheppard T. Powell.

W. F. Ryan.[10] The authors are to be congratulated on the impartiality with which they have presented the facts in regard to these two types of steam-generating equipment. If they have any preference it cannot even be inferred from their paper, and the reader is left to draw his own conclusions. This form of presentation is as commendable as it is unusual in engineering literature.

Steam consumed by the circulating pumps means little unless translated into energy; the latter is obviously a charge against the efficiency of the forced-circulation unit. No discussion is offered of the greater space and building costs required for a natural-circulation design. At Kobuta, it appears that the building design was determined by the space required for the larger boiler and hence no appreciable savings accrued from the installation of a single forced-circulation unit. These savings might have been considerable, however, had the building been designed for four forced-circulation units.

It is unfortunate that Figs. 2 and 3 of the paper, showing cross sections of the two boilers, are not shown to the same scale. The tabulations, however, show that the natural-circulation boiler has 4500 cu ft greater furnace volume. For four boilers, this amounts to 18,000 cu ft which might have been saved had the building been designed for the forced-circulation type of boiler only. Weights are not given, but from the data on heating surface, tube sizes, and water volumes, it is clear that the weight of the natural-circulation boiler, filled with water for test, is more than twice the weight of the forced-circulation unit. As shown in the tables, the operating weight of water in the natural-circulation boiler is more than 4 times that in the other type. These factors materially affect the cost of building steel and foundations and should ultimately have an appreciable effect on the cost of equipment as well.

These are the reasons, of course, that manufacturers and operators are willing to spend time and money on such developments of the art. What we all want are better boilers at less cost than we now have. It is apparent from this paper that forced circulation is a constructive step in this direction.

Authors' Closure

The silicate treatment as mentioned in Mr. Harvey's discussion definitely showed promising results as to the elimination of sludge in the natural circulation boilers. Duplicate treatment in the forced-circulation boiler has not produced hoped for results and all inspections of this boiler unit since the treatment was initiated revealed scale at the orifice strainers in amounts equal or greater than on previous inspections. Sludge accumulations were, however, somewhat reduced. Operations at this boiler plant are now such that continued observation of this method of feedwater treatment is not possible as the forced circulation boiler has been out of service since early in November due to low steam demand to process. The elimination of the troublesome scale at the orifice strainers remains as an important factor in securing greater availability of the forced circulation unit, and the authors believe that feedwater consultants will overcome this difficulty by introduction of other suggested treatments, should the silicate not produce the desired results. The divergence in results of this duplicate treatment of the feedwater for both types of boilers further demonstrates that the natural circulation boilers are less susceptible to scale formation under equivalent feedwater conditions than the forced circulation unit.

Mr. Patterson's discussion of certain design features and potential operating assets of the forced circulation boiler enhances the value of the paper for design engineers and operators of boiler plants. The authors, as operators, are naturally inclined to overlook design features unless they materially affect the boiler operation or are modified to improve the operation. The references to savings in weight, "secondary generator," "water-cooled beams," and drum location will no doubt be of great interest to all readers, and the authors concur in his discussion on certain minor advantages gained by low weight of water and lower requirements for acid cleaning. The further explanations of Mr. Patterson in regard to pump operation, soot blowers, and steam consumption of the pumps contributes much to enlighten the reader on points which the authors unintentionally might have slighted.

The conclusion that the natural circulation boiler has greater availability has been demonstrated by the operating records of the two types of units. While operating at near peak demands, the outage schedule required that each natural circulation boiler be taken off the line every six months with the outage time limited to three days. The outage schedule of the forced circulation unit required an outage each two months with outage time limited also to three days. The amount of maintenance work required on both types was relatively equal. Thus it can be seen that on a percentage of availability basis the natural circulation boilers would reach 98.36 per cent or 6 days outage per operating year while the forced circulation boiler would reach 95.08 per cent or 18 days outage per operating year. While the percentage availability difference does not seem too great, it is significant that the scheduled outage time required by the forced circulation unit amounts to three times that of the natural circulation boilers.

The authors appreciate the discussions of all these engineers and the favorable comments contained in these discussions. That the Kobuta Plant has had such an outstanding operating and performance record is partially due to the suggestions and recommendations of these outstanding men of the steam-generation field.

It is well to point out that since preparation of this paper all the 3 in. tubes between the pump discharge header and the orifice headers were mechanically turbined. The amount of scale removed during this operation has led us to believe that these tubes are the source of scale particles, and their scheduled turbining at times of boiler outages would do much to increase the operating time between outages of the forced circulation boiler.

It will be noted that the operating assets of the forced circulation unit are inherent for this type of boiler unit, while those of the natural circulation boiler are not limited by its type. It would thus seem that further developments to overcome any deficiency of operating assets for forced circulation will enable us to attain better boilers at less cost as asked by Mr. Ryan.

Operating History and Performance of 2000-Psi Forced-Circulation Boiler at Somerset Station of Montaup Electric Company

By G. U. PARKS,[1] W. S. PATTERSON,[2] and W. F. RYAN[3]

In this paper the operating experiences with the high-pressure forced-circulation boiler at Somerset station of the Montaup Electric Company are given in considerable detail. Special test and research activities on the installation are reported in this and companion papers. The conclusion is reached that the selection of a bare-tube, slagging-bottom, radiant, forced-circulation boiler for this high-pressure application has been verified by its operating record.

The forced-circulation boiler at Somerset Station was installed during 1940–1942, as part of the topping installation. Initial pressure and temperature were dictated by the necessity of obtaining 25,000 kw by topping a 375-psi 750 F plant. The size and shape of the boiler were determined by the floor space and headroom available in a vacant space in the existing boiler room which had been allocated in 1925 to a future boiler of 120,000 lb per hr capacity.

The subject boiler has a guaranteed maximum output of 650,000 lb per hr at 960 F at the superheater outlet. Drum safety valves are set to blow at 2000 psi, but average drum pressure over an extended period of time has not exceeded 1925 psi. Pressure at the superheater outlet averages approximately 1850 psi, which gives name-plate pressure at the topping-turbine throttle. The reheater takes exhaust steam from the topping turbine at 400 psi 603 F, and exhausts to the station's low-pressure header at 380 psi 765 F. The boiler and related equipment have been described in detail in references (1)[4] and (2).

Normally the station burns West Virginia semibituminous coal or bunker "C" fuel oil, and the boiler was therefore designed to use either fuel or any combination of the two. Since the station's pulverized-coal system is of the storage-bin type, and it is necessary to supply this new slagging-bottom furnace and the older dry-bottom furnaces from the same supply, the furnace and combustion equipment were so designed that coals with ash-softening temperatures between 2200 F and 2600 F could be used satisfactorily.

It is the purpose of this paper to discuss the operation problems encountered and their solution and present the results of research and tests on circulation, tube temperatures, and performance.

Although all equipment manufacturers have been very co-operative, wartime conditions have made it impossible to effect some changes when they were desired. It is hoped that the complete topping installation can be discussed at some later date when changes and modifications in equipment in no way related to the boiler have been completed.

After 3 months' preliminary operation, delivering steam through the by-pass line, the boiler was placed in commercial operation with the turbine on October 26, 1942, and has been taken out of service 54 times from that date to the present time, November 1, 1945.

The longest outages, which are identified by numbers in Fig. 1, were chargeable to equipment as listed below the chart. Table 1 supplements this list and shows that there were in the first three years of commercial operation, 8 forced outages and 46 scheduled outages, about half of which were directly chargeable to research and tests. Most of the outages charged to research merely consisted of taking the unit off the line for a few hours for checking dissolved and suspended solids in the boiler water. The scheduled outages charged to other equipment were sometimes also used for scheduled boiler maintenance if time permitted. On the other hand, the forced outage in 1944, charged to slag in the superheater, was caused by malfunctioning of the air-flow recorder and operation with low excess air.

Fig. 1 also shows average output calculated from steam-flow-integrator readings for the duration of each operating period, without correction for pressure or steam temperature. The meter is calibrated for 1825 psi and 960 F.

Although the boiler has been operated in excess of 650,000 lb per hr with both coal and oil firing, output during the past two years was normally limited to approximately 585,000 lb per hr, and the average monthly load is under 500,000 lb per hr. This has been for the following reasons, rather than desire or necessity due to boiler limitations:

(*a*) The necessity for keeping spinning reserve on the system at other points.

(*b*) The large amounts of hydro-generated power which tie lines make available during evening and night hours.

(*c*) The rebuilding of the 10-in. pressure-reducing and desuperheating station which leaves only the 4-in. station with 200,000 lb per hr capacity in case of turbine failure.

(*d*) Vibration and shaft whip in the topping turbine under certain load conditions.

(*e*) Inability of the low-pressure plant to absorb more than 500,000 lb per hr when either low-pressure unit is not on the line.

Since October, 1942, it has been impossible for the station to receive coal from the normal suppliers in the Pocahontas No. 3 seam or the Sewall seam. Based on monthly composite samples, the heat content of coal as received has varied from 13,000 Btu per lb to 14,000 Btu per lb, moisture from 4 to 8 per cent, ash from 6 to 13 per cent, and grindability from 70 to 100 per cent on the Hardgrove scale. Ash-softening temperature has varied between 2100 and 2800 F. A substantial part of the coal burned has been from either West Virginia or Pennsylvania strip operations.

Due to overworked mills, the amount of pulverized coal through a 200-mesh screen has rarely been as high as 80 per cent, and averages 70 per cent, with 3 to 4 per cent retained on 60 mesh.

The normal operating crew has been the boiler operator, stationed at the control panel, and his assistant who keeps the log sheet and also operates blowdown, soot blowers, and attends to changing and cleaning oil burners. They are assisted part of the time by an oiler on the feeder and fan floor, who also works on the fans and feeders of five low-pressure boilers, and by a pump tender who operates the high-pressure heaters and drip pumps, as well as the circulating pumps. When coal from normal suppliers is available, the latter also acts as ashman. Feedwater chemistry is directly controlled by the station's own laboratory on a single-shift basis. The high-pressure-turbine operator acts as chemist on the other two shifts.

The arrangement of the boiler unit as originally installed with changes and modifications from 1942 to 1945, inclusive, indicated in notes, is shown in Fig. 2. Following is a summarized description of operating experiences with the boiler unit including a discussion of changes made and the reasons for them.

Operating History and Changes

Evaporating Surface. A furnace-tube failure occurred within the first 2 months of preliminary operation. It was in the front wall a short distance below the roof and in the second tube from the right side wall. A short section of tube was welded in for repair. Microscopic examination of the failed section indicated overheating but the reason for overheating was not immediately determined.

A second tube failure occurred in January, 1943, in the furnace roof in the same tube that had failed previously. This failure was occasioned by pitting on the inside surface of the tube, one of the pits having extended entirely through the tube. A large amount of solid deposit found on the inside surface of the tube was considered to be a contributing factor to the corrosion. Repair was made by welding-in a replacement section, and an attempt was made to locate any source of free oxygen which might have contributed to this failure. Consultants were also engaged to study the conditions which caused the deposition of foreign matter on the inside tube surface.

The third tube failure occurred in February, 1943, while this investigation was in progress. This failure was in the left side wall, third tube from the rear wall. Microscopic examination of the failed portion indicated overheating and the cause was thought to be plugging of one of the orifice strainers.

Each time the boiler was drained substantial amounts of foreign matter were found in the orifice headers, particularly near

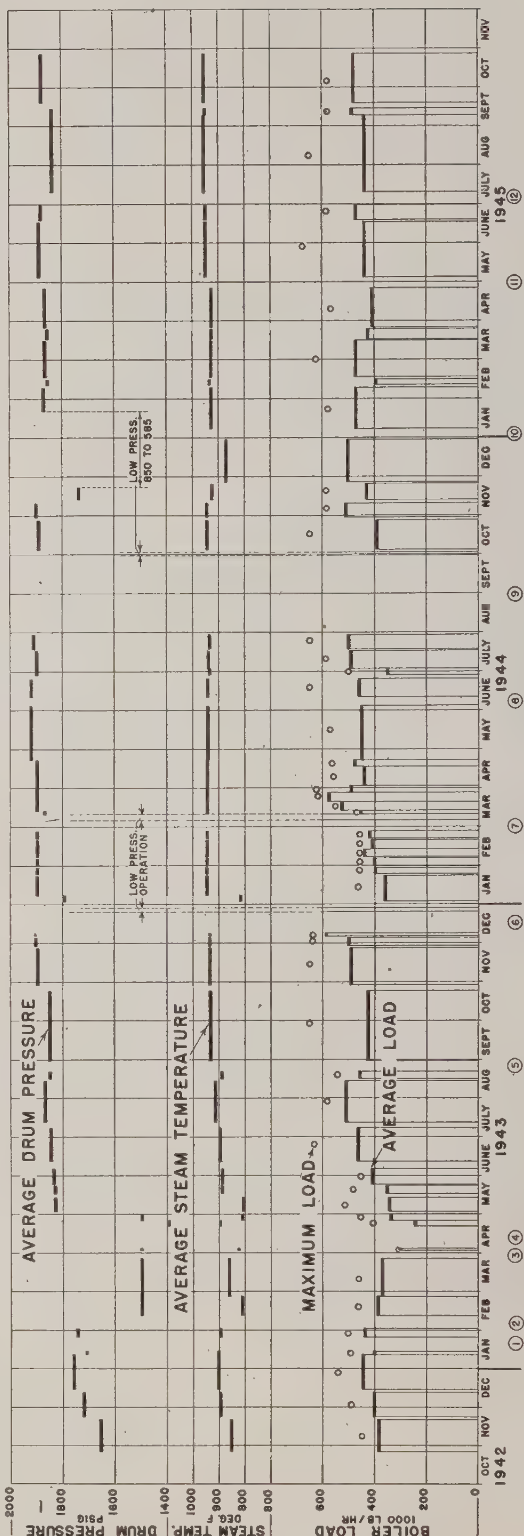

Fig. 1 Load, Temperature, Pressure, and Outage Chart

The numbered outages were charged as follows:

1 Furnace tube failure
2 Furnace tube failure
4 Acid-cleaning boiler
5 Miscellaneous boiler changes
7 Miscellaneous boiler changes
8 Drum internal changes
10 Pressure-reducing station
11 Reheater repairs

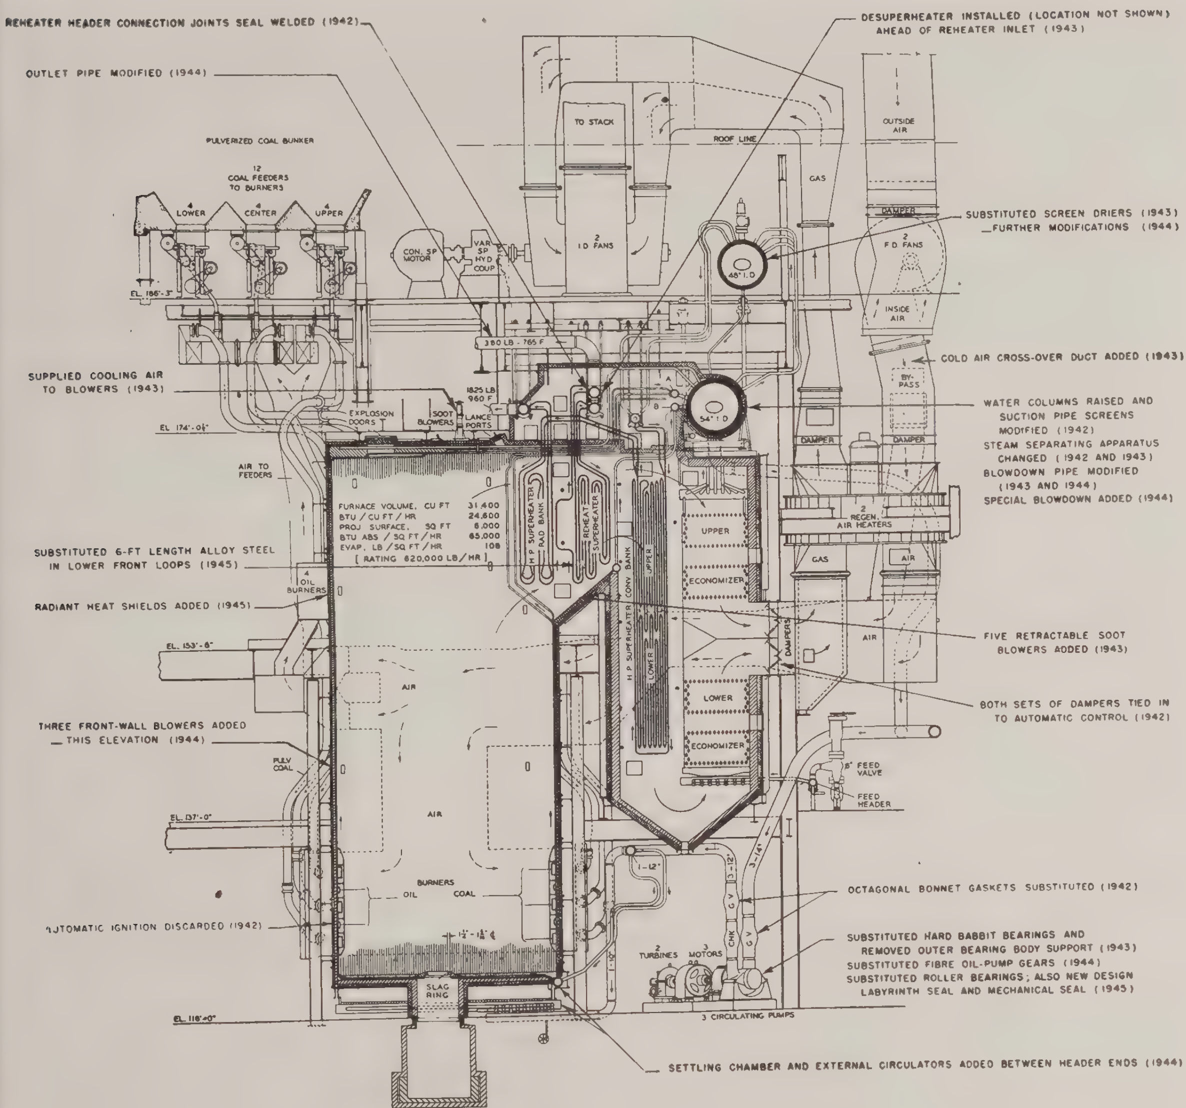

Fig. 2 Arrangement of Boiler Unit as Originally Installed With Changes From 1942 to 1945, Inclusive, Indicated by Marginal Notations

the ends. Prior to the second tube failure, a sample of header washings was found to contain 66 per cent iron shot, 17 per cent mill scale, and miscellaneous oddments such as steel shavings, turnings, chips, and weld splatter. A sample collected at the time of the second failure contained 30 per cent weld splatter, 20 per cent mill scale, and 13 per cent iron shot, plus oddments.

The 54-in. boiler drum had been shotblasted in the shop after the junction headers had been attached and, although the headers had been blown out with compressed air, it was impossible to do an adequate job, since the header ends were closed at the time. The boiler had been carefully washed out and boiled out, with the orifices and strainers removed, prior to operation. Headers were washed at every available opportunity but the recurrence of foreign particles and substantial amounts of mill scale persisted for some time in the lower headers. There was also evidence of chemical hide-out whenever the boiler was taken off the line.

In order to clean tube surfaces thoroughly and remove mill scale, the boiler was washed with inhibited hydrochloric acid in April, 1943. All orifices were removed and the circulating pumps were not operated during the washing and it was therefore impossible to maintain uniform temperatures. In spite of this, tests showed that substantial amounts of mill scale and foreign material had been removed. Prior to this time feedwater was normally treated with standard sodium chemicals (phosphate, hydroxide, and sulphite). After the acid cleaning the potassium treatment developed by Dr. R. E. Hall was introduced (3, 4).

In December, 1943, after 7 months' operation with potassium treatment, including silica feed, the fourth tube failure occurred. This was the third failure in the same tube (second tube from the left side wall), and was in the section of the tube which passed across the roof of the furnace. The inside surface of several other tubes examined at the same time was coated with thick

sludge and scale, but the actual failure was considered to be caused by a plugged orifice strainer. The evidence of such plugging was missing, due, no doubt, to the disturbance created in the header when the tube failed; but repeated failures only in tubes served by orifices close to the dead end of the headers indicated the most probable cause to be sludge accumulations at the header ends.

Study of orifice-header pressures showed that there was sufficient pressure difference between the rear and the side headers so that if a small circulator were installed between each end of the rear header and the rear end of each side-wall header, there would be sufficient flow between the interconnected headers to preclude any sludge accumulation near the orifice strainers which serve the tubes in which failures had occurred. Circulators of $1^1/_4$ in. were installed between the rear header and the side headers, each provided with a small baffled settling chamber with sampling connections and blowdown valves and upper closure plugs to permit measuring the depth of sludge in the chambers. After establishing the fact that they collected a considerable quantity of sludge, they were connected into the existing drain lines, and are blown down once a week as part of the operating routine. Since the headers have been interconnected, very little sludge accumulation within them has been evident and very few of the strainer openings are found closed. In fact the strainers have not been removed in nearly 2 years except a few for inspection purposes.

At the time of the fourth failure representative tubes were sampled. There were substantial sludge deposits on all of them and acmite scale on most. Therefore, before the boiler was returned to service it was again acid-cleaned, using inhibited hydrochloric acid, supplemented by a fluoride. In order to insure a thorough acid cleaning at recommended temperatures, one circulating pump was operated 1 min during each half hour of the cleaning period, and thermocouples installed for the purpose showed that recommended temperatures were being maintained. Immediately after the cleaning and washing period the circulating pump was dismantled and the impeller removed for examination. There was no evidence of any attack by the acid.

Since this fourth failure the potassium treatment of feedwater without silica has been used: Tube samples taken in February, 1944, August, 1944, and September, 1945, from several parts of the walls showed very little sludge accumulation, and what did exist was not adherent but easily brushed away. There was evidence of very little, if any, corrosion or pitting of wall surfaces.

Periodically throughout the 3-year operating period of this boiler the external surfaces of representative furnace tubes have been checked for external corrosion. Although an adherent "enamel" coating of fused slag has been found, similar to that which has been credited with causing corrosion in other furnaces, actual corrosion has been negligible or nonexistent up to October 26, 1945.

On October 26, 1945, about 22 months after the last internal cleaning of the boiler, three small leaks occurred in the rear furnace wall, one located less than 1 ft above the floor and two about 20 ft above the floor in a different tube. The tubes which had failed were found to be heavily coated with sludge and, on the fire side, iron-oxide scale had formed between the sludge and the tube wall, indicating that the sludge had caused overheating of the tubes. An adjacent tube near the floor in the rear wall was in similar condition on the inside but a tube almost directly opposite, near the floor of the front wall, although heavily coated with sludge, had most of the deposit on the casing side where it could not cause overheating. This latter tube was perfectly clean at an elevation 17 ft above the floor, and a tube in the right side wall 15 ft above the floor was also nearly as clean as the same tube had been a month earlier.

There is evidence to indicate that a recent disturbance has caused this trouble because on this last outage there was appreciable external tube corrosion on some of the rear-wall tubes in the region of the lowest leak. Due to failure of the water seal below the slag hole and malfunctioning of the flue-gas oxygen recorder a deficiency of air near the walls and consequent abnormally high gas temperatures probably occurred.

Before the boiler was again placed in service it was acid-cleaned, using one circulating pump a few minutes of each hour to maintain uniform solvent temperature throughout the unit. Two tubes were sampled after the cleaning to make sure of a thorough job.

Superheater: High Pressure. There have been no failures, changes, or maintenance in either the convection bank or radiant bank.

It had been originally expected to obtain automatic superheat control by having the controller operate only the by-pass dampers located at the outlet of the upper economizer. However, it was found that manual operation of the main-passage dampers at the outlet of the lower economizer was necessary to obtain quick response. The controls were therefore modified so that both sets of dampers are automatically operated, that is, as the by-pass dampers open the other dampers close a proportionate amount.

Superheater: Reheat. The steam reheater which operates at 400 psi was provided with bolted ball-and-socket joints where the elements are attached to the headers. On account of numerous leaks during the first 2 months and the difficulty of access to the joints for refacing, it was decided to seal-weld all these joints.

Operation at high rates of output indicated that reheated-steam temperatures would be too high at maximum load for continuous operation with carbon-steel reheater elements. It was decided not to reduce the heating surface but rather to correct the difficulty by installation of a manually controlled steam-atomizing spray-type desuperheater. This was installed between the high-pressure turbine and the reheater in July, 1943, and has given satisfactory control.

It will be noted from the side-elevation view of the boiler that the lower portion of the front loop of the reheater is not effectively screened from the radiant heat of the furnace, particularly if the rear-wall screen tubes are kept clear of ash accumulation. Soon after a soot-blower overhaul in August, 1944, reheater-tube failures in this front loop began to occur. These were quickly repaired on each occasion by welding-in a new piece of carbon-steel tubing, but at the end of April, 1945, the lower end of the front loop, including the lower bend, of all 58 elements, was replaced with chrome-molybdenum-titanium alloy tube sections about 6 ft long. This is the same material as used in the front section of the superheater for 960 F steam temperature and since the reheated-steam temperature is only 765 F, no further trouble from this cause is anticipated. All other parts of the reheater are quite effectively shaded from radiant heat.

Economizer. There have been no failures or changes in the economizer. There has also been no maintenance except to seal up a few air leaks at the economizer doors and in the suspended arch where the hanger rods pass through the roof.

Steam Drums and Drum Internals. Because of the forced-circulation feature it was possible to operate the pumps with cold water and observe the flow of water into and out of the drum with the manholes open. Before placing the boiler in operation the flow of water toward the two suction pipes at the ends of the drum was photographed, and it was observed that a vortex was created over each suction-pipe nozzle, and that air was drawn into the suction pipes when the water level was low. The design of suction-pipe screens was changed and a coverplate was incorporated to eliminate the undesirable turbulence.

In reference (1) Fig. 13, it will be noted that the feedwater from

the economizer outlet discharges into the drum through tubes entering the bottom of the shell and that a deflecting baffle was installed directly above the outlet of these tubes. It was found that this resulted in low shell temperatures between this region and the suction-pipe nozzles. This baffle was removed in December, 1942, in order that the feedwater, which is at a temperature 100 deg F below that of the boiler water, can mix with the latter more quickly and thus eliminate this undesirable condition.

The original steam-separating means consisted of a combination of "hydraulic baffle" and metallic baffles in the wet drum and a combination of baffles and rod-type drier in the dry drum. During the first few months of operation the boiler was sensitive to carry-over when the water level approached the center line of the drum and, because the feedwater regulators were not functioning properly, the capacity was limited to 400,000 lb per hr, although higher capacity could have been carried with better water-level regulation. Minor modifications were tried but showed little promise of correcting the trouble so an entire new set of wet-drum internals of the "reversing-hood" type was substituted in October, 1942 (see Fig. 13 of reference 1 of Bibliography).

The blowdown line in the boiler drum as originally installed was found to be unsatisfactory after the reversing-hood type of internals had been installed because considerable feedwater was entering the blowdown piping. To correct this condition, six open-ended collecting pipes were extended upward above the water level so that concentrated boiler water from the hoods would discharge directly into the collecting pipes.

Although the reversing-hood steam separators in the wet drum resulted in satisfactory steam purity at loads up to 500,000, it became obvious in June, 1943, that further improvements would be necessary to meet the guarantee of 0.50 ppm solids in steam. Furthermore, the gaskets of the drum internals had deteriorated during the acid wash of the boiler in April, 1943, so that in August, 1943, the wet-drum internals were regasketed with copper-covered asbestos and screen driers were substituted for the rod driers in the dry drum.

Early in 1944 special laboratory evaporating apparatus, which permitted the determination of solids in steam by evaporating a 4-liter sample every 24 hr, was used to check the solids in steam. It was found that at maximum guaranteed output the guaranteed 0.50 ppm was being exceeded. Part of the difficulty was believed due to the fact that the steam-discharge tubes from the dry drum are not uniformly spaced along the drum but are arranged in three groups. A new set of low-velocity screens was substituted and a perforated baffle plate was installed ahead of each group of steam-discharge tubes to produce uniform velocity through the screens.

The steam line supplying the high-pressure soot blowers was originally connected to a nozzle near the center of the dry drum. The steam was taken out of the drum from the space between the screen driers and the steam-discharge tubes, and it was found that when the soot blowers were operated there was an increase in moisture in the steam in the saturated header of the superheater. To improve this condition the soot-blower steam nozzle was extended to take steam from the drum before it passes through the final drying screens. Gasketed joints in the wet drum were seal-welded at this time.

Excellent steam quality is now obtained from this unit and the results are included elsewhere in this paper.

Although there are generally only 10 to 20 lb of sludge in the wet drum after several months of operation, it has been noted that when the fires are extinguished preparatory to taking the boiler out of service, the blowdown water sample always becomes very turbid. The theory was advanced that the most quiescent zone in the wet drum during the steaming period is on the bottom of the shell between the 18 feedwater discharge nozzles which project into the drum about 2 in. This would then be a logical place for sludge to accumulate; but when the feedwater flow rate is reduced on shutting down the boiler the flow of water toward the suction pipes might wash this deposit away. Accordingly, in February, 1944, a special blowdown pipe was placed on the bottom of the drum and connected externally, through valves, to the continuous blowdown pipe. A study was made of the increase in turbidity of the blowdown sample on opening these valves and it is now part of operating routine to operate this special blowdown once a week.

In a boiler of this type it is possible to check the circulating ratio quite accurately by determining the solids concentration in the water at the circulating pumps and in the concentrated water leaving the steam-generating circuits, provided a representative sample of the latter can be collected. Fig. 3 shows a novel means

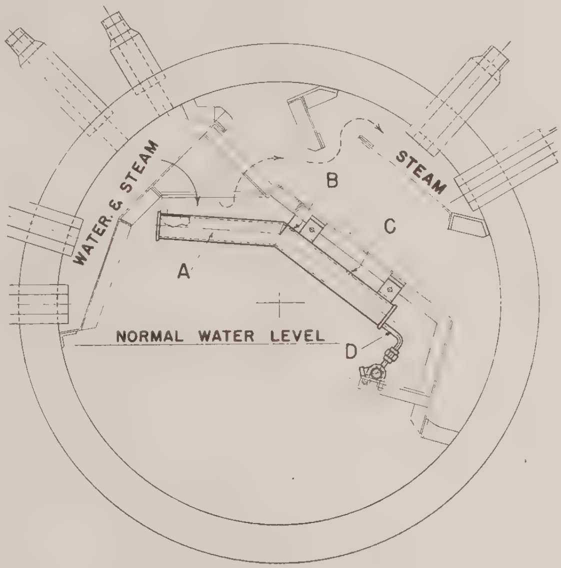

Fig. 3 Arrangement of Continuous Blowdown Collectors

of collecting this sample from the concentrated water discharged into the drum above the water level. Six such blowdown collectors are uniformly spaced across the drum. The horizontal portions *A* are located directly under the slots of the reversing hoods which discharge water and steam into the drum. The upper surface of pipe *A* is perforated and designed to collect water at a rate several times greater than the maximum rate of blowdown. Any steam which enters pipes *A* is vented through an opening at *B* and the excess water is discharged through an opening at *C*. By proportioning the latter opening properly, a high collecting rate can be maintained in pipe *A* without filling the pipe, and the collecting rate is also independent of the rate of blowdown from the lower end of the collector at *D*. These blowdown collectors have been very satisfactory and result in minimum blowdown rate since they collect only the concentrated water which is discharged from the steam-generating tubes.

Air Heaters. The air heaters have given excellent service and there has been practically no maintenance. The steam soot blowers have never been used nor have the heaters been washed. They have been air-lanced on three or four occasions during scheduled outages but the necessity for this has never been urgent. In accordance with manufacturers' recommendations, compressed-air blowers were recently installed to bring the installation up to date.

Soot Blowers. Fig. 2 shows the location of the low-pressure soot-blower elements and also the position of the high-pressure retractable blowers located in the roof. These latter blowers had a sleeve around the blowing nozzle providing an annular passage to permit room air to be drawn in by furnace draft for cooling the blowers. After about a year of operation it was found that the portion of the sleeve projecting into the furnace was burned off and that the blowing elements were also badly damaged. In October, 1943, air under pressure was piped to these blowers to provide additional cooling.

When the boiler was operated at 550,000 lb per hr or higher, continuous output, it was found that an accumulation of ash occurred in the crotch and on the slope below the reheater. There was a tendency for this accumulation to grow quite rapidly and extend up the sloping screen tubes to the superheater. Five retractable mass-type blowers were installed on the slope in August, 1943.

In 1944 the coal was poorer than normal and quite variable. Slag was sometimes difficult to remove from the furnace walls. The soot blowers in the superheater-reheater zone were badly damaged and practically useless and it was found that the steam pressure at the high-pressure blowers was considerably below the recommended operating pressure. Since the coal situation might get worse before it got better, it was decided to review completely the soot-blower situation with the manufacturer and take steps to improve the situation during the August, 1944, annual outage.

During overhaul, additional bearings were provided for several of the low-pressure elements, particularly in the superheater-reheater zone. Replacement elements with larger nozzles were installed between reheater and front superheater and the wall boxes which were out of alignment were relocated. Operating mechanism of all blowers was overhauled and some changes made to facilitate operation. Two of the roof blowers were moved down to the side walls to replace wall blowers at the elevation of, and just in front of, the bottom of the slope below the reheater to assist the slope blowers which were not very effective near the side walls. The two side blowers thus replaced, plus one blower "stolen" from the upper front wall above the auxiliary burners, were located in the front wall at the elevation of the first row of observation doors above the burners.

During the process of overhauling all the retractable blowers it was found that part of the damage and malfunctioning was due to lack of lubrication. A lubrication schedule was set up and central lubricating stations were installed so that several blowing elements could be lubricated from each station. With the exception of the slope blowers there was very little soot-blower maintenance during the following year and at the end of that time all of the blowers except those in the slope were still in good condition. The cleaning effectiveness of the blowers as a whole has also been very good since this August, 1944, overhaul. Part of this improvement can be attributed to the higher steam pressure available at the high-pressure blowers after repairing the pressure-reducing valve through which this steam passes.

At the present time the nozzles of the slope blowers do not retract far enough to protect the blowing heads and there is considerable maintenance. Also, in spite of frequent lubrication, some of these blowers have become inoperative due to the action of heat on the lubricant. Correction of these difficulties is still being followed by the soot-blower manufacturer, but in fairness to him it should be pointed out that space limitations had made it necessary to install blowers with only 5-in. travel. The blowers must advance far enough so as not to cut the tubes in the slope and at the same time retract far enough to be out of the heat, and the blowing head is about 2 in. long with three large nozzles covering about 100 deg of blowing arc.

Circulating Pumps. Except for two leaks at the circulating-pump heads, the circulating pumps performed satisfactorily during the first 3 months of preliminary operation but toward the end of October, 1942, trouble developed in the labyrinth of one of the pumps. As described in reference (1) the labyrinth provides a means of sealing the pump against leakage of hot boiler water at nearly saturation temperature by introducing lower-temperature feedwater at a higher pressure at one end of the labyrinth passage. The labyrinth is a close-clearance passage between moving and stationary parts and as the sealing water flows toward the leak-off point adjacent to the packing gland the pressure breaks down to about 150 psi. An increase in leak-off pressure could be caused by increased flow through leak-off piping and is an indication of increased sealing-water quantity due to excessive wear in the labyrinth. This is how the first labyrinth trouble was detected. When the pump was opened up, the labyrinth surfaces were found to be badly worn, but new parts were installed without any changes except to realign the pump.

The *A* pump which had a labyrinth failure in October, 1942, had another similar failure in November, 1942, and toward the end of December, 1942, the labyrinth in the *B* pump failed. New sleeve bearings were installed in the *A* and *B* pumps during January, 1943, and the bearings of all three pumps were changed to hard babbitt in February, 1943.

During the overhaul for bearing replacement on the *C* pump, it was discovered that the pump could not be rotated until the support under the coupling end of the bearing body was removed, and in March, 1943, the supports were also removed from under the coupling end of the bearing body on both *A* and *B* pumps. Indicators were used to record the amount of vertical and horizontal movement of each bearing body when the support was removed. It was found that these supports had been exerting a strain on the bearing body which probably was resulting in misalignment of the shaft in the labyrinth. It was later found that temperature changes within the pump and/or piping would produce a few thousandths of an inch movement of the floating end of the bearing body and that the upper and lower parts of the bearing-body bracket were not at the same temperature. Insulation was added to the lower part of the bracket to correct this latter condition.

Also in March, 1943, the *A* pump labyrinth failed for the third time but the trouble was found to be corrosion or erosion of the casing in the labyrinth section. This was repaired by applying stainless steel and remachining. The other two pumps were overhauled during April and May, 1943, and there were no further failures in the labyrinths. However, there were several failures of *B* and *C* oil-pump spur gears later in the year; fiber gears were substituted and gave much longer life than the bronze gears.

Bearing troubles were encountered not only with the circulating-pump motors but on other pump motors in the station. The trouble in the case of the circulating pumps was diagnosed as being due to expansion of the pump shaft toward the motor a sufficient amount to put a thrust on the motor bearings. This movement had not been allowed for in the design of the motors. After the replacement of several sets of motor bearings, the pump manufacturer corrected the trouble by the installation of limit stops in the flexible couplings located between motor and pump.

Although there was no trouble or maintenance on the circulating pumps since the spring of 1943, except oil-pump drive gears, the amount of water used to seal these pumps greatly exceeded the manufacturer's predictions. The pipe carrying this water to the pumps from boiler feed pump discharge was therefore much overloaded, thus making it necessary to carry a pressure at the feed pumps about 200 psi above boiler pressure in order to have sufficient sealing-water pressure at the pumps. In order to be able to operate with closer clearances in the labyrinth, to reduce the sealing-water requirements, the pump manufacturer decided to rebuild the bearing body and to substitute roller bearings in

place of the babbitted sleeve bearings. The design of the labyrinth was also changed to accommodate a mechanical seal between the sealing-water injection point and the impeller chamber. This seal reduced the leak-in of seal water to the pump practically to zero. Further reduction in sealing-water requirements was accomplished by the close clearances in the labyrinth passages so that the over-all result was to reduce the injection water, leak-off and leak-in, to amounts far below the original predictions, and the high-pressure leak-off was eliminated completely. One of these pumps was rebuilt about February 1, 1945, and there has been no perceptible increase in sealing-water requirements. This pump was dismantled after 2 months' operation and the boundary surfaces of the labyrinth passage were in excellent condition. The second pump has just been changed over and the third pump will have also been rebuilt by the time this paper is presented.

Water-Level Indicators. Four water-level devices were installed on this boiler, consisting of a recorder and an Eye-Hye gage on the operating panel, a double-window Bi-Color gage with 21-in. visibility and mirrors on one end of the drum, and a double-window Micasight gage with 18-in. visibility on the other end of the drum. The indirect-type gages have been very satisfactory but they do not give a true indication when the pressure is below the design value, due to change in water density.

The center of both water-level gages was originally located 10 in. below the drum center line. This meant that in one gage the water level was still visible when there was only $6^1/_2$ in. of water in the drum, which would expose the modified suction-pipe cover plate, and result in steam entering these pipes. The water columns were both raised so that the normal water level and center of gage are now 5 in. below the center of the drum.

Illumination of the double-window Micasight gage was not sufficiently bright to permit the water level to be observed from the operating floor. The manufacturer decided that it would be a physical impossibility to line up the double-window gage for good visibility because there was only one spot on the operating floor from which the gage could be seen and part of the window was obstructed by a steel beam. A single-window gage of 12-in. visibility was substituted in August, 1943, but after a short period of operation the image of the water level became too faint to be seen from the operating floor. In October, 1945, the gage manufacturer installed a new improved illuminator and mirrors to reflect the water-level image to a convenient point near the operating floor. Visibility of the image with new mica windows was very clear but decreased rapidly. It remains to be determined how often the mica will have to be renewed to maintain satisfactory visibility.

The Bi-Color gage has required frequent maintenance. It has been necessary to have a spare gage available for replacement due to the frequency of failures. One of the gages was modified by the manufacturer in February, 1944, but the modified gage was no improvement. The other gage was modified in a different manner in September, 1945, but failed after 8 days in service. One of the gages was recently assembled in an improvised manner and at the time of writing, has been in service 5 weeks which is the best record so far. However, visibility of the water line at the end of that time is only fair due to dirty mica.

Burners. The automatic ignition system used light oil, mechanically atomized and electrically ignited. From a control station it was possible to start up the oil pump, insert the ignition torches and ignite the oil. The principal trouble encountered was with the mechanism used to insert and retract the oil burners. The automatic features were discarded in favor of torches of steam-atomizing type using heavy oil and which are moved into position by hand.

The pulverized-coal burners are located in the four corners and fire tangentially. No changes have been made except to incline the lowest row slightly downward to improve slag fluidity on the floor.

There are four auxiliary oil burners in the upper front wall which are required to maintain maximum steam temperature at reduced load when the unit is operating with a clean furnace and 100 per cent oil fuel. These burners are not required to supplement coal-firing nor are they necessary with intermittent coal and oil firing. They have never been used and were found to be damaged due to radiant heat from the furnace after a year of disuse. The vanes and other metal parts were burned or distorted. They were repaired and removable Fahrite protecting plates inserted to shield them from the furnace heat.

Miscellaneous: Valves, Piping, Ducts. During the period of preliminary operation, with frequent starting and shutting down, considerable trouble was encountered due to leaks in the bonnet joints of the large gate valves in the suction and dicharge lines of the circulating pumps. These flanged bonnets were originally installed with ring gaskets of oval section. Leakage troubles were corrected by changing to gaskets of octagonal section.

Two outages were charged to safety valves because two shutdowns were scheduled to lap-in the seats of leaky valves.

There are two forced-draft fans and two air heaters with a common preheated-air duct below the air heaters. Although dampers were provided at the inlet to each fan and air heater and, in the cold-air by-passes, these dampers did not prevent the preheated air from leaking through to the idle fan, when only one fan was in operation, and burning the paint on the fan. A crossover duct was installed in 1943, between the cold-air outlet ducts of the two fans to correct this condition.

A program involving several changes in the exhaust-steam piping between the high-pressure turbine and the low-pressure station header is in progress at this station for the purpose of reducing the pressure drop between those points. The first change was to modify the outlet connection of the reheater, in August, 1944, when it was realized that a reduction in pressure drop of several pounds per square inch could be obtained. The reheater originally had a single outlet near the center of the outlet header, and two additional 6-in. outlet pipes were added.

Another piping modification was to install a by-pass line around the high-pressure feedwater heaters permitting both heaters to be out of service without having to shut down the high-pressure boiler. The by-passline also increases flexibility of operation by facilitating an increase in the quantity of low-pressure steam from the high-pressure boiler without increasing the output of high-pressure steam. Under certain load conditions this would obviate the necessity of placing another low-pressure boiler in service or in any event decrease the urgency.

Research and Tests

Special Provisions. Before the boiler was placed in operation more than 100 thermocouples were installed at various points throughout the unit for the purpose of checking operating metal temperatures on furnace-wall tubes, superheater, reheater, economizer, steam drum (lower), feedwater connections to drum and circulating-water connections to pumps. Nearly one half of these wereinstalled on the hot face of the furnace-wall tubes at an elevation about 3 ft above the furnace floor. Pressure taps and Pitot tubes were also installed at various points in the circulating system, as illustrated in Fig. 4. Actually, the Pitot-tube locations were further from the elbow than this sketch indicates.

During the course of subsequent special studies, after the boiler had been placed in operation, additional thermocouples were added to lower drum, circulating pumps, reheater, and on the furnace tubes at different elevations, bringing the total number of thermocouples installed up to about 275.

Steam-sampling connections were initially provided on super-

heater inlet and dry drum, but for special studies additional sampling connections were made at dry drum, reheater outlet, high-pressure-turbine inlet, and high-pressure-turbine outlet.

A special calorimeter was installed to check for the presence of steam in the suction pipes to the pumps and its operation is described in reference (5).

The method of installing the thermocouples and the technique of using Pitot tubes has been described in references (6) and (7).

Circulation. One of the first research studies was to check the total circulation and distribution of circulation to the four separate groups of parallel circuits comprising the four furnace walls. In each wall one circuit had been chosen for installation of a pressure tap on the downstream side of the orifice. The pressure difference between header and the downstream tap beyond the orifice could then be used to determine the rate of flow through the orifice, using calibration data reported in reference (8) Fig. 39, which were determined for the orifice assembly shown in Fig. 38, this being an exact replica of the arrangement used in the Montaup boiler. All the orifices serving the circuits of a given wall are the same size; and, since the pressure drop across the orifices is large compared to the drop across the parallel heated circuits, very little error is introduced by using the flow through one orifice to calculate the flow for the entire wall. Furthermore, all heated tubes of a given wall are nearly the same length and all have approximately the same exposure to heat. By measuring the pressure drop across four furnace-wall orifices, it was therefore possible to determine the total circulation of the unit since there is no other steam-generation surface or no other stray circuits except a connection to the economizer inlet; this is used to circulate boiler water through the economizer when the unit is being brought up to pressure preparatory to placing in operation.

The Pitot tubes in the two suction pipes to the circulating pumps provided another means of determining the total circulation, except that this would not include the sealing water which

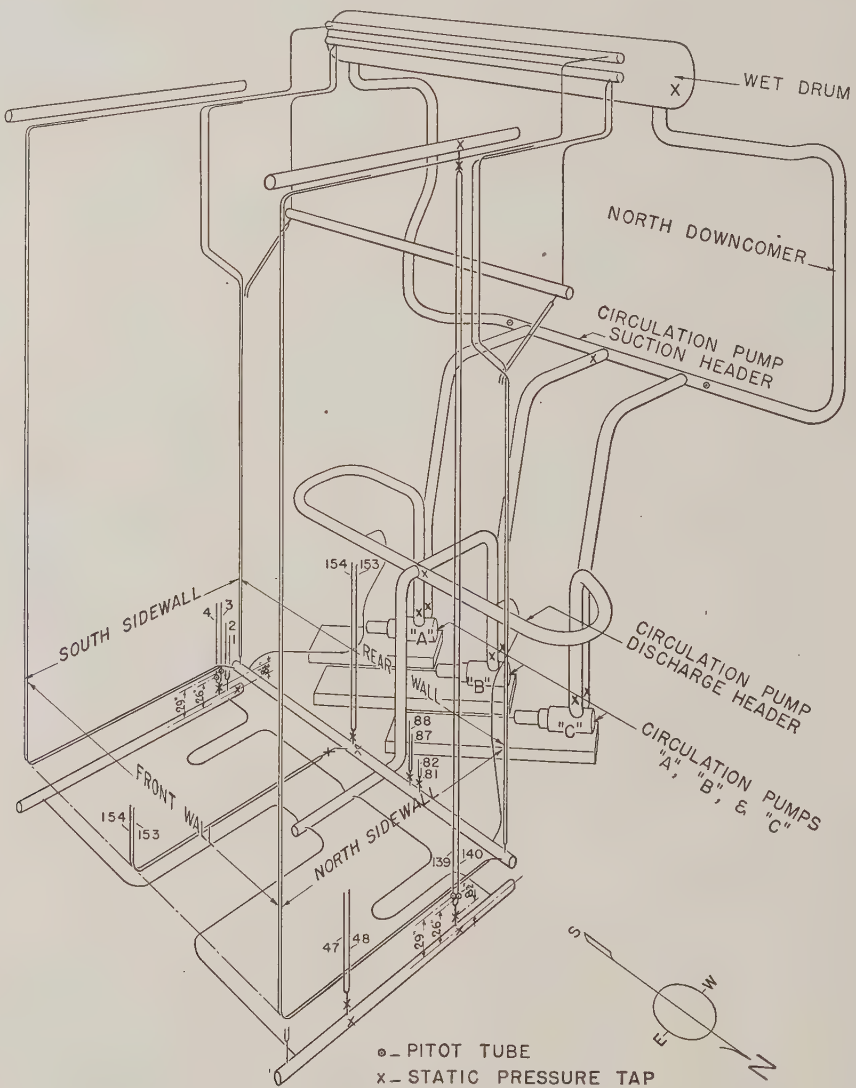

FIG. 4 ISOMETRIC SKETCH SHOWING LOCATION OF SPECIAL PRESSURE CONNECTIONS USED IN TESTS ON CIRCULATION

leaks into the pump. This leak-in can be checked by determining the difference between rate of feedwater flow and steam flow and of course making an allowance for blowdown. This was done on certain tests during 1944, but the flow data were taken during 1942 and 1943, and no correction for leak-in was made because the quantity was of the order of 0.50 to 1 per cent of the water being handled by the pumps, and the accuracy of the flow data did not warrant this refinement since it is not claimed to be correct within 1 per cent.

Measurement of the pump head provided a third means of checking the pump capacity because a pump characteristic curve had been determined by shop test. Unfortunately, however, these tests were conducted up to a capacity of only 5000 gpm and the curve had to be extrapolated for comparison with some of the field data.

A fourth method of checking the total circulation was by determining the difference in solids concentration in the water at pump discharge and leaving the evaporating circuits. The following equation shows the relationship of the variables involved

$$W/S = C_1/(C_1 - C_e)$$

where W = weight of water entering furnace circuits
S = weight of steam generated in furnace circuits
C_e = concentration of solids in water entering, ppm
C_1 = concentration of solids in water leaving, ppm

Since the feedwater is introduced at the bottom of the drum and does not mix with the steam in the drum, it is not heated to saturation before entering the suction pipe. There is, of course, some condensation of steam in both drums, and this would tend to make the weight of steam generated in the furnace circuits greater than the weight of steam metered at the superheater outlet. Consequently, the determination of W by using the weight of metered steam for S would give a value of W which would be lower than the true value.

When this method was first used the difference in concentration of chloride, sulphate, and total solids were all determined for comparison of the results but the time required for analysis of the water samples was too great to permit frequent checking. The results reported herein are based on analysis for chlorides only. The chloride concentration at the pumps was generally between 200 and 260 ppm, and it was considered possible with this concentration to determine the chloride by titration without involving an error of more than about 2 ppm.

Fig. 5 shows a plot of the total flow of water through the orifice headers, based on measured orifice pressure drop using a mercury manometer. The data were collected at different operating pressures and rates of output, but the total flow appears to be independent of these variables over a wide range. There is, however, a marked increase in circulation when the boiler is not steaming and when the water temperature is low.

Fig. 6 is a similar plot of flow data based on pressure differential measured by a mercury manometer across the Pitot tubes in the suction pipes. There is a greater spread in the data probably due to the effect of variable leak-in of sealing water, and the effect of the economizer circulating line which was open during the period when most of the downtake flow data were taken. However, this plot substantiates the previous statement that the total flow is quite independent of load and pressure. Figs. 5 and 6 illustrate the fact that the flow with one pump is about 70 per cent as great as with two pumps. Three pumps were not operated during the period when these data were taken, except at atmospheric pressure with cold water (100 to 125 F) under which conditions three pumps produced only 15 per cent more flow than two pumps.

Fig. 7 is a plot of measured flow rate in the suction pipes and

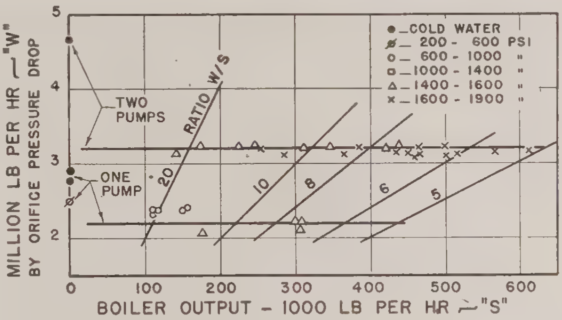

Fig. 5 Total Circulation to Lower Furnace-Wall Headers Based Upon Pressure-Drop Measurements Across Orifices

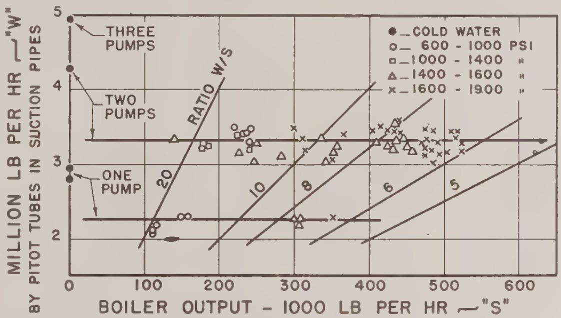

Fig. 6 Total Circulation Entering Pumps Based Upon Pressure Drop Measurements Taken on Pitot Tubes in Suction Pipes

measured pressure difference between pump outlet and pump inlet, uncorrected for acceleration across the pump, superimposed on characteristic pump curves. The pressure difference was determined by dual connections to a 12-in. Crosby test gage having 5-lb graduations which may have introduced considerable error in the pressure data. This may explain why some of the data do not fit the characteristic curves too well, but a small error in the flow rate may also be partly responsible. Also, the pump-head curves are plotted for 1750 rpm, and the pumps are motor-driven and operate at considerably less than full load amperage, particularly when the water density is low, so the actual pump speed may have at times approached 1790 rpm. The pump speed was not determined but the extent to which this variation would displace the head curve is indicated on the chart. The system resistance lines drawn through the test data can be considered as only approximate since the data for one pump operation are meager and subject to large error in the pressure reading.

Fig. 8 is a plot of total water flow calculated from chemical concentration at pump discharge and leaving evaporating circuits, the latter based on water samples from the continuous-blowdown collectors shown in Fig. 3. The data are plotted for two-pump and three-pump operation and two chemists worked independently on these results which explains why two different kinds of points are plotted for each series of tests. No allowance was made for steam condensed in the drum, which explains why total circulation by this method is lower than the results of the two other methods.

It has been shown that the total circulating-water flow calculated from the pressure drop across four orifices checks very well with the total flow calculated from Pitot-tube measurements in the suction pipes. The distribution of circulating water to the

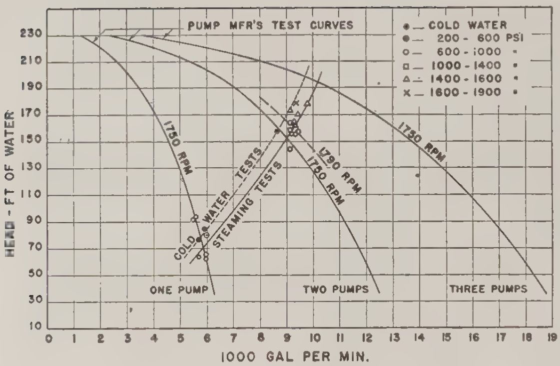

FIG. 7 CIRCULATING-PUMP CHARACTERISTICS, COMPARED TO MEASURED PUMP HEAD PLOTTED AGAINST SUCTION-PIPE FLOW RATE

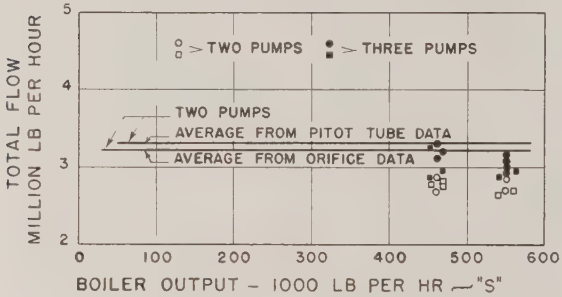

FIG. 8 TOTAL CIRCULATION CALCULATED BY CHEMICAL METHOD COMPARED TO AVERAGES BY OTHER METHODS

walls can therefore be quite accurately determined from the same orifice pressure-drop measurements and the results of several tests are given in Table 2. When this unit was designed the orifices were selected so as to control the water flow to each wall in proportion to the calculated distribution of heat to the walls. The table shows how closely this distribution and control are being realized with only two orifice sizes, namely, 0.34 and 0.40 in., and also illustrates that the distribution is practically the same for any load or pressure.

The distribution of water to the two suction pipes was found to be practically 50–50 when the two outside pumps or the center pump was operating. It was sometimes nearly equal when the center and one of the outside pumps were used but on other occasions the distribution was 45–55.

Fig. 4 shows that pressure drop could be measured across two orifices in the right side wall. Equal pressure drops were often noted but the maximum difference in flow rate on any test was 1.5 per cent.

A study was also made of water distribution to the two legs of bifurcated circuits in the right-hand and left-hand walls. These circuits are indicated in Fig. 4. In each circuit the orifice pressure drop was measured to determine water flow to the circuit and average velocity in the two tubes, assuming equal distribution. A calibrated Pitot tube was installed in each leg to check the distribution of flow. The average velocity based on Pitot-tube differential was lower than the velocity calculated from the measured orifice flow but the distribution was nearly equal as indicated by Table 3.

A calorimeter similar to that described in reference (5) was used to check for the presence of steam in the suction pipes. These tests involved not only the measurement of water temperature in the pipes but a check on the heat exchange in cooling this water

about 200 F in the calorimeter. This gives a check on the presence of entrained steam and none could be detected by this method.

Other tests were conducted to check the water temperature at several points in the suction pipes between the drum and the pumps, by the use of iron-constantan thermocouples peened into the metal of the pipes under the insulation. A precision potentiometer, using an ice cold junction, was used and the data of Table 4 are typical of the results obtained with two-pump operation. The difference between saturation temperature in the drum and the measured temperatures was 6 to 9 F which is about one half the calculated difference assuming no condensation of steam to heat the feedwater in the drum. Therefore these tests indicate that the rate of steam condensation in the drum was 10 to 15 per cent of the rate of steam flow leaving the unit and this correction, if applied to the Fig. 8 data, would bring the results of the chemical method in very close agreement with the total flow determined by Pitot tube and orifice pressure drop.

Furnace-Tube Temperatures. The measurement of the fire-side skin temperature of furnace-wall tubes is of considerable interest to boiler manufacturers and users. Thermocouples if carefully installed will give reliable readings over a period of several months and some have been in service more than 2 years. The skin temperature can be used to give an approximate evaluation of the rate of heat absorption at different levels in the furnace and to study the rate of slag or ash accumulation, as well as the effect of slag removal by blowers or by lowering the rate of steam generation. Several papers discussing the effect of slag and ash on heat absorption are to be found in a recent publication (9), and some of the results of the studies at Montaup are included in these papers.[5] Another reference (10) discusses the effect of metal thick-

[5] Reference (9), Fig. 9, p. 13; (see Fig. 14 of this paper).

ness, heat absorption, and internal-surface factors on the tube-metal temperature.

The data obtained at Montaup and already published show that even in a bare-tube furnace and in the zone of highest flame temperature with pulverized-fuel firing, the hot face metal temperature with normal slag covering was only about 50 deg F above saturation temperature. The tubes are $1^1/_4$ in. OD 0.165 in. minimum wall thickness, but the average wall thickness is probably more nearly 0.180. It may therefore be readily calculated from the charts and equations of reference (10) that the heat absorption at the point of temperature measurement was only about 50,000 Btu per hr per sq ft, allowing for reasonable drop at the evaporating film. These data also show the effect of deliberately removing the slag and ash coating from a portion of the wall, thus exposing a small surface to the full radiation of the flame at a temperature approaching 3000 F. Under these conditions the skin temperature rose to a maximum value 172 deg F above saturation (786 F — 614 F saturation temperature), and the corresponding heat-absorption rate would be about 150,000 Btu per hr per sq ft, allowing for temperature gradient between inside surface and the evaporating water. These values represent the extreme rate of heat absorption to which these bare tube walls could be subjected because if a larger area in the zone of high temperature were clean the radiating temperature and the average heat-absorption rate would both be lower.

In June and July, 1943, a study was conducted to learn the effect of circulation rate on the polished interior surface of several tube specimens installed in several furnace-wall circuits. In each of three circuits having different-size orifices a pressure tap was available on the downstream side of the orifice so that the water-flow rate in each could be determined by measuring the orifice pressure drop. The results of the flow measurements appear in Table 5, section A.

There were three thermocouples at the 30 ft elevation on side-wall tubes Nos. 3 and 5, and at the 24 ft elevation in the rear wall there were three couples on tube No. 87 and two on tube No. 81. When tube-temperature measurements on the side-wall tubes are compared to those on the rear-wall tubes, it should be considered that the side-wall tubes are very close to a corner of the furnace. The couples on tubes Nos. 81 and 87 were quite close to a furnace wall blower, and the temperature readings reflected the effect of blower operation. At the end of 2 weeks continuous operation, with coal-firing, and with the boiler operating at maximum guaranteed output, tube-temperature data were collected; some of the readings are included in Table 5, section B.

All these thermocouples were read daily at less than hourly intervals for a month. It was noted that tube No. 81 was more sensitive to wall blowing than No. 87 but never did the temperature of either tube exceed 720 F even immediately after operating the blowers. On some occasions after soot-blowing, the temperature spread for the five couples was less than 10 deg F. From these observations it was concluded that variation in circulation from 57 to 230 per cent of normal had no effect on the tube temperatures.

TABLE 5 EFFECT OF VARIABLE ORIFICE SIZE ON CIRCULATION AND TUBE TEMPERATURE AS SHOWN BY (A) FLOW DATA AND (B) TEMPERATURE DATA

* There was no downstream orifice pressure tap on this circuit but the water-flow figure given was obtained on the same size orifice in the opposite side wall.

In October, 1944, the boiler was placed in operation with oil-firing after an outage. Under these conditions the furnace walls were clean and remained clean while tube temperatures were taken. Oil was fired tangentially through burners interposed between the coal burners, and it would therefore be expected that tube temperatures in the lower part of the furnace would be much higher than with coal-firing. Fig. 9 illustrates the results of these tests and shows the variation in tube temperature at different elevations above the furnace floor when the boiler output was varied from 260,000 to 560,000 lb per hr. At each elevation noted two thermocouples were installed 1 in. apart, one as a check against the other, because previous experience had indicated that a couple sometimes becomes shorted against the cover plate, thus giving a high and erroneous reading. At the time these studies were made a panel of eight tubes in the right-hand side wall was being used for another special study of the effect of the orifice size on internal tube conditions, but tubes No. 133 and 139 were the only two tubes of the group which had couples installed at the 5-ft and 11-ft elevations. Tube No. 133 is one of a pair served by a normal-sized 0.34 in. orifice in the trunk of the bifurcate; tube No. 139 was one of a pair having no orifice below the bifurcate but having an individual orifice of 0.25 in. in each tube above the bifurcate. The calculated water-flow rate to each of these tubes is the same. The location of this group of tubes is one where maximum flame temperature would most likely occur but it will be noted that the maximum tube temperature measured was 720 F.

The object of the special study started in 1944, and just mentioned as involving a group of eight tubes in the right side wall, was to confirm over a 1-year operating period, with routine boiler-water control, the general conclusions resulting from the shorter study of tube temperature and interior-surface condition of the rear-wall and left side-wall tubes. The four bifurcated elements chosen were side by side in a zone of high heat absorption and actually straddled a wall-blower element located about 34 ft above the furnace floor. Test specimens of new tubing were installed in all eight tubes, extending from approximately 18 to 25 ft above the floor, and two thermocouples were installed on each tube at each of the following elevations: 18 ft, 24 ft, and 26 ft. One bifurcated circuit had a normal orifice, one an oversize, one an undersize, and one element had individual orifices in each leg which were installed at two butt-welded tube joints in the form of a diaphragm-backing-ring with the orifice hole drilled through the center of the diaphragm. During the first month the boiler was coal-fired at design pressure and daytime load generally be-

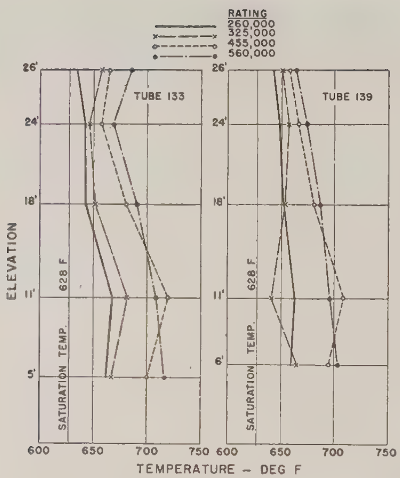

FIG. 9 PLOT SHOWING EFFECT OF RATING AND ELEVATION IN FURNACE ON TUBE TEMPERATURES WITH OIL-FIRING

tween 550,000 and 610,000 lb per hr, followed by 4 days' operation with 100 per cent oil at 550,000 lb per output. Table 6 presents the range of readings at each elevation on each of the eight tubes during these two periods of operation.

It will be noted that tube No. 139 had abnormally high temperatures at the 18-ft elevation, although they were normal at the two higher elevations. The boiler was taken off the line July 16 for a scheduled outage, and a blister was found on tube No. 139 at about 10 ft above the floor. A short piece was welded in and the boiler placed in operation the following day, but temperatures were still somewhat higher than normal at this one elevation. Subsequently, a probe was run up into these two individual orifices to make sure they were clear and after that the boiler was operated for over a year with normal temperatures. In October, 1945, these individual orifices were removed and it was discovered that the probable cause of the blister was welding scale which had formed on and near the orifice during welding and which had subsequently flaked off and restricted the flow. In further discussion of the temperatures in Table 6, the figures given for tubes Nos. 139 and 140 will not be considered.

Table 6, section A, shows a wide variation in temperature due to the effect of ash building up and falling or being blown off the tubes. At the lower elevations the metal was practically at saturation temperature when covered with ash and never exceeded 705 F under normal operating conditions. At the highest elevation which was still about 8 ft below the nearest wall blower the minimum and maximum temperatures were higher due to more effective cleaning and lower rate of accumulation after cleaning. Table 6, section B, shows that with oil-firing the spread in temperature at all couples was much less than with coal, due to more uniform ash conditions at the absorbing surface. This part of the table also shows that with oil-firing the tubes are hotter at the lower elevations as would be expected with a cleaner furnace. In no case is there any significant difference in temperature that can be attributed to orifice size.

Steam Purity. Because of the several changes and modifications which were necessary before satisfactory steam purity was obtained, considerable data were collected on this subject. During the early part of this work samples were taken from the "dry" drum to determine the effectiveness of the separating apparatus in the "wet" drum and from the inlet header of the superheater to determine the final result. However, it was found that

under certain conditions the steam conductivity was lower (indicating better purity) entering the final drying screens than leaving the screens, as determined by the superheater inlet-header sample. Switching the conductivity cells at the two sampling points did not change the results. Some time later it was discovered that if steam conductivity data were collected during a period when saturated steam was being taken from the dry drum for operation of the soot blowers, the conductivity of the superheater inlet-header sample fluctuated rapidly, and the average was much higher than when the soot blowers were not being used. This led to the installation of a sampling nozzle in the superheated-steam line near the high-pressure-turbine inlet, and it was found that this sample had a lower conductivity and did not fluctuate or increase very much during soot-blowing periods.

When the final changes were made to the dry-drum internals, a long sampling nozzle was installed at the outlet of the final drying screens between the screens and the several off-take tubes leading to the superheater. Furthermore, the off-take nozzle for supplying soot-blower steam was extended through the screens, as mentioned elsewhere in this paper. A sampling connection was made in the side of a horizontal run of this small soot-blower steam pipe (dictated by convenience), and subsequent checks on steam purity entering the final drying screens were made only during periods of soot blowing.

It was found that the source of make-up water and the season of the year had a very marked effect on steam conductivity leaving the high-pressure boiler. For example, there was a period during the spring of 1944, when it became necessary to use one of the low-pressure boilers as an evaporator for the make-up water. Raw water was evaporated in the boiler and condensed in the low-pressure units and it was found that the conductivity almost immediately increased about 1 mmho all through the station at points where it was being measured, such as at condenser hot wells, feed line and high-pressure-boiler steam outlet. This increase was found to be due to an increase in ammonia. There is also a seasonal variation in ammonia caused by the make-up water from the evaporators, even though the make-up is only about 2 per cent. For example, the uncorrected conductivity of steam in August, 1945, was about 3.5 times greater than the corrected value but less than 1.5 times greater in the month of May, 1945. The corrected value is currently obtained by passing the condensed sample of steam through a degassifier; earlier values of the gas correction were obtained either by checking for ammonia and carbon dioxide in the sample or by comparing the uncorrected conductivity with the results of gravimetric measurement of the total solids.

Fig. 10 shows the relation between total solids, determined by evaporation, and the conductivity of undegassed samples of condensed steam. The generally accepted conversion factor by which conductivity of a degassed-water sample is multiplied to obtain ppm of dissolved solids, is 0.60. Fig. 10 shows that when the evaporators were used for make-up the factor was about 0.40 in the cold-weather months, and 0.20 or less in the warm-weather months; but when the low-pressure boilers were used to evaporate the make-up, the factor was only about 0.20, even in the cold-weather months.

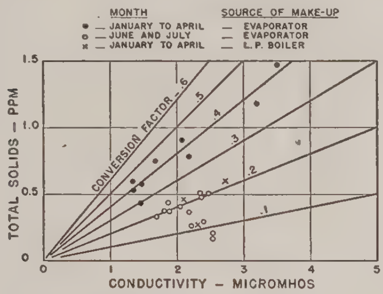

FIG. 10 RELATION BETWEEN CONDUCTIVITY AND TOTAL SOLIDS DETERMINED BY EVAPORATION

All the condensed-steam samples which were evaporated for total-solids determination after the final changes were made in the drum internals were obtained at boiler loads between 550,000 and 650,000 lb per hr. For each of these determinations a 3-liter sample was evaporated to dryness in the special steam-sample evaporator which is described in another paper of this series (11), and the results are given in Table 7.

The conductivity of undegassed-steam samples taken from the dry drum ahead of the final drying screens was found to be 4.23 mmho and 4.56 mmho at boiler loads of 620,000 and 650,000 lb per hr, respectively. Other samples, evaporated during the same week, indicated that the conversion factor was 0.20 or less, so the corresponding total solids in the dry drum would be 0.85 and 0.91 ppm, respectively. This would indicate that without the dry drum the purity would be equal to or better than the minimum guarantee of 1 ppm which has now been recommended by the American Boiler Manufacturers Association and Affiliated Industries (A.B.M.A. and A.I.). The guarantee on this unit was 0.50 ppm, and the screens in the dry drum removed enough moisture to bring the final results below the guarantee as will be seen from the results given in Table 7.

TABLE 7 STEAM-PURITY DETERMINATIONS BY EVAPORATION

June 13 to July 20, 1944

Boiler Output lb/hr	Number of Determinations	Boiler Water Avg.* T.S. ppm	Steam Sample Avg.* T.S. ppm
550,000	3	593	0.34
572,000	3	1107	0.34
610,000	7	598	0.37
650,000	1	1137	0.37

* T.S. is total solids determined by evaporation.

Effect of Circulation Rate on Internal Surface of Tubes. In June, 1943, the boiler was placed in operation with one oversize and one undersize orifice. The location of the circuits, orifice size, and relative circulation rates are given in Table 5, section A. Table 5, section B, lists the number and location of thermocouples which were installed in 2-ft-long sections of new tubing having polished inside surfaces. These sections were installed to determine whether corrosion would occur on polished surfaces with the new potassium treatment, including the feeding of silica, and whether rate of circulation had any effect. A polished section was also installed in the adjacent rear-wall circuit near the discharge end, in the zone above the furnace roof where the tube would not be exposed to heat.

At the end of 1 month of operation at 470,000 lb per hr average load and 630,000 lb per hr maximum load, one half of the polished sections were removed from the two rear-wall tubes. A superficial examination revealed no difference between the two tubes; each was lightly and uniformly coated on the inside with a film of gray sludge, and under the coating of each the metal had been slightly attacked on the fire side but less so on the side toward the casing.

At the end of another month of operation at an average load of 510,000 lb per hr, the remaining half of the original polished sections were removed from the rear-wall tubes. Again a superficial examination revealed no difference between the two sections but there were a few small pits on each. The polished sections from the side wall were not removed for examination at this time since the study of the rear-wall tubes had shown no difference in appearance even with relative circulation rates of nearly 2 to 1. The results of a more elaborate examination of the foregoing and other polished sections removed at later dates are discussed in another paper of this series (12).

In June, 1944, when it had become apparent that the omission of silica from the water treatment had resulted in improved conditions, another special study was commenced involving four circuits in the right side wall as previously mentioned and described (see Table 6). After a year of operation tube sections were removed from these circuits in September, 1945. Again, superficial examination of the tubes indicated that the rate of circulation, within the range of 200 to 75 per cent of normal, had little effect on the appearance of the surface. Regardless of rate of circulation, all the tubes had a light coating of black sludge of less thickness than had been found the year previous; the side toward the fire was much cleaner than the side toward the casing; metal under the film was very smooth on both fire side and casing side except for numerous small pinpoint pits which occurred more frequently on the unheated side than on the heated side.

Table 8 shows the marked difference in weight of deposit for the fire side compared to the casing side; in each case the tubes were split along the vertical axis separating the fire side and the casing side, and all the sludge deposit from a 5-in. length was removed and weighed. It will also be noted that the tube which had the highest rate of circulation also had the largest deposit of sludge.

TABLE 8 COMPARISON OF WEIGHT OF SLUDGE SCRAPINGS FROM TUBES WITH UNDERSIZE, OVERSIZE, AND NORMAL ORIFICES

Orifice Designation	Oversize	Normal	Undersize
Orifice Diameter - in.	0.50	0.34	0.30
Tube Number	138	134	136
	Weight of Sludge - Milligrams		
Fire Side	162.1	96.0	97.5
Casing Side	244.1	179.0	146.7
Total	406.2	275.0	244.2

The results of a careful examination of the surfaces of other specimens from the same tubes are discussed in another paper of this series (12).

PERFORMANCE

Circulating Pumps. The boiler is normally operated with two

pumps running and the third pump idle with suction and discharge valves closed. Normally, at least one dual-drive pump is always in service and after 3 years of operation a power failure did occur and trip out both pump motors; the turbine drive on one pump took over the load and maintained full speed on one pump. Test data plotted in Figs. 5 and 6 show that two pumps handle about 3,200,000 lb per hr and since the operating water content of the boiler is about 30,000 lb (exclusive of economizer), this represents a recirculation rate of more than 100 times per hr. The ratio of water to steam for any rate of output can also be readily determined from either Fig. 5 or Fig. 6. It will be noted that at maximum load of 650,000 lb per hr, this ratio is about 5 with two-pump operation, and the same ratio would be maintained with one pump up to a load of about 450,000 lb per hr. At 650,000 lb per hr load with one pump the water-to-steam ratio would be nearly 3 to 1, a condition which should not cause any trouble during an emergency period since it has been proved in experiments with circuits that operation at one half normal circulation over a period of 2 months produced no ill effect. It has, however, been the practice not to exceed 400,000 lb per hr output with one pump, particularly if the other two pumps were not in condition to operate. There were short periods early in 1943 when only one pump was in operating condition, but Table 1 shows that no outage of the boiler was ever caused by the circulating pumps.

The circulating-pump specifications rate each pump at 3500 gpm 50 psi head (184 ft) when handling water at 630 F and operating at 1750 rpm, but shop tests by the manufacturer indicated the total head to be 192 ft at the capacity mentioned. Owing to conservative pressure-drop calculations for the circulating system, the actual resistance for a given flow rate is lower than anticipated, and consequently, the pumps operate at higher than design capacity. Fig. 7 would indicate that when two pumps are operating, each is handling about 4600 gpm rather than 3500 gpm and that with single-pump operation the capacity is nearly 6000 gpm.

With two-pump operation each pump uses an average of 37 amp at 2300 v which is equivalent to about 3,500,000 Btu per hr in fuel fired, or a gross input to the two motors equal to less than 0.5 per cent of the fuel fired at maximum load. The hydraulic horsepower under the same conditions would be 240 for two pumps, which represents input of energy to the water at the rate of about 600,000 Btu per hr, so the net consumption of the pump drivers would be equivalent to 0.35 per cent of the heat in the fuel fired at maximum output.

Heat Absorption and Distribution. No attempt was made to check the actual distribution of heat to the various furnace walls but it can be calculated from average heat-absorption rate and exposed surface with due allowance for surface effectiveness. Table 2 shows that measured distribution of water to the various furnace walls is almost identical to calculated distribution of heat.

Distribution of heat to various other parts of the unit such as superheater, reheater, economizer, and air heater, is readily checked by measuring temperature rise or drop of one or both fluids and calculating or measuring the quantity of the fluids. Total heat absorption of each part of the unit was very close to manufacturer's predictions, except in the case of the reheater which was too conservatively designed. The method of correcting the reheated-steam temperature has been discussed elsewhere in this paper.

Figs. 11 and 12 show the results of informal tests in October and November, 1943, with both coal and oil firing, compared to predicted performance for coal-firing represented by the curves. The steam-temperature controller was set to maintain 950 to 960 F, according to the Micromax recorder, and the reheat temperature was also being regulated according to recorder, but at the end of the tests the recorder was checked and found to be reading 15 deg F too high. The corrected temperatures are plotted and therefore fall below the predicted values. However, for the tests above 450,000 lb per hr output higher steam temperature could readily have been obtained, because during these tests the by-pass dampers were being used to reduce the temperature of high-pressure steam, and the reheated-steam temperature was being reduced by desuperheating.

In comparing the results of the oil-firing and coal-firing tests it should be noted that oil was used only for the duration of the tests and coal was used during about 16 hours of each day. Therefore the furnace walls and other heating surfaces were not as clean as would be the case with prolonged used of oil.

Although the average gas temperature leaving the two heaters was close to contract predictions, the air temperature during these tests was higher than predicted. The three factors responsible for this were: (*a*) lower ratio of air to gas (*b*) higher gas-inlet temperature, (*c*) higher air-inlet temperature; but because of conservative selection of air-heater surface, the air-heater heat absorption was close to predictions. Air leaks into the economizer were responsible for the low ratio of air to gas, and these have been stopped, thus reducing both air-outlet and gas-outlet temperatures.

Superheat Control. Steam temperature from the high-pressure superheater is automatically controlled and the equipment used is described in another paper of this series (13). Automatic regulation of both sets of dampers at the economizer outlet results in very close regulation. Starting with the conditions which exist immediately after operating the furnace wall blowers, the by-pass damper is fully closed or slightly open depending upon the rate of output. As the furnace accumulates ash and the gas temperature increases, the by-pass dampers automatically open and maintain the steam temperature within ±5 F of the desired limit. At the end of an 8-hr operating period the by-pass dampers will be 50 to 80 per cent open, depending upon the output rate and the nature of the coal. Then, as the wall blowers are operated, the by-pass dampers operate automatically to compensate for the effect of removing the ash from the walls and maintain the same close regulation of steam temperature during the cleaning period. Tests were conducted to determine the full effect of operating the by-pass dampers from closed to 75 per cent open. As mentioned elsewhere the lower economizer dampers close as the by-pass dampers open, but a stop on the regulator cylinder prevents the former from closing fully, because full closing has never been necessary to obtain the desired control. Fig. 13 shows the results of these tests and illustrates how the heat absorption of the combined economizers increases as the by-pass dampers open, thus compensating for the decreased superheater absorption and resulting in very little increase of final gas temperature. Oil-firing was used in order to maintain uniform conditions of furnace cleanliness during the tests.

Capacity and Flexibility. The maximum peak capacity of the boiler has never been determined. The maximum demand has been 670,000 lb per hr but the feeders, burners, fans, and circulating pumps are adequate for higher output.

At reduced pressure there is no decrease in circulation, and the volumetric percentage of steam in the mixture leaving the generating tubes will increase so the average velocity in the tubes is greater. The unit is therefore very flexible as regards operation at variable pressure, and the upper limit of capacity would be governed by considerations of steam purity and steam temperature rather than circulation. These upper limits were not determined. During special tests on the high-pressure turbine, wide swings in pressure, output, and steam temperature were accomplished very rapidly and with an excellent degree of control.

The boiler has a very stable water level even under extreme op-

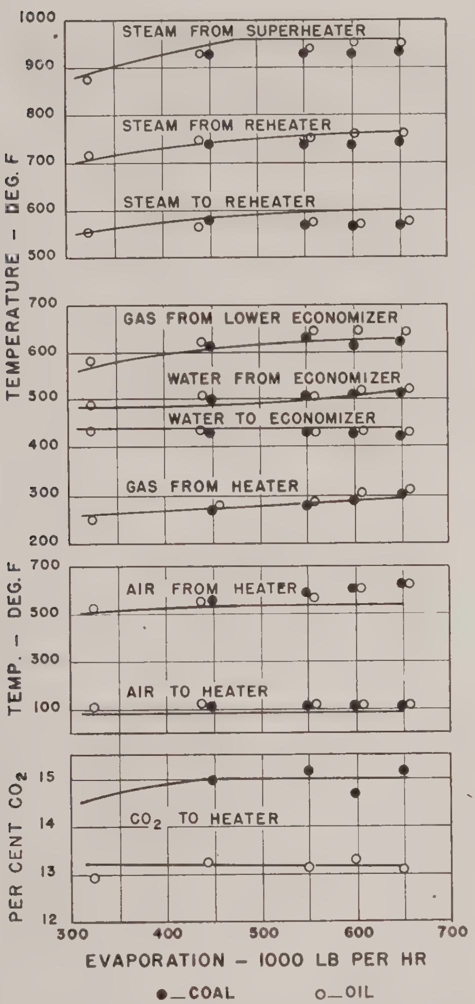

Fig. 11 Results of Tests With Coal- and Oil-Firing Compared to Predicted Performance

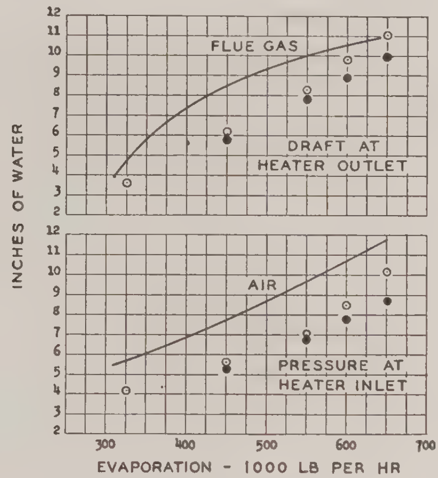

Fig. 12 Results of Tests With Coal- and Oil-Firing Compared to Predicted Performance

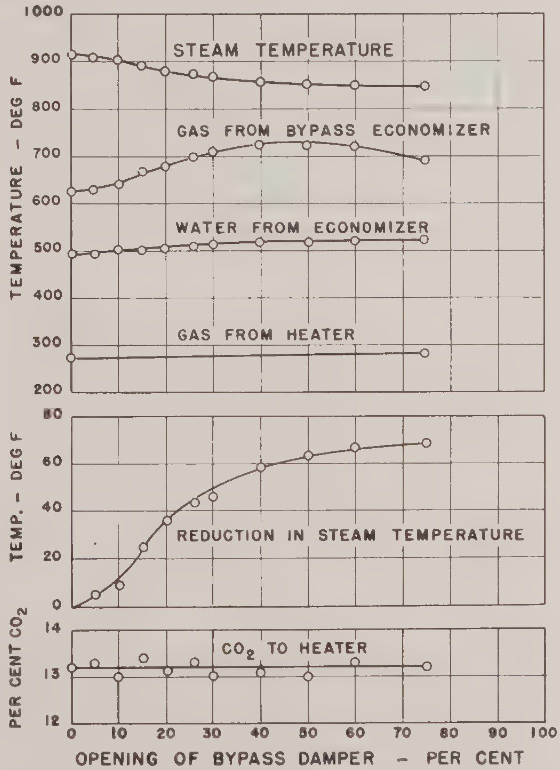

Fig. 13 Results of Superheat-Control Test, Oil-Firing, 560,000 Lb Per Hr Output, 1900 Psi Drum Pressure

erating conditions of sudden load increase or decrease. In fact, sudden emergency load changes have occurred without any perceptible change in water level. Also, on the occasion of furnace-tube failures, it has not been difficult to maintain water level while reducing load and pressure in an orderly manner.

Efficiency. Coal and ash samples were not collected during the informal tests conducted in 1943, so complete heat-balance figures are not available.

The contract over-all efficiency with coal-firing at 650,000 lb per hr output was 89.3 per cent, based on coal of 14,200 Btu per lb, with 2.8 per cent moisture as fired; and based on 15 per cent CO_2 in gases at the economizer outlet, with 290 F gas temperature leaving the air heater, 80 F entering-air temperature, and with 0.6 per cent allowance for unburned combustible.

During the reported tests at 650,000 lb per hr output, the CO_2 at the economizer outlet averaged 15.2 per cent, the air entering the heaters was 110 F, and gas leaving the heaters 306 F. Tests to determine heat loss due to combustible in fly ash were conducted at a later date when the maximum load demand on the boiler averaged 572,000 lb per hr, the CO_2 entering the convection superheater section was 16 per cent, and the average heat loss in the fly-ash combustible for two tests was 0.47 per cent. The results of two other tests with 15 per cent CO_2, at the same output, averaged 0.34 per cent heat loss in the fly-ash combustible.

Conclusion

The authors have revealed all the experiences with this high-

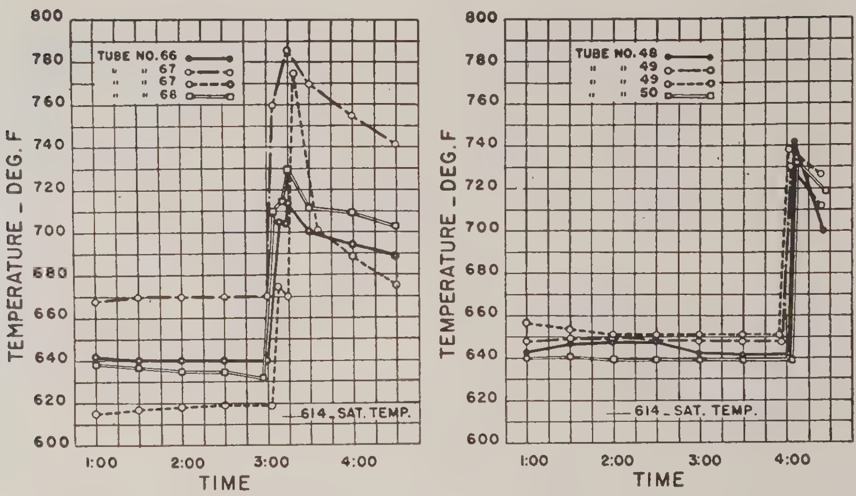

Fig. 14 Effect of Furnace Wall Cleaning on Hot Face Tube Temperature

pressure boiler in considerable detail so that others may benefit from a knowledge of what has been going on at this station during the last 3 years. The special test and research activities reported in this and its companion papers (11, 12, 13) represent only a part of the total number of special studies conducted. Many of these were associated more with operation problems of the station as a whole than with problems peculiar to the forced-circulation boiler. The judgment of those responsible for selecting a bare-tube, slagging-bottom, radiant, forced-circulation boiler for this high-pressure application has been verified by the operating record of this boiler.

Discussion

Lewis J. Dawson.[6] It may be in order at this time to restate the suction conditions under which the circulating pumps operate in order that the importance of the labyrinth design can be understood. The water handled by the impeller is at full boiler pressure of about 1900 psi and at the corresponding saturation temperature of 630 F. The pressure, temperature, and incipient flashing preclude the possibility of using a conventional stuffing box in which the packing is subjected to suction conditions. The injection and bleed-off arrangement is required to give safe stuffing-box conditions and normal packing life. The labyrinth must be of a reasonable length and of close clearance to reduce injection water requirements. These two factors make it important that labyrinth alignment be maintained.

After it became apparent that misalignment was causing the labyrinth failures, the support under the coupling end of the bearing body was removed which allowed the pump to move freely with the piping so that no internal misalignment could occur. Measurements were taken of the movement of the free end under various operating and stand-by conditions. These measurements revealed that pipe movement was the major factor, with uneven bracket temperature of secondary importance. Variations in these measurements, both vertical and horizontal, could be obtained by warming and starting one of the remaining two pumps, showing that temperature changes in the common piping affected alignment of the unit being measured. Equalization of bearing-bracket temperature did not restore alignment.

The units are equipped with spacer-type gear couplings, so that the resultant 0.030 to 0.040 in. misalignment between pump and driver can be tolerated. In connection with the couplings, the author has mentioned the limit stops which were installed to prevent motor bearing failure. It is a sad commentary on motor design that all large motors must be protected in this manner because of inadequate thrust-bearing capacity.

Failures of oil-pump spiral drive gears were found due to wear in the oil-pump shaft bearings. This resulted in improper alignment and tooth contact between gear members. The new-design bearing housing has incorporated a ball-bearing oil-pump shaft support.

---

[6] Field Engineer, Cameron Engineering Service, Ingersoll-Rand Company, Phillipsburg, N. J. Jun. A.S.M.E.

With reference to Fig. 7 of the paper, it is probable that the actual operating speed is close to 1790 rpm under the reduced horsepower loading. The majority of the steaming test points fall reasonably close to the revised head-capacity curve. We note that the field points having greatest deviation are all from high-temperature water readings. Checking the point of greatest deviation, calculating the water horsepower and comparing it to brake horsepower input, we arrive at a pump efficiency 21 per cent greater than the manufacturer's shop test curve value at the corresponding capacity. This would lead us to believe that the Pitot tube calibration is off at high water temperatures and corresponding low densities.

Authors' Closure

The same data which Mr. Dawson used in arriving at his statement that pipe movement was the major cause of pump misalignment can be interpreted differently when all the operating procedures occurring at the time of measurement are also taken into consideration.

Fig. 4 shows the position of the suction pipes to each pump, and the suction header which is common to all three pumps. The horizontal movement of these three pipes was measured at an elevation 20 ft above the pumps during the process of raising pressure on the boiler and it was found that there was no movement of the center pipe while the movement of each outside pipe was about $^1/_4$ in., but in opposite directions, as would be expected due to expansion of the suction header. This being the case, one would expect the movement of the coupling end of the bearing to be in opposite directions on *A* and *C* pumps, and no movement on *B* pump, if due to pipe strain. Instead this end of the bearing body moved downward on all three pumps, from a cold to hot condition, and the cause of the pump misalignment therefore is a controversial subject. The fact remains that the trouble was corrected by merely allowing the coupling end of the bearing to float freely and by taking steps to equalize upper and lower bearing bracket temperatures.

The authors desire to comment further on the tube failures which occurred on October 26, 1945. The amount of sludge found in the drum after this failure was greater than had previously accumulated during any operating period of equal duration, and this sludge was nearly 70 per cent copper. Sludge deposits from the generating tubes were also higher in copper content than previously noted. This would indicate that prior to this failure unusual feedwater contamination in the form of corrosion products, including copper, had been prevalent.

The failures located 20 ft above the floor were diagnosed as having been caused by sludge deposits and subsequent overheating sufficient to cause weakened metal and intergranular rupture. The failure close to the furnace floor may also have been started by sludge accumulation which increased the outside surface temperature a sufficient amount to accelerate external tube corrosion. Concurrently corrosion was causing a thinning of the metal from the inside and laying down a deposit of the corrosion product, iron oxide, to further insulate the inside of the tube. When the tube became thin enough a small bulge occurred which quickly overheated locally until rupture occured.

After acid washing the boiler, thermocouples were installed at four elevations between 8 in. and 24 ft above the floor on the tube which had failed close to the furnace floor. During the past five months these couples have been read twice daily and some of them connected to a recorder for a continuous record. The metal temperature 8 in. above the molten slag on the floor varies between saturation temperature (about 630 F) and 765 F but there has been no gradual increase as would be expected if sludge were again accumulating on the inside surface. The maximum temperature at higher elevations has been 10 to 20 deg F lower. The furnace tubes were checked for external corrosion about January 1, 1946, and there was no evidence of any further attack on any of the walls.

Special Studies of the Feedwater-Steam System of the 2000-Psi Boiler at Somerset Station of Montaup Electric Company

By W. D. BISSELL,[1] B. J. CROSS,[2] and H. E. WHITE[3]

In conjunction with other studies on the high-pressure forced-circulation boiler at the Somerset Station of the Montaup Electric Company during the past 3 years, tests to determine, particularly, the extent of dissolution of iron throughout the system, and the formation of high-iron sludges were made. A summary of the findings of this investigation are given in this paper.

During the course of a complete investigation of the high-pressure forced-circulation boiler at the Somerset Station of the Montaup Electric Company covering the past 3 years, a special study was made on the feedwater and steam system particularly with regard to the dissolution of iron throughout the system, and the formation of high-iron sludges within the boiler. This paper gives a summary of the findings of these studies.

The period covered by this work was from January, 1944, to October, 1945. The boiler was thoroughly cleaned by acid treatment late in December, 1943. The boiler water has been continually on potassium-salt treatment since May, 1943.

Over the past few years the occurrence of iron oxide in boilers has become a matter of interest, if not concern, to operators of high-pressure boilers, as the presence of this substance must always indicate corrosion in some part of the system. Usually the amount of iron oxide is small by comparison with the large area of steel surfaces involved, and the indicated loss of metal, if uniformly distributed, is not large enough to be a cause of great concern. If, however, there are small areas of concentrated attack, the amount of iron oxide found may well indicate serious corrosion leading to failures.

Even in the case of uniform corrosion of iron which in itself may not be a serious matter, the accumulation of the solid products might lead to failures in the boiler by insulation effect on surfaces receiving heat and also by obstructing passages and thereby interfering with circulation of water.

Sludge deposits found in the high-pressure boiler at the Somerset Station were of particular concern because tube failures that had occurred were attributed to these deposits either on the surfaces of the tubes or on the strainers protecting the orifices in the tube circuits.

The examination of samples of tubes cut from furnace walls at periodic examinations disclosed a thin film of deposit on the entire inner surface of the tube. On the evaporative surfaces the deposit was usually baked on in a semiscalelike form. On the inactive surfaces it occurred as a slime which dried out to a dust. Both types of deposits could be removed with a stiff brush. Slime deposits of sludge also were found in the inlet headers, on orifice strainers and on other surfaces not exposed to external heat. Scalelike flakes of caked sludge have been found lodged in the holes in the strainers. Some of these flakes had a curvature indicating that they had formed in headers or downtake piping. Deposits found in the drum were more granular than those found in the tubes and probably represent the heavier components of the sludge.

The composition of the sludge varied somewhat with location but all deposits had a high proportion of black iron oxide. Typical analyses of sludges are given in Table 1.

TABLE 1 TYPICAL ANALYSES OF SLUDGES

SAMPLE NUMBER	1	2	3	4	5	6
IRON AS Fe_2O_3 - PER CENT	53.3	47.0	78.3	27	63	42
PHOSPHATE AS P_2O_5 - PER CENT	18.5	3.3	6.0	20-25	6-8	12-15

1. SUSPENDED SLUDGE AT BLOW DOWN.
2. DRIFT DEPOSIT IN WET DRUM.
3. DEPOSITS ON STRAINERS.
4. DEPOSIT ON DOWNCOMER SCREENS
5. DEPOSITS IN REAR HEADER COLLECTING CHAMBER.
6. SLUDGE FROM REAR HEADERS.

The high proportion of iron oxide in these sludges naturally led to some concern as, if it were formed entirely within the boiler, it might indicate severe local corrosion or pitting that would result ultimately in failure.

The accumulation of sludge, regardless of its composition, in the boiler might result in stoppages of furnace circuits or overheating of metal by insulation of heat-absorbing surfaces. Corrosion may occur as a result of the concentration of boiler-water salts under deposits of sludge on heating surfaces. It is known that adherent scales may form under such deposits on steam-generating surfaces as a result of the concentration of the components in the sludge "sponge" and the higher metal temperature resulting from the insulation of the metal.

The high-pressure boiler at this station delivers steam at 1850 psig and 950 F to the high-pressure turbine. This turbine exhausts through a reheater to the low-pressure system. The water supplied to the boilers is condensate with make-up supplied by evaporators. The principal outside sources of contamination were condenser leakage and evaporator carry-over.

A simplified diagram of the feedwater system is shown in Fig. 1. The condensate from the hot-well pumps passes successively through the oil cooler, 15th-stage heater, deaerating heater, 10th-stage heater, low-pressure feed pumps, exhaust heater, extraction heater, high-pressure feed pumps, high-pressure heaters, and to the economizer. The drips from the various heaters are re-

This diagram represents the condition at the time most of the work reported was done. Minor changes have since been made.

SCOPE OF INVESTIGATION

The feedwater study may be divided into several phases both on the basis of the nature of the work done and on the time periods. Because of wartime restrictions of both manpower and equipment, all of the work could not be carried on simultaneously. Each phase of the investigation is listed in the following tabulation and is discussed in order:

Period 1.

(*a*) The continuous measurement of hydrogen in feedwater and steam and oxygen in feedwater.

(*b*) The measurement of total solids in feedwater, steam and blowdown.

(*c*) The measurement of suspended solids in boiler water at shutdowns of the boiler.

(*d*) The study of gases in steam, particularly as affected by small variation in boiler-water conditions and the normal irregularities in the functioning of auxiliary equipment.

Period 2. The exploration of the feedwater system for dissolved hydrogen, dissolved iron and changes in alkalinity (pH).

Period 3.

Miscellaneous studies as follows:

(*a*) Copper in feedwater.
(*b*) Bead column and ion exchanger column tests.
(*c*) Tube-temperature measurement.
(*d*) Corrosion detector.

The work under Period 1 was done during January, February, and March, 1944.

Period 1 (*a*). Recording hydrogen meters were set up to give a continuous record of the dissolved hydrogen in feedwater and in the steam delivered by the boiler. As hydrogen is one of the products of the reaction of water with iron, the amount of hydrogen evolved may be taken as a measure of the rate of corrosion. As irregularities in the performance of the deaerating heater were suspected, a dissolved-oxygen meter was also installed to sample the feedwater to the boiler. With the exception of short outages for adjustments and maintenance, these instruments have been in continuous operation since January, 1944. Originally they were installed close to the point of sampling but later moved, when stainless-steel tubing became available, to a more convenient location for observation by the boiler operators.

The hydrogen record for the 3-month period, January, February, and March is plotted in Fig. 2. Steam flow and boiler pressures are also shown on this chart. It may be seen that while the hydrogen content of the feedwater is substantially constant, the hydrogen in steam showed relatively high values in the early part of January, with a gradual reduction in these values until they leveled out at $1^1/_2$ to 1 part per billion over the feedwater values. While the high hydrogen values during the first week of the month may be partly accounted for by the lower rating, it is believed that they are in greater part due to residual hydrogen in the system following the acid wash.

The feedwater sample was usually taken from the economizer inlet. It was, however, occasionally taken at the economizer outlet. The values for hydrogen at the economizer outlet fell between those of the inlet and the steam leaving the boiler.

The significant feature of these hydrogen curves is the fact that they show that a large part of the hydrogen in the steam enters the boiler with the feedwater. Also there is an indication from the few readings taken that there is an increase in hydrogen across the economizer.

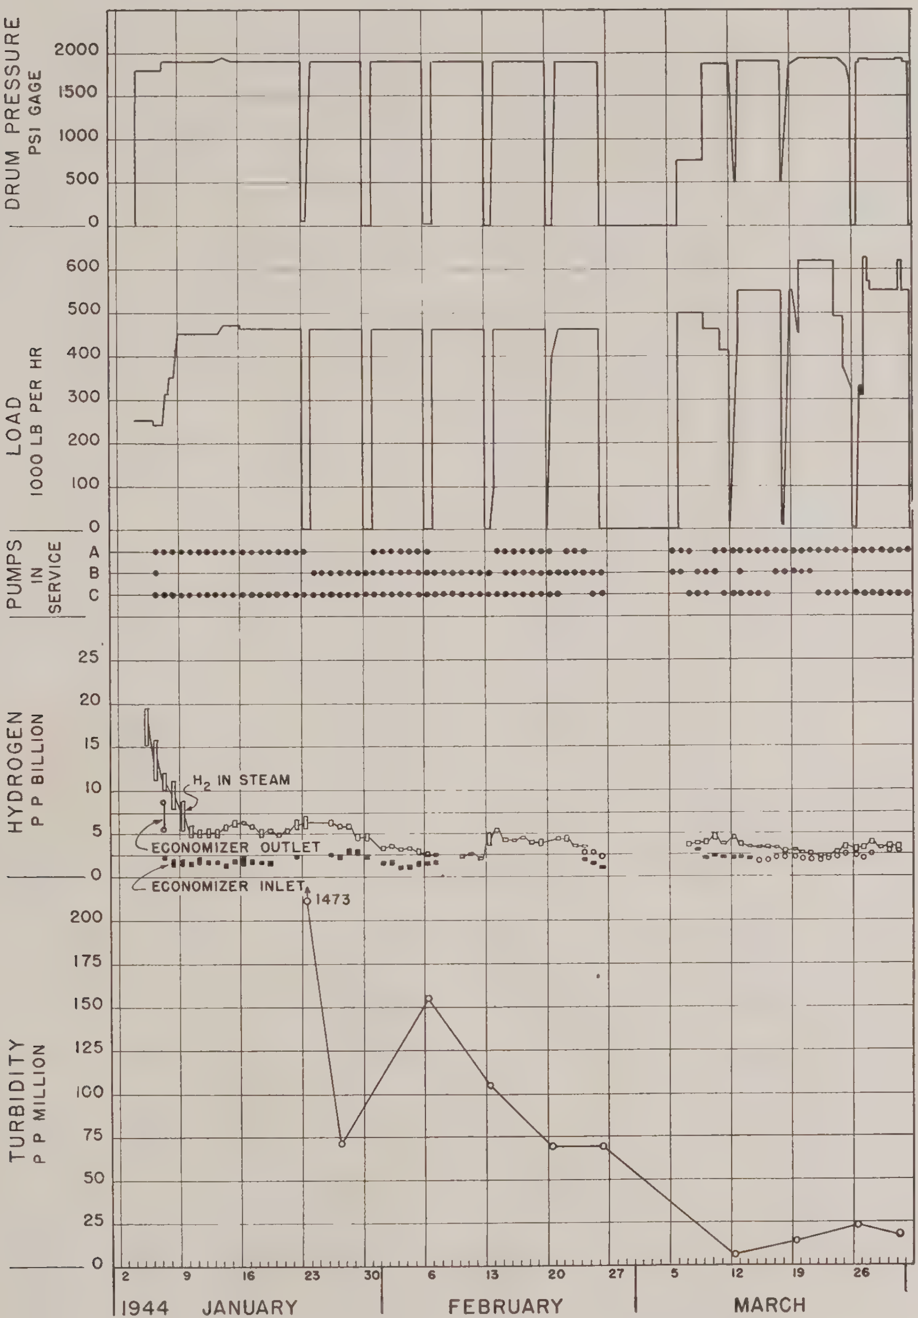

Fig. 2 Hydrogen Content Record of Feedwater for 3-Month Period

A consideration of the probable reaction of iron with water presents the possibility that hydrogen may be evolved in the economizer and boiler without any reaction involving the metal of the boiler. It has been proposed that in the lower-temperature areas the reaction may be

$$Fe + 2H_2O \rightarrow Fe(OH)_2 + H_2$$

At the higher temperature of the boiler and economizer the ferrous hydroxide may react to form magnetic oxide

$$3Fe(OH)_2 \rightarrow Fe_3O_4 + 2H_2O + H_2$$

If, however, all of the hydrogen formed in the boiler came from this second reaction, the relative amounts of H_2 in feedwater and

steam would be 3 to 4. Actually it is nearer to 2 than 3, which indicates some reaction with the boiler metal.

During the 3-month period represented by this chart there were sporadic occurrences of small amounts of dissolved oxygen in the feedwater to the high-pressure unit. Changes in the deaerating system, made in the spring of 1944, resulted in consistently good removal of air and since that time the feedwater has been substantially oxygen-free.

Period 1 (b): Total Solids in Feedwater, Steam, and Blowdown. The first approach to the sludge problem was a study of the amounts of total solids delivered to the boiler in the feedwater and leaving the boiler with the steam produced and the blowdown removed. Samples of feedwater, steam and blowdown were collected in hourly increments over an 8-hr period. These samples were evaporated to dryness and the residues weighed. The standard-size samples were 3 liters for the feedwater, 3 to 4 liters for the steam, and 1/2 liter for the blowdown. All samples were evaporated without boiling in closed containers ventilated with filtered air.

The results of a number of determinations are given in Table 3, with the calculations leading to the total amounts of solids delivered to the boiler and removed from the boiler for a 24-hr period. Feedwater and steam flows were taken from station meters. The boiler blowdown was passed through cooling coils and weighed. Because of the dilution of the feedwater with condensate from the high-pressure and the extraction heater after the point of sampling, it was necessary to correct the total solids in feedwater by analysis for this dilution. Also, because some of the steam produced is diverted through the high-pressure heater and returned to the boiler as feedwater, the measured steam flow must be reduced by that amount.

It will be noted that there is in each case a positive unaccounted-for balance which presumably remains in the boiler.

In a number of tests the iron content of the total-solids residues was determined. The calculations for iron were carried out in the same manner as for the total solids and a figure for iron remaining in the boiler was obtained. These results also are given in Table 1. As with total solids, there is a positive unaccounted-for amount of iron.

Period 1 (c): Suspended Solids in Boiler Water. A measure of the relative amount of sludge formed and remaining in the boiler was afforded by the determination of turbidity of the boiler water that occurs when the boiler is taken out of service. It had long been noted that on shutting down the boiler the water becomes turbid and that the maximum concentration of suspended solids occurred at the pressure interval of 600 to 400 lb pressure; this being at the time the fires were extinguished. Advantage is taken of this period to remove much of the accumulated sludge by blowing down. During January, February, and March, 1944, each week was a test period during which modifications in operating procedure were tried. After each week the boiler was taken out of service and the turbidity measured while the boiler was being blown down.

A graphic log of a typical shutdown is shown in Fig. 3. The various observations and measurements are plotted against time.

The rate of reduction in load and pressure is shown in the lowermost graphs with notation of various operations. The

boiler had been in operation approximately 1 week using the *B* and *C* circulating pumps.

The dissolved hydrogen in feedwater and steam are plotted only up to the time that reduction in pressure occurs. The readings beyond that time had no significance as the flow of sample was too much reduced. The slight rise in hydrogen as the steam flow is reduced is characteristic of most of the shutdowns and may be due to the increased concentration of hydrogen with reduced flow of steam.

The reduction in concentration of chloride and sulphate is the result of increased rate of blowdown and is a measure of the dilution of boiler water with the increase in feedwater rate.

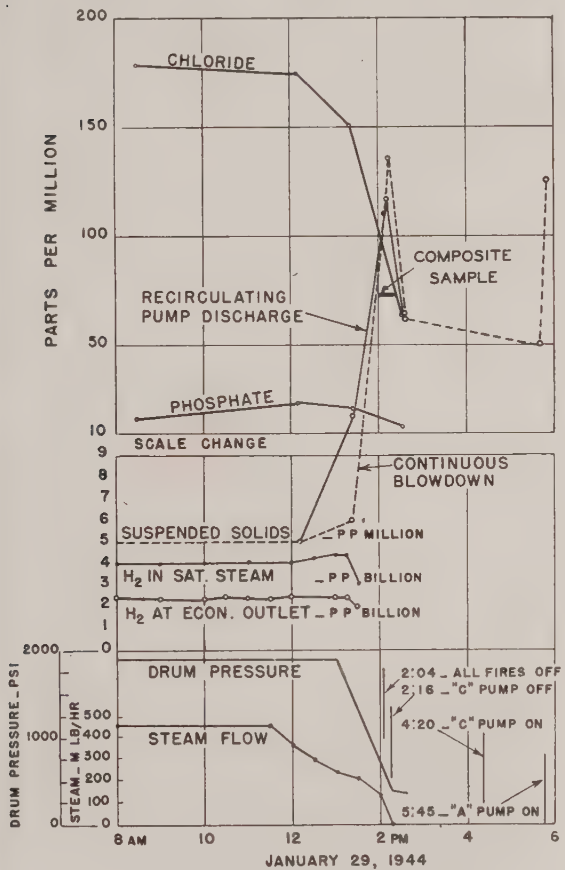

FIG. 3 LOG OF A TYPICAL BOILER SHUTDOWN

The phosphate does not show a corresponding reduction in concentration, indicating a slight "hideout" of that chemical. When corrected for dilution, a recovery of about 1 lb of phosphate as PO_4 is indicated. There is also a slight increase in the silica content of the water.

There are two graphs for boiler-water turbidity, one based on samples taken at the boiler blowdown, the other on samples taken at the discharge of the circulating pumps. While there is good agreement in the two sets of samples, the latter are regarded as the more accurate as the sampling lines were much shorter. The turbidity rose sharply to a maximum value of 135 ppm at the time the fire was extinguished, then decreased to 50 ppm by 5:40 pm. At that time the *A* circulating pump which had been out of service for a week was started. The increase in turbidity from 50 to 125 ppm was caused by the sludge that had settled out on the valves at the pump. As the water content of the boiler under nonsteaming conditions is about 50,000 lb, this increase in turbidity corresponds to $3^1/_2$ lb of sludge.

The composite sample taken over a 20-min period at the time indicated in the graph was assumed to represent the maximum sludge brought into suspension. The peak turbidity was of short duration and the sludge was probably not thoroughly distributed in the mass of the boiler water.

The shutdown procedure, as indicated on this chart, was established for the shutdown of January 29 and was followed as closely as possible on all subsequent tests.

The results of the turbidity measurements for January, February, and March, 1944, have been plotted in the lower graphs of Fig. 2 using, with the exception of January 22, the results of the composite samples. On the January 22 shutdown no composite sample was taken and the point indicated off scale was that of the maximum turbidity sample.

As may be noted, there is a decrease with time in the amount of sludge stirred up at shutdown periods. The high turbidity of the January 22 samples, which represented a full-pressure operating period of about 2 weeks, may be attributed at least in part to the effect of the acid wash. The gradual reduction in sludge over the 3-month period was principally the result of a closer control of condenser leakage and evaporator carry-over. Subsequent to this period of operation, sludge-collecting chambers were installed between the ends of the rear-waterwall inlet header and the side-wall inlet headers and also a sludge blowdown pipe was installed at the bottom of the main boiler drum. These were blown down once a week and the accumulated sludge thus removed during operation.

Period 1 (d): Gases in Steam. The study under this item was in greater part unrelated to the work covered in this report. A portion of the program, however, was a measurement of the gases in feedwater and steam and the results afforded an independent check on the hydrogen, indicated by the recorders. Samples of water and steam were passed through a special degasifier and the gases removed were accumulated until the quantity was sufficient for analysis by a modified Orsat apparatus. The results of these determinations indicated hydrogen values of the same order as those shown by the recording instruments. The readings of the dissolved-oxygen recorder were also checked using a modification of the Winkler test.

Period 2: Hydrogen, Iron, and pH. The work covered by this period was carried on during the interval, October, 1944, to April, 1945, after two additional hydrogen recorders had been acquired. The two original recorders had been set up permanently to sample the feedwater entering the economizer, and the steam leaving the desuperheater. One of the new recorders was set up at the hotwell-pump discharge, and the second one was arranged so that it could be moved to various locations along the line of feedwater flow.

The pH of the water was measured at the sampling points and samples were taken for the determination of iron. The pH was measured by an electrometric meter using a flow cell located at the point of sampling. It was found to be essential in the measurement of pH of water of high purity that the samples be not exposed to the air. Large errors may result from absorption and possibly the release of gases. Water samples of 1 liter were taken in hourly increments for the iron determination. A laboratory sample of 500 ml was evaporated to dryness in a dust-free atmosphere, then taken up with 1 ml of hydrochloric acid and diluted to 50 ml. The iron was determined by a colorimetric method using a photoelectric colorimeter.

In the determination of these very small quantities of iron

extreme care was necessary to avoid contamination of the samples. For this reason the samples were not filtered as this operation would involve a hazard of contamination through exposure to the air. Although the samples were all crystal-clear, occasionally one would show an inordinately high iron content, and it was suspected that an unnoticed particle of sludge had been included. In such cases the result was discarded.

The results of a number of tests are shown in the graphs in Fig. 4. Various conditions of load and pressure are represented. The values for dissolved hydrogen, pH, and iron are plotted for the various sampling points. The plotted points represent the average of daily samples taken over a 6- to 8-day period. It was not possible to take samples from all points during any one test period and usually 6 points were selected for each test. The selection was varied for different tests so that samples at all points were obtained during the course of the study.

For the study of hydrogen the plan was to have one meter stationed at the hot well and to advance the second one successively to stations along the line of flow. The hot-well sample consistently showed zero hydrogen throughout the study. No hydrogen was found at the deaerator outlet or the 10th-stage-heater outlet. Sporadic readings of low values were obtained at the discharge of the low-pressure boiler feed pump. From this point on there was a gradual increase in the quantity of dissolved hydrogen along the path of flow to the maximum values shown for the superheated steam. This study shows that all of the hydrogen which appears in the boiler feedwater originates in the feedwater system. The hydrogen in the steam is removed

in the condenser and none is recirculated to the feedwater.

The pH value of the samples varied over a relatively narrow range during this series of tests. The pH values at the hot well were between 8.3 and 8.6. There was a reduction in the deaerator due to removal of gases, apparently NH_3. The rise in pH at the extraction heater is ascribed to the effect of the treatment chemicals that are introduced ahead of that point, although it may be due in part to vapor from the evaporators which is introduced into the deaerator.

The values for the iron content of the water at the various sampling points are given in the upper group of points. The points of each test are connected by lines to form curves only the better to identify the several points of the test. While there is wide divergence in values, particularly at the economizer inlet, the points of each test form the same general pattern. No relation is evident between the iron content of the water and changes in pressure and boiler load. It may be concluded only that iron and dissolved hydrogen increase together. If we may be permitted to use the average of the rather scattered points for iron values at the economizer inlet, it may be pointed out that this average value corresponds closely to the amount of hydrogen in the superheated steam. From the equations given earlier, of the probable reactions for the dissolution of iron, one part per billion of hydrogen is the equivalent of 0.021 ppm of iron. The average hydrogen of the steam is 3.3 ppb corresponding to 0.069 ppm of iron. The average of the economizer feedwater is 0.079 ppm iron. There is as close an agreement as could be expected.

The miscellaneous projects listed under Period 3 represent work done at various times during the course of the investigation.

Period 3 (a): Copper in Feedwater. The measurement of copper in the feedwater was made because of the presence of that element in all deposits found in the boiler. As the condensers were suspected of being the principal source of contamination from copper, the study was limited to this equipment. Samples of condensed steam from the 15th-stage-heater drips were taken as representative of steam delivered to the condenser and a sample was taken at the discharge of the hot-well pumps for comparison. Samples were also taken of water leaving the deaerator and saturated steam leaving the boiler.

The analysis was made on 500-ml samples evaporated to dryness in the same manner as for iron. The determination of copper was by a colorimetric method. As there was a question of possible contamination of the samples by the use of copper cooling coils, a comparison was made between copper and monel coils and between copper and stainless-steel coils. There was no indication of contamination from the copper coils and in fact the very small differences in copper content of the samples from the three coils favored the copper coils. The sample reported is that taken with the stainless-steel coil.

The results of the series of tests are given in Table 4. Daily results for a 5-day period are given with the average for this period and the average for two similar periods. While the amounts of copper reported are quite small, there is a consistent increase across the condenser. The indication of copper in the condensed-steam sample is rather surprising. These samples were condensed in a monel coil, and there is a possibility of contamination from that source. The comparative tests of monel and steel coils at the deaerator outlet where the sample was cooled only in the coil cannot be taken as assurance that there is no contamination under condensing conditions.

It should be noted that there are other possible sources of copper contamination than the condenser that were not investigated. These are the 10th stage heater and low-pressure pumps having bronze impellers. There are also steam-air heaters in the coal-preparation house, the drips from which are returned to the feedwater system.

Period 3 (b): Bead and Ion-Exchange Columns. The plating out of iron-rich deposits on conductivity cells, glass tubing, and rubber tubing through which samples of feedwater and steam were drawn has been observed in a number of plants.

At the Somerset Station attention was first called to this phenomenon by the necessity of cleaning the conductivity cells and their glass containers at least once a week. It was first assumed that the deposit was a result of oxidation of a ferrous salt and the deposition of the more insoluble ferric compound. The cell and thermometer were inserted in the container through a rubber stopper, not necessarily an airtight seal. It was, however, noted that the glass and rubber connections between the cooling coil and the cell, where there was little possibility of air leakage, were also coated with a similar deposit.

This deposit was easily removed by washing with dilute hydrochloric acid. Usually a slight to strong odor of hydrogen sulphide was noted when the cell on the steam sample was washed.

In order further to study this plating-out effect, bead columns were made up consisting of $^1/_2$-in-ID pyrex tubing packed with $^1/_8$-in. soda-glass beads. These were set up at sampling points so that a sample could be drawn through them slowly and at a measured rate. The sample stream was arranged to flow across the top of the column into a spill tube, and the sample to the column was drawn from this stream. There was thus no syphon effect and the pressure at the connections was always above atmospheric. The rate of flow was adjusted to 1 liter per hr, and the tests were continued until 25 liters were drawn through the column. The effluent was measured in 10-liter graduated bottles.

A synthetic-resin ion-exchange column, operating on the hydrogen cycle, was prepared and tested together with the bead column. It had substantially the same dimensions as the bead column and took a sample from the same stream and at the same rate of flow. The purpose of the test was to determine the possibility of the quantitative removal of small amounts of dissolved salts and their recovery in the column wash in more concentrated solution. If successful, this method could be used instead of the usual one involving the evaporation of large samples, except, of course, where the determination of silica is involved. The exchange medium used was an analytical grade of a commercial product.

Daily samples were taken of the influent and analyzed for iron. Electrical conductivity and pH were measured for both influent and effluent. At the end of the sampling period the deposit in the bead column was dissolved with dilute hydrochloric acid, and the total solids as chlorides weighed. Iron and copper were determined in the residue. The ion exchange column was regenerated with dilute hydrochloric acid followed by a rinse with distilled water, and the extracted solids were recovered. Total solids as chlorides, iron, and copper were determined.

The results of two tests, one on a sample from the deaerating heater and the other on a sample from the extraction heater are given in Table 5. The ion exchange column is designated by the letter A and the bead column by B. The columns were in operation for 8 hr daily for a period of 3 days. Based upon the inlet and outlet samples, the recovery of iron on test 1 was 100 per cent for the A and 50 per cent for the B column. The actual recovery by extraction of the columns was 63 per cent for A and 25 per cent for B. It was found that the extraction of the ion-exchange bed was incomplete, and in the second test the acid strength was increased with resulting better recovery.

The recovery of iron for test 2 on the basis of inlet and outlet samples was 69 per cent for the A column and 39 per cent for the B column, compared with 99 per cent and 39 per cent, respectively, by extraction. The values by extraction are believed to be more nearly correct as at the higher concentration a greater accuracy of analysis is possible.

It will be noted that both conductivity and pH are reduced by the bead column which might indicate that the iron removed is in the form of ferrous hydroxide. The changes in conductivity and pH across the ion exchange column are what would be expected. When the positive ions are retained in the ion exchange process an equivalent amount of acid is produced.

The principle involved in the plating-out effect exemplified in the bead column is not known but is believed to be a surface-adsorption effect. Iron appearing in the deposit is in the form of ferric oxide; hydrated ferric oxide and magnetite. Silica also is present, its source probably being the soft glass beads. It is probable that the silica in the deposit is incidental and is not involved in any reaction with the iron. The iron deposits occur in pyrex tubing, rubber tubing, and on the inner surfaces of the various cooling coils. The entire feedwater system is undoubtedly lined with this deposit and probably much of the iron de-

posits noted in the boiler tubes may be accounted for by this property of plating-out on all surfaces.

The concentration of salt cations by means of the ion-exchange column did not work out well, principally because it was difficult to make a complete extraction of the retained material, and particularly the iron. While the residue remaining in the bed after regeneration was very small, even when the conventional wash was used, it represented a relatively large percentage of the total. This objection could be met by using a larger sample so that the unextracted portion would be negligible. The actual capacity of the bed was in only very small fraction realized by the 25-liter sample used. It is believed that this method of concentration of sample has promise and should be further explored.

Period 3 (*c*): *Tube-Temperature Measurement.* Tube-temperature measurements have been reported in another paper of this group. One purpose of these measurements was to determine whether or not there was any progressive increase in tube temperature that might be ascribed to internal deposits. Daily readings of temperatures of a group of tubes in the north wall gave no indication of appreciable internal deposits. The thermocouples were located at elevations of 5 to 25 ft above the hearth. A recent inspection following a tube failure at a 1-ft level, however, disclosed sludge deposits that would have been indicated by a couple at that elevation.

Period 3 (*d*): *Corrosion Detector.* In an attempt to obtain a quantitative check on the rate of solution of iron in the feedwater, a corrosion detector was installed in one branch of the boiler feed line leading to the economizer. This corrosion detector consisted of a short rod of carbon steel machined flat on two sides. It was mounted so that it could be removed without disturbing any of its original surface. This detector was recently examined after an exposure of 1 year. After being carefully cleaned in an ammonium-citrate solution, it was found to have lost 0.25 g of its original weight of 14 g. This loss if evenly distributed corresponds to 0.0001 in. penetration. There was, however, one small pit of about 0.005 in. depth. The surface was darkened and coated with a powdery film of what appeared to be an iron oxide. This corrosion detector was returned to its position in the feed line and will be again examined after a period of exposure.

The rate of metal loss, as indicated by the direct determination of iron content of the water and also by the measurement of the evolved hydrogen, is not large. Translated into inches penetration per year over the areas of the preboiler equipment and of the boiler itself, it would not be an impressive figure and would not lead to any great apprehension as to the imminent failure of any part of the equipment. There would, however, be cause for concern if the loss of metal were restricted to local areas such as has been noted in boiler feed pumps. While the hydrogen evolution appears to indicate a greater activity in the high-temperature end of the feedwater system, there is no evidence to indicate that localized attack occurs. It is, however, doubtful that loss of metal from erosion, such as may occur in feed pumps, is accompanied by the evolution of hydrogen.

The rate of loss of metal from the steam-side surface of the condenser tubes, as indicated by the measurements of dissolved copper, is extremely low. The loss on the cooling-water side is probably much greater, and also localized attack is known to occur. Failure of condenser tubes is more likely to occur as a result of attack on the outside, that is, the cooling-water side of the condenser.

One disquieting thing about the dissolution of iron and copper in the feedwater system is that the mechanism of the corrosion is not well understood, nor have preventative conditions been well established. It is generally agreed that dissolved ammonia is the principal factor in the corrosion of copper, and methods for the removal of this substance have been proposed. It is indicated that the dissolution of iron can be reduced by the control of pH. However, the permissible range of pH in the feedwater is limited by boiler-water conditions particularly when the rate of boiler-water blowdown is low.

The principal concern over the presence of iron and copper compounds in the boiler feedwater is caused by the propensity of these substances to form adherent sludges on the boiler surfaces. The iron is transformed probably completely to magnetic oxide and the copper is in large part at least reduced to the metallic state.

Slime deposits of sludge are found on all internal surfaces of the boiler and are often heavier on the unheated areas than on active steam-generating surfaces. It is indicated that this deposit is laid down mechanically, that is, there is no general chemical attack under sludge deposits. Small pits of pinpoint dimensions have been noted but are believed to be only incidental and not generally related to the deposits. While the sludge-collecting pots at the waterwall headers and a special sludge blowdown in the drum permit the removal during operation of accumulated sludge, they have not completely eliminated the hazard. The chief danger of the sludge deposit lies in its insulating effect on active steaming surfaces where it may build up to a thickness that results in overheating of the tube metal.

Basically the sludge problem in boilers results from the introduction into the boiler with the feedwater of solids or salts that form solids, at a higher rate than the rate of removal. Inevitably this must lead to trouble.

There are two obvious lines of attack on this problem: (*a*) to prevent or minimize the production of the metallic ions which are the principal components of the sludge in the feedwater system, and (*b*) to provide for a better continuous removal of sludge with the blowdown from the boiler.

The chances of complete solution of the problem by either or both of these efforts are not particularly promising and it is probable that a periodic cleaning of boilers will be necessary.

Apparatus and Methods

The hydrogen analyzer and recorder used in the investigation was a commercially available instrument utilizing the difference in thermal conductivity of gases. The analyzer consists of a Wheatstone bridge, two legs of which are formed by identical platinum-wire spirals. These spirals are electrically heated, a constant potential being applied. One of these spirals is surrounded by saturated air and the other by air that has bubbled through the sample which flows to the analyzer at a measured rate. Hydrogen of the sample is present in the latter air in proportion to its concentration in the sample. Because of the higher thermal conductivity of the air containing hydrogen, the temperature of the second spiral and hence its electrical resistance is reduced and the bridge is thrown out of balance. The balance is then restored automatically by a potentiometer which records the off-balance as hydrogen. At the usual low concentrations of hydrogen in feedwater the unit is parts per billion.

The principle of the dissolved-oxygen recorder is similar to that of the hydrogen recorder. Pure hydrogen which is generated electrolytically surrounds the reference spiral and hydrogen which scrubs the sample and has the equilibrium content of oxygen surrounds the analyzer spiral.

These instruments are extremely sensitive. Two parts of hydrogen in 10 billion parts of sample will give a scale deflection. It is necessary to check the zero of these instruments daily and it is desirable also to make frequent checks of the scale. This is done by introducing hydrogen to the sample at a measured rate. The hydrogen is made electrolytically and the rate of introduction of hydrogen is measured by current used.

While the meters are simple in principle, considerable attendance is required in order to assure their continuous accuracy.

The steam-sample evaporator is shown in Fig. 5. It consists essentially of a 5-liter flask having a tubulature extending downward with the open end in the evaporating dish in which the sample is being evaporated. The end of this tube is ground to a standard taper to which a platinum thimble is fitted. This thimble is weighed with the dish. As the water level in the dish recedes, the open end of the tube is uncovered allowing air to enter the flask and more water to flow into the dish. In starting the evaporator, the stopper is inserted at the end of the delivery tube and the measured sample, 3 to 4 liters, is poured in at the top opening. The cap with the manometer is then replaced and suction is applied to obtain an indication of about 1 in. on the manometer, and the stopcocks A and B are closed. The weighed dish is then placed in position on the heater assembly which is held on a ring stand below and to one side of the evaporator bell. The stopper is then removed and the heater and dish assembly quickly placed in the operating position. To do this without spilling the sample requires practice, and it is recommended that the operation be rehearsed with the flask empty until the necessary skill is acquired. The stopcock B is open during the evaporation.

The sample is evaporated without boiling, most of the heat being applied over the surface of the liquid. When the sample container is empty, the mercury switch closes and actuates a relay which shuts off the current to the heaters and closes the valve through which the air is admitted. There is enough residual heat in the heater and bell to complete the evaporation. At the end of the evaporation the flask is rinsed with a jet of distilled water and the washings added to the dish and evaporated. The rate of evaporation is about 200 ml per hr.

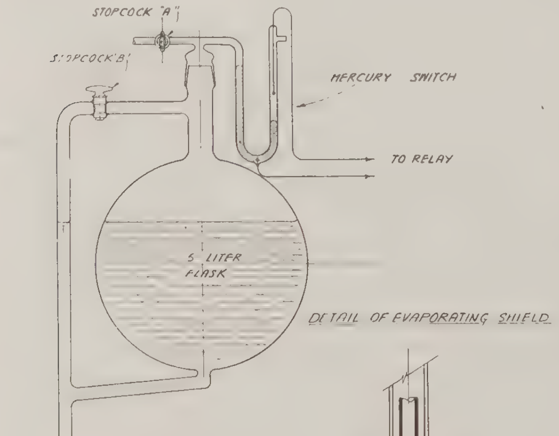

Fig. 5 Steam-Sample Evaporator

The sample concentrator for the determination of iron is shown in Fig. 6. It consists merely of a 1-liter Erlenmeyer flask covered with a vented hood through which filtered air is blown. A 500-ml sample is evaporated to dryness without boiling in about 4 hr. The residue is then taken up in 1 ml of concentrated acid and diluted to 50 ml for analysis.

Most of the analyses were made by a colorimetric method using thiocyanate. Measurement of color was by means of a photoelectric colorimeter. A second method using orthophenanthrolene was tried and although it proved more sensitive, it also required concentration of the sample and the simpler thiocyanate method was preferred.

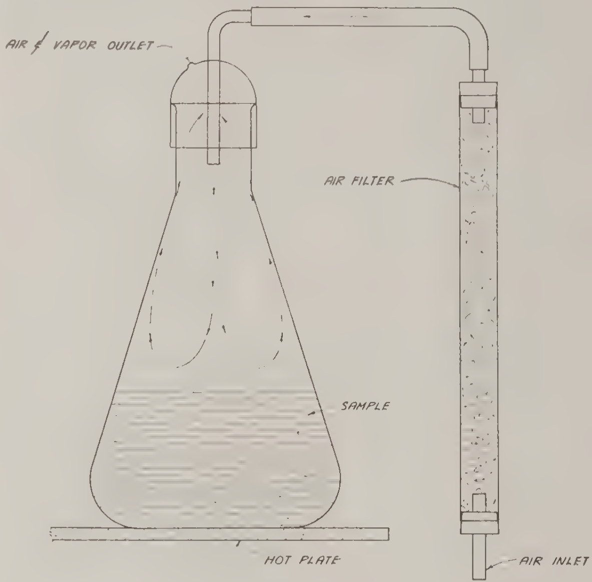

Fig. 6 Sample Concentrator for Determination of Iron

Extreme care is necessary to prevent contamination of the samples. It was found that if a sample was stored even for a day an appreciable amount of iron was lost because of the plating-out effect on the walls of the flask. To reduce the error due to the plating-out tendency, a small measured amount of acid and an organic reducing agent were placed in the flask in which the sample was collected, and the storage time was reduced to a minimum. Any iron present in reagents was corrected by means of blank samples.

Samples for copper determinations were prepared in the same apparatus used in the iron analysis. A colorimetric method using sodium diethyl-dithio carbamate in alkaline solution was used. This method was generally very satisfactory. In a very few instances an interfering turbidity resulted and it was necessary to extract the color with an organic solvent.

The bead-column and the ion-exchange-column arrangements are shown in Fig. 7. The columns were set up at the point of sampling. The sample flow was arranged so that a constant head was provided and also so that all connections were under pressure and no air would be drawn into the columns. The rate of sample flow was 1 liter per hr, and the effluent was collected in calibrated bottles so that the total flow could be measured.

At the end of a sampling period the assembly was taken to the laboratory where the extracts were removed by acid treatment and the columns prepared for another run. A 10 per cent

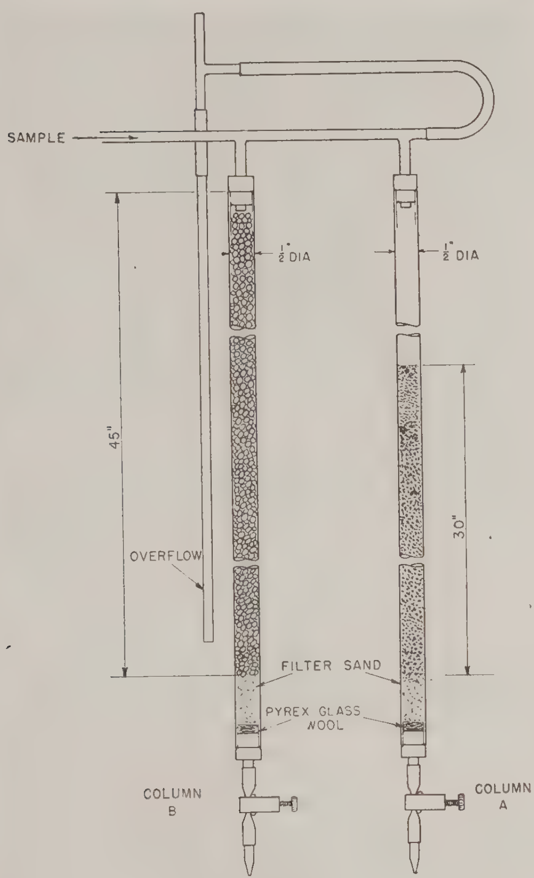

Fig. 7 Bead Column and Ion Exchange Column Arrangements

hydrochloric acid, 300 ml in amount, was used in regeneration of the ion exchange column, followed by a 300-ml water wash. Distilled water that had previously been passed through the bed was used for the wash water.

The 600-ml recovery sample was reduced to 500 ml for convenience and analyses were made on aliquot portions. Colorimetric methods previously described were used for the iron and copper determinations.

Discussion

R. C. Corey.[4] The excellent experimental data presented by the authors serve, among other things, to place one important phase of corrosion in high-temperature steam cycles on a factual basis, and those concerned with iron-oxide sludges now have available something more substantial than opinion or, as is frequently the case, " . . . . ill-begotten equations supported by bad data;" as it is stated by Lewis and Randall.[5] The experimental work conducted by the authors to establish the source of iron oxide in boilers and the probable mechanism of its formation, by means of hydrogen and dissolved-iron surveys of the steam and water cycles, is unique to the extent that no published data from similar work are to be found elsewhere. In some respects, which will be mentioned later, their results confirm certain conclusions of laboratory and theoretical studies of the fundamental reactions between iron and pure water. To this end there is support of the contention that there are yet many more questions than there are answers to the problem of corrosion by pure water at elevated temperatures.

It is a curious fact that although one may find in corrosion literature data on the rate of corrosion of iron and steel in contact with almost every conceivable inorganic or organic material, under widely different conditions of independent variables, there are no published data on the rate of corrosion of iron and steel in pure water. A possible reason for this may lie in the fact that in pure water the rate of corrosion is insignificant compared to that in acids, bases, and certain salt solutions. It is obvious, however, from the results of the present paper and the current problem of feed-pump corrosion which appears to be related in some way to pure condensate, that there is a definite need for an investigation of the rate of corrosion of iron and steel in pure water up to around 600 F, and under various conditions of flow and pH.

Evaporated feedwater make-up and highly efficient steam-washing and deaerating equipment result in feedwater of extreme purity, and as so clearly expressed recently,[6] "It dissolves to some extent anything that it comes in contact with on its way from the condenser to the boiler. This dissolving action starts in the last stages of the turbine where the first condensation occurs." It may be asked what is meant by "pure" water. Qualitatively it may be defined as water which contains no dissolved gases and which produces no residue on evaporation. A quantitative definition for pure steam condensate might be based upon its electrical conductivity when there are no ions present other than hydrogen and hydroxyl ions resulting from the ionization of the water.

On the other hand, it is possible that the conductivity of pure water may not change after contact with an iron vessel, due to the formation of Fe_2O_3 or FeOOH which are insoluble. In such a case the buffer index might be a useful criterion for purity, this being defined as the differential ratio dB/d(pH), in which d(pH) is the increment of pH when an increment of base dB, in terms of gram equivalents of hydroxyl ion, is added. An increment of hydrogen ion would be equivalent to —dB. Thus pure condensate would have a buffer index of 0.1429, and if iron oxide were added this value would increase due to the fact that the oxide would react with added hydrogen ion.

The authors have shown clearly that in the subject plant most of the hydrogen and dissolved iron result from corrosion of external piping and heat-exchange equipment, a very small amount being due to corrosion within the boiler. They postulate that the ferrous hydroxide formed in the primary corrosion reaction decomposes to Fe_3O_4 and more hydrogen. There is experimental and theoretical work to support this. Schikorr[7] found that when iron turnings were placed in contact with pure water, pressures of 18 atm and higher of hydrogen developed, and Fe_3O_4 was formed. In later experiments he demonstrated that ferrous hydroxide spontaneously decomposed to hydrogen and Fe_3O_4 at a rate inversely proportional to the pH.[8] Investigation of the

reactions at room temperature between iron and pure water[9] demonstrated that Fe_3O_4, hydrogen, and about 0.2 ppm of dissolved ferrous iron were the final products, and the pH rose to 8.3. The dissolved iron was considered to be an intermediate stage in a chain of reactions,

$$Fe \rightarrow Fe^{++} \rightarrow Fe(OH)_2 \rightarrow Fe_3O_4$$

No attempt was made, however, to correlate the dissolved-iron concentration and pH because of (*a*) lack of information on the state of the dissolved iron, that is, whether it was colloidal or poorly ionized; (*b*) disagreement in the literature as to the solubility and the solubility product of $Fe(OH)_2$; and (*c*) inability to determine which of the foregoing reactions controlled the rate to the right. Thermodynamic calculations have shown[10] that iron reacts with oxygen-free water to form Fe_3O_4 more readily than $Fe(OH)_2$, although it is conceded possible that the latter may be an intermediate phase. Thus it is a necessary conclusion that $Fe(OH)_2$ will decompose to Fe_3O_4 and hydrogen.

All of these facts find confirmation in the results obtained by the authors if it is kept in mind that it is very unlikely that equilibrium between iron and condensate ever is attained in the short time of contact between the hot well and the boiler. Thus the relative amounts of Fe^{++}, $Fe(OH)_2$, Fe_3O_4, and H_2 may be expected to vary considerably from equilibrium values.

One question concerning these investigations with iron and pure water is whether the iron determinations represent only dissolved iron or varying mixtures of dissolved iron and an extremely finely divided form of magnetite.

In one of the afore-mentioned investigations,[9] there were indications that despite careful filtering a small amount of iron oxide, possibly of colloidal dimensions, occasionally contaminated the samples. This is merely a question of academic interest, related to the fundamental corrosion reaction, and therefore does not affect the results and conclusions of the authors.

It may be asked, why, if the rate of corrosion of iron and steel by pure water at elevated temperatures is insignificant when uniformly distributed throughout the system, it receives the attention it does in the present paper. The authors have very clearly resolved the problem in two parts: (1) There was the question whether the iron oxide originated in the boiler as the result of attack of steaming surfaces; and (2) the possibility that excessive deposits of iron oxide on steaming surfaces would lead to overheating due to a decrease in the over-all coefficient of heat transfer. In so far as the subject plant was concerned, it was demonstrated that the greater part of the iron oxide was carried into the boiler from external sources. This confirms the consensus of a number of operators. Regarding the ultimate effect of deposits of iron oxide on steaming surfaces, there is, in addition to the insulating effect, the possibility that boiler-water salts may concentrate in and beneath the oxide, and if sufficient free caustic is present localized, rapid attack may occur.[11]

Another factor that may be considered is the possibility that metallic copper, invariably associated with iron oxide in boilers, deposited on a baked-on sludge of iron oxide may set up an electrolytic cell, the tube metal being anodic, the copper cathodic, and the iron oxide between, serving as a porous matrix for salt-saturated liquid. This, of course, is hypothetical and until data are available on the emf between copper (or copper oxide) and iron, and on time-potential curves, which indicate whether anodic or cathodic polarization is controlling the rate of corrosion, this theory offers possibilities.

Thus as suggested by the authors, iron-oxide deposits in high-pressure boilers cannot be ignored, and if it has been established that excessive quantities of iron oxide are being carried into a boiler from outside sources, then steps should be taken to minimize corrosion in external equipment even though the rate is not sufficient to cause significant attack in such equipment itself. Theoretically attack can be minimized either by raising the pH of the feedwater or by applying a protective coating to the ferrous materials with which the feedwater comes in contact. Assuming, however, that there were no practical difficulties to the first of these steps, the fact remains that we do not know the optimum pH at which the feedwater should be maintained to minimize corrosion under operating conditions, because no investigation has been made of the rate of corrosion of steel under these conditions at various values of pH.

The data on hydrogen and iron throughout the system are extremely interesting. Regarding the increase in hydrogen across the economizer, not shown in Fig. 4 of the paper, it would be of interest to know what values were obtained at the economizer outlet and also the iron determinations, if available. If the iron and hydrogen did not increase together then it might be inferred that the increase in the hydrogen was the result of decomposition of ferrous hydroxide rather than corrosion in the economizer.

If the authors have made any conductivity determinations at the various sampling points, they would be a valuable supplement to the other data and may help to explain some questions of fundamental importance.

It was noted that the concentration of hydrogen in the steam did not vary with the load. This confirms experiments conducted by the American Gas & Electric Service Company at Logan, where the concentration was found to be constant at about 3 ppb between a steam output of 400,000 and 850,000 lb per hr.[12] The average concentration at Montaup was 3.3 ppb.

Regarding the results for dissolved iron, it is interesting to note that the iron in the steam was approximately the same as found in the hot well. It would be of interest if the authors described the method they adopted for determining the iron, that is, whether it was a modified thiocyanate, orthophenanthroline, or similar scheme.

At the present time little can be said about the manner of formation of metallic copper in the boiler or its effect with regard to corrosion. It has been stated[13] that the corrosion of copper or copper alloys by ammonia is negligible in the absence of oxygen. Relatively, this may be so but it appears that in oxygen-free condensate sufficient solubility, in the presence of less than 0.1 ppm NH_3, occurs to produce large amounts of copper in boilers. Dissolved carbon dioxide, either as free CO_2 or bicarbonate ion, also is a factor in the corrosion of copper.

The corrosion detector, installed in one branch of the boiler feed line leading to the economizer, offers excellent possibilities for determining, under actual operating conditions, the rate of corrosion of low-carbon steel. It is suggested, however, that it is not advisable to re-use the specimen for a subsequent test, more acceptable results being obtainable if new specimens are used for each test. Also, if possible, it would be desirable to install an identical specimen in a location where the temperature and pH of the liquid are the same but of different velocity.

[13] "The Reaction of Copper and Oxygen-Saturated Ammonium Hydroxide," by R. W. Lane and H. J. McDonald, *Journal of Corrosion*, Aug., 1945, pp. 1–8.

The experiments with bead columns to study the effectiveness of various materials in removing small amounts of solids from water are of considerable interest, particularly with regard to the comparative efficiency of the glass and the synthetic resin.

The authors suggest that silica is not involved in the action between the glass beads and iron-bearing water. The writer submits that in experiments with pure water and iron in pyrex vessels there seemed definitely to be reaction of dissolved iron with the glass. The pH of the water rose to 9.0–9.5 and a flaky anisotropic material formed which microchemical tests showed to contain iron and silicon; possibly being a hydrated iron silicate.

In conclusion, it is believed that this investigation has emphasized the need for more fundamental work on the reactions of iron with pure water. A program for such an investigation might be as follows:

1 Determination of the rate of corrosion of iron and steel in water as a function of pH, velocity, and temperature, up to 600 F.

2 Study of the time-potential curves for iron under the same conditions as item 1.

3 Preparation of pure ferrous hydroxide and determination of the following:

(a) Its solubility and pH in pure water.

(b) Rate of decomposition to Fe_3O_4 and H_2 as a function of temperature and pH.

The results of such an investigation should, among other things, determine the minimum pH of feedwater required to effect maximum protection of steel surfaces, at various temperatures related to operation.

E. R. Mueller.[14] Of interest primarily to chemists rather than engineers is the reference given in the subject paper to the use of an ion-exchange material as a tool in the analysis of feedwater or steam samples. The application discussed is a clear-cut example of the manner in which the analytical grade Amberlite resins can be used as analytical tools. The investigators are taking advantage of the unique properties of these resinous exchangers, in this case, the cation exchanger, one such property being the complete adsorption of heavy metal ions such as iron, copper, etc.

It has been stated in the paper that dilute hydrochloric acid was first employed with incomplete recovery of the full metal content from the exchanger. Although the concentration was not indicated in the paper, this was pointed out to be 5 per cent. By the use of 10 per cent acid, the higher concentration referred to in the paper, better results were obtained. It is suggested that in both cases more complete recovery of the metal ions from the exchanger could have been accomplished by the recycling of a relatively small but adequate portion of either concentration of acid. This technique would have the added advantage of keeping the eluting solution at the smallest possible volume, thereby reducing the time required later for evaporation.

Since the resinous exchanger is entirely organic in composition, it is suggested that the analytical technique might be improved upon by wet-ashing the entire sample of exchanger upon which the metal ions have been adsorbed. This would eliminate the elution step altogether, thereby insuring the analyst against an error in the results brought about by incomplete elution of the metal ions.

In general, the particular problem represents an unusual application of the properties of ion-exchange resins.

[14] The Resinous Products & Chemical Company, Philadelphia, Pa.

W. F. Ryan.[15] A becoming but regrettable modesty has restrained the authors of this paper from acclaiming the outstanding achievement of their part of the investigations at Montaup. The statement "recording hydrogen meters were set up" is a masterpiece of condensation. The "setting up" of these meters required many weeks of painstaking engineering, involving a degree of scientific knowledge, technical skill, patience and determination more readily associated with the instrumentation of the atomic-bomb project than of a steam boiler. Perhaps Mr. White can be persuaded at a later date to publish in detail this story of measuring hydrogen in fractions of a part per billion under the pressure and temperature conditions prevailing in this station, and securing accurate and continuous records, in spite of the difficulty in maintaining reasonable equilibrium between the fluids being analyzed and the metals which contained them.

The hydrogen-meter installation was expensive not only in money but in engineering manpower, and there were many discouraging periods during which the patience of operators and contractor's representatives was sorely tried, and many of us would cheerfully have thrown the project overboard. Fortunately, however, the work was carried to successful completion, and the importance of the results well repaid the time and effort expended.

The boiler, presumably in common with all boilers working at elevated temperatures, is subject to continuous, but infinitesimal, widely distributed, and therefore substantially harmless, oxidation. It may also be subject, at irregular and unpredictable intervals, to intensified localized oxidation. When the meter shows a sudden or abnormal evolution of hydrogen in the boiler it is a clear indication that such oxidation is taking place; the meter is raising a danger signal as significant as low water in a gage glass and calls for equally prompt and vigorous action.

We are feeding all of the high-pressure boilers in the country with water contaminated by oxides. The deleterious effects may not be serious in some instances but it is not of record that it ever did a boiler any good. We are now groping in the dark to combat, in the boiler, a contaminant which should never have been allowed to enter it, and there have been widespread difficulties with boiler feed pumps and high-pressure heaters that are all a part of the general problem. Mastery of the hydrogen-meter technique offers an opportunity at least to locate the source or sources of the trouble. It is hoped that some utility or combination of utilities may sense the importance of this possibility and undertake to measure hydrogen evolution throughout a high-temperature cycle from the superheater outlet to the condenser and back again through the feed heaters, feed pumps, economizer, boiler, and superheater. When this work is undertaken, the project will be greatly facilitated by the solution at Montaup of the many and difficult technical problems involved.

T. J. Finnegan.[16] The record of hydrogen throughout the cycle given in this paper by Bissell, Cross, and White adds confirmation to the opinion held by many persons that much of the loose black-oxide sludge in the boiler is of external origin. They do not accept the theory voiced by some extremists that none of the black oxide is formed in the boiler, except perhaps where overheating occurs. They support their opinion by the implied acceptance of the two equations which would explain the formation of hydrogen by decomposition of $Fe(OH)_2$ rather than by direct attack of the metal. In other words, they admit the possibility that the fundamental corrosion reaction

[15] Assistant Engineering Manager, Stone & Webster Engineering Corporation, Boston, Mass. Fellow A.S.M.E.

[16] Chemical Engineer, Buffalo, Niagara Electric Corporation, Buffalo, N. Y. Mem. A.S.M.E.

$$3Fe + 4H_2O = Fe_3O_4 + 4H_2$$

might occur in two steps, the velocity of which is strongly influenced by temperature.

While it is almost certain that the fundamental reaction is a chain one, it has yet to be established that the separate steps of the chain can occur at a delayed rate. For example, it is easily shown that when iron is placed in oxygen-free water at room temperature the products are loose Fe_3O_4 and hydrogen. Whether or not a large amount of $Fe(OH)_2$ may be mixed with the Fe_3O_4 and have potentiality for decomposing at higher temperatures is an interesting question.

Theoretical speculations of this sort as well as those referring to the reaction of copper given in the comment on the limitations of the hydrogen recorder in the paper by Bissell and Powell[17] make one admire the attempts which are made to give a rational explanation to the observed phenomenon, but they also emphasize the need for more fundamental work on the pure chemistry of the water-metal systems. We are continually being confronted with the results of chemical reactions, the nature of which we do not understand because they have not been thoroughly studied, especially over extended ranges of temperature.

An investigation made some years ago showed that the products of the reaction of iron with oxygen-free water at room temperature are hydrogen and Fe_3O_4.[18] The oxide did not form a protective coating but settled as a loose powder on the bottom of the reaction vessel. This investigation was made in a power-company laboratory which was not equipped for carrying out the obvious extension of the work, and it would be interesting if some research organization would repeat the experiments and continue them into higher-temperature regions, with particular attention to the matter of protective coatings, the existence of $Fe(OH)_2$, and to any factors which tend to limit the reaction.

Authors' Closure

The authors appreciate Mr. Corey's very carefully prepared discussion. His observations on the possible reactions that may take place in the feedwater system emphasize the need for further work on that subject. While no quantitative data were obtained, there is evidence that iron in the feedwater at the Somerset Station occurs both in colloidal and dissolved states. The iron is reported as total iron as the samples were evaporated to dryness and the residues were taken up with acid. In some samples where the iron content was high enough to be determined without concentration of the sample, lower values for iron were obtained on the sample before evaporation than on an evaporated sample. When the sample was acidified and heated increasing values for iron were obtained with increasing time of digestion.

[18] "pH, Dissolved Iron Concentration and Solid Product Resulting From Reaction Between Iron and Pure Water at Room Temperature," by R. C. Corey and T. J. Finnegan, Proceedings of the A.S.T.M., vol. 39, 1939, p. 1242.

There is also evidence that much of the iron is in the ferrous state. For example, in bead column tests a heavier deposit is obtained when the sample is aerated. The deposit is also of a deeper red color.

Mr. Corey suggests that there may have been a reaction between the glass of the beads and the iron in the water. Our conclusion that the silica was only incidental was based on the fact that the same type of deposit occurred in rubber-tube connections and also in the copper tubes of the cooling coils. This, of course, does not preclude the possibility that an iron-silica reaction does take place—the source of the silica being other than the glass.

While the hydrogen content of the steam is reasonably constant in the record shown in Fig. 2, the variation in rating is not large. There is, however, a definite trend of increase in hydrogen concentration with decrease in load. This may be noted in the hydrogen curves of Fig. 4 and also in Fig. 3. The change in the hydrogen values is not large and is sometimes masked by other unexplained variations.

As reported in the paper the corrosion indicator was removed for weighing at the end of one year and was at once restored to service in the pipe line. A duplicate corrosion indicator of carbon steel was machined, however, and was installed in October, 1945, in place of the original one, just as Mr. Corey has proposed.

His suggestion is that an additional corrosion indicator be installed where it would be exposed to identical conditions except for velocity would yield informative data. Because of daily and seasonal variations in boiler load, however, the present indicator is exposed to appreciable changes in velocity, and under existing conditions it appears impracticable to select a second location where the feedwater velocity would remain in approximately constant ratio to that at the existing corrosion indicator.

The valuable suggestions of Mr. Mueller are appreciated. The advantages of the ion exchange method of sample concentration are many and the results so far are encouraging. The alternate method of evaporation is laborious and time-consuming and it requires a very careful technique for its successful application.

The authors are gratified by Mr. Ryan's very kind discussion and appreciate his comments on the broader significance of the investigation.

The authors must agree with Mr. Finnegan that in what little experimental work has been done on the reactions of water and iron, there is little or no evidence of ferrous hydroxide in the corrosion products. The experiments, however, have been conducted under conditions such that chemical equilibrium was established. It is doubtful that such equilibrium could be attained in the feedwater system at the Somerset Station.

Recent analyses of bead-column deposits indicate that 50 to 70 per cent of the iron is in the ferrous state. The work is being continued and the feedwater system will be explored for the ferrous ferric ratio. There is no question but that the final product is Fe_3O_4. Under nonequilibrium conditions the ratio of ferrous to ferric iron should depend upon the relative reaction rates of the formation and decomposition of ferrous hydroxide.

Water Conditioning for the 2000-Psi Boiler at the Somerset Station of Montaup Electric Company

By W. W. CERNA[1] and R. K. SCOTT[1]

Considerable interest has been aroused in the chemical treatment used for the high-pressure boiler at the Somerset Station of the Montaup Electric Company. The theoretical aspects of the present treatment, which has been in use since January 1, 1944, are given in a paper by Hall.[2] Details of the results obtained with the different types of treatment used on this boiler have been given in a paper by Parks.[3] It is largely the purpose of this paper to present the reasons for the various methods of chemical treatment which have been used, and for the changes made, which have resulted in stabilization of the boiler-water conditioning since January 1, 1944.

Period of Sodium Treatment

When the high-pressure boiler of the Somerset Station first went into operation in the summer of 1942, a fairly standard treatment, using sodium chemicals, was used with the following control limits:

Alkalinity as sodium hydroxide, NaOH, ppm	50–60
Sodium phosphate, Na_3PO_4, ppm	50–70
Total solids, ppm (max)	1000

Some months later it was also decided to feed and maintain a positive reserve of sodium sulphite in the boiler water. During the period this treatment was used several tube failures occurred, as discussed in a previous paper of this series by Parks, Patterson, and Ryan.[4] Internal boiler conditions were also found unsatisfactory as described in the reference paper by Parks.[3] Evidence of the "hide-out" of sodium sulphate and sodium phosphate was also found which indicated that some of the boiler water was being concentrated very much beyond the limits of the normal over-all boiler water.

For example, using the published data of Schroeder, Berk, and Gabriel[5] for the solubility equilibria of sodium sulphate and sodium phosphate at boiler temperatures, a boiler water at 595 F, containing 350 ppm of sodium sulphate (Na_2SO_4) and 70 ppm of trisodium phosphate (Na_3PO_4) representative of that in the Montaup boiler at the time, would have to concentrate about 185 times before the first deposition of these substances would commence. Neglecting the effect of the sodium hydroxide on the solubility equilibria, which would actually be in the direction of increasing the number of concentrations, no deposition of sodium sulphate or sodium phosphate from the boiler water would be possible until the concentration of sodium hydroxide had likewise increased 185 times. If the initial concentration were 60 ppm of sodium hydroxide, the water just about to lay down solid sodium sulphate and sodium phosphate at the evaporative surface would necessarily contain 11,000 ppm of sodium hydroxide or a 1.1 per cent solution of NaOH. Thus it is apparent that in establishing the water conditioning for such high-pressure boilers, it is necessary to think in terms of the concentrated films, and not merely of the over-all boiler-water analysis, such as represented by the analysis of a representative sample taken from the boiler.

In so far as the over-all boiler water was concerned we had protective conditions. But the change which could occur on concentrating the boiler water from 60 ppm NaOH to 11,000 ppm NaOH is well illustrated by the curve in Fig. 1, originally developed by Partridge and Hall[6] from the experimental data of Berl and van Taack.[7] With 60 ppm caustic soda, the concentration is in the region of the most protective-to-iron zone. At 11,000 ppm NaOH (275 epm), the rate of attack found by Berl and van Taack on steel powder at 590 F was as great as in an acid solution containing about 25 ppm, HCl (0.7 epm).

The 11,000-ppm caustic-soda solution may seem fancifully high and difficult to attain. Actually, this is not the case. Dissolved substances lower the vapor pressure of a solution at any definite temperature. Correspondingly, under an externally applied temperature increase, the concentration of dissolved solids in a film of boiler water must necessarily increase to maintain constant pressure. As the terms Δt and Δts will be used frequently in this paper, a graphic representation of the meaning of the terms is given in Fig. 2 which consists simply of the vapor pressure-temperature curves of water and a saturated solution of potassium chloride. The Δt is the difference between the temperature of the concentrating film at the heat-transfer surface and the boiling temperature of pure water at the same pressure. The Δts is the Δt which corresponds to the existence of a saturated solution. If Δt is increased beyond this point, a solo solution will evaporate to dryness. Thus from Fig. 2, the film temperature can exceed the over-all boiler-water temperature at 1950 psia by about 140 deg F before potassium chloride will go to dryness in solo solution. At lower film temperature or Δt

differential, the film boiler water will simply concentrate to keep its vapor pressure the same as that of the over-all boiler water. If the film temperature or Δt exceeds 140 F the water will evaporate from the solution leaving a dry residue of potassium chloride.

Fig. 3 shows the caustic-soda concentrations produced in solo solution by various Δt values. How much Δt would be required to produce the 11,000 ppm NaOH concentration? The answer is only a little more than 1 deg F. With a Δt of 5 deg F the film concentration would be about 45,000 ppm (1125 epm) NaOH, with corrosive action (from Fig. 1) at relatively the same rate as an acid solution of about 300 ppm (8 epm) HCl.

That such small or even larger increases in film temperatures can result in a high-pressure boiler is hardly to be denied. Fortunately, for the most part such concentrated films are not continuous, but when they are, failure soon results. However, even with relatively good circulation such small increases in film temperature, or Δt, and concentrated solutions if soluble solids are present, can occur for at least short periods of time. Examples of such periods would be occasions when the slag falls off of a section of waterwall, exposing the tubes to higher temperature than the surrounding area which is insulated by the slag covering, or in certain tube sections immediately following soot blowing.

Obviously, in view of such factors, it becomes the duty of the water-conditioning engineer to think in terms not only of protective conditions for the over-all normal concentration of boiler water, but also in terms of maintaining the concentrating film as protective as possible.

Fortunately, by the time the need for improving boiler-water conditions at Montaup became apparent, considerable of the work developed in the paper by Hall[2] had already been made available. Therefore the boiler was cleaned of existing deposits by means of inhibited acid (Dowell) and a different treatment instituted.

Preliminary Potassium-Treating Period

The studies developed by Hall[2] indicated that while sodium silicate would "hide-out" and be scale-forming, the same was not true for potassium silicate as long as the silica-to-alkali ratio, in equivalents, was maintained at 1.6 or less, so that the highly soluble potassium metasilicate or disilicate would exist, even though considerable concentration due to film-boiling might occur. This made the maintenance of some silica in the boiler water, if it could be kept in the soluble form, desirable as a means of decreasing the amount of sodium-hydroxide concentration which could develop in a concentrating film. Furthermore, considerable magnesium phosphate had been found in various boiler deposits during the period of sodium treatment, and the maintenance of some silica in the boiler water would be advantageous for precipitating the magnesium as magnesium silicate, which has been proved to be the most desirable form of magnesium sludge in boiler water, with minimum tendency for the formation of adherent deposits. To obtain the advantage of these developments the boiler-water-conditioning control, started after the acid cleaning in April, 1943, was established as follows:

pH value	10.2–10.7
Phosphate (PO_4), ppm	30–50
Sulphite (SO_3), ppm	2–5
Silica (SiO_2), ppm	7–10
K to Na ratio, equivalents (min)	2:1
SiO_2 to alkalinity ratio, equivalents (max)	1.2:1

Inasmuch as the plant uses tidewater for cooling purposes, so that even small amounts of condenser leakage introduced considerable sodium in the boiler water, it was necessary to feed potassium chloride, in addition to the potassium phosphate, sulphite, and silicate, to maintain the desired potassium to sodium ratio.

A number of tests which were conducted after the boiler was returned to service with the use of potassium chemicals showed quite promising results. One of the most interesting features was the virtual elimination of sulphate and phosphate hide-out. The results of typical hide-out tests during the periods of sodium and potassium treatment, respectively, are shown in Fig. 4. The upper curves show the chloride concentrations as the load on the boiler was decreased. The lack of hide-out with potassium-treated boiler water contrasts sharply with the large amount of hide-out indicated by the sodium sulphate and sodium phosphate, obtained during the period of sodium treatment.

Several boiler inspections after relatively short runs, following the use of potassium chemicals, also showed promising results inasmuch as the boiler internals proved to be quite clean. Therefore the boiler was operated at full design pressure and the maximum load desired by the plant, generally between 550,000 and 600,000 lb of steam per hour.

A series of special tests were also made during this period which produced a number of interesting results. For example, it was found that in this boiler high-silica concentrations were unstable, and it was therefore inadvisable to try maintaining more than 10 ppm of silica in solution in the boiler water.

The work of Hitchens and Purssell[8] indicated that very little decomposition or auto-oxidation of sodium sulphite occurred up to a steam pressure of 1775 psi. However, in the Montaup boiler, considerable decomposition of sodium sulphite had been indicated whenever efforts were made to maintain more than a few ppm thereof in the boiler water. In this respect the potassium sulphite proved similar, and therefore the decision was made to maintain only a few ppm of sulphite in the boiler water, to serve primarily as an indicator of whether or not dissolved oxygen was entering the boiler with the feedwater.

[8] "The Behaviour of Sodium Sulphite in High-Pressure Steam Boilers," by R. M. Hitchens and J. W. Purssell, Jr., Trans. A.S.M.E., vol. 60, 1938, pp. 469–473.

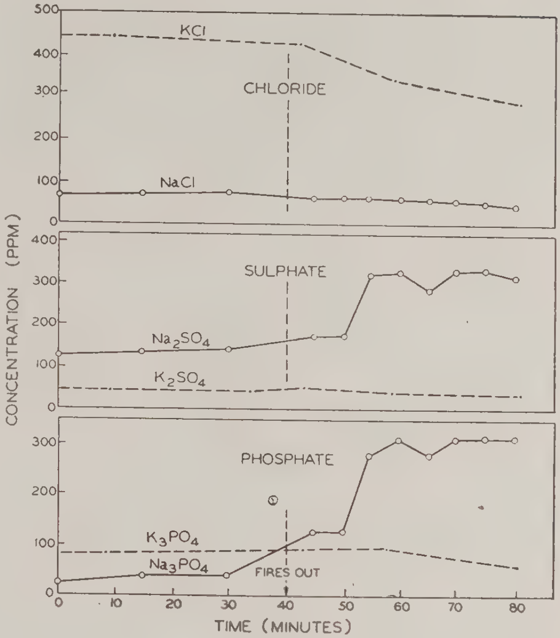

Fig. 4 Presence and Absence of Hide-Out With Na and K Salts

In December, 1943, No. 2 roof tube failed, apparently due to sludge accumulation in the rear-wall header around the strainer supplying the orifice which fed this particular tube. A number of tube sections were cut out at this time and considerable iron-oxide formation was found on the tubes, particularly on the fire side. Pickling some of the tube sections also disclosed a thin yellow ribbon of acmite, sodium iron silicate scale, on the fire side of a number of the tubes. Details of this are given in the reference paper by Parks[3] and need not be repeated here. It is perhaps noteworthy that during the period of potassium and silicate treatment the boiler had been operating at full design pressure and had generated considerably more steam with but one tube failure than it had during the period of sodium treatment during which three tube failures had occurred.

The boiler was again acid-washed by Dowell, using inhibited hydrochloric acid with some bifluoride added in order to remove the silicate scale as well as the iron-oxide formation. In order to eliminate further sludge accumulations at the ends of the rear header, arrangements were also made to interconnect each end of the rear-wall header with the adjacent side-wall header.

Potassium Treatment in Use Since January 1, 1944

In putting the boiler back on the line, it was decided to discontinue the feed of silica because of the slight but definite acmite formation which had been produced on the fire sides of a number of the tubes. It was also deemed advisable to continue with potassium boiler-water treatment because of the lack of hide-out when potassium chemicals were used in the boiler-water conditioning. Furthermore, a number of other plants which had substituted potassium chemicals in place of sodium chemicals for high-pressure-boiler water conditioning, had also found considerably less phosphate sludge in the boilers following this change

even though silica feed had not been used. This factor was also an influence in the decision to continue with potassium treatment.

Our laboratory has been doing considerable work with various solo solutions and mixtures of various salts in high-temperature bombs to determine the vapor pressures of the solutions at various temperatures and pressures. The results of a series of such tests are plotted in Fig. 5, from the data of Kaufman,

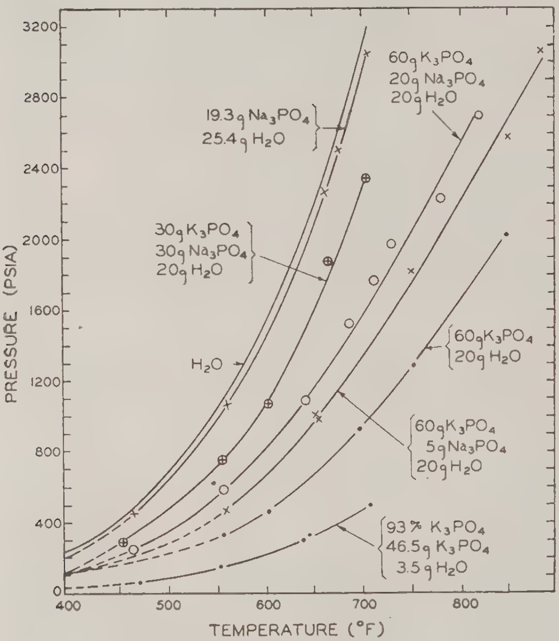

Fig. 5 Vapor Pressure of Sodium Phosphate, Potassium Phosphate, and Mixed Phosphate Solutions

Marcy, and Trautman.[9] These curves show why hide-out is readily obtained with sodium phosphate and not with potassium phosphate. For example, the Δt for sodium phosphate is only approximately 5 to 9 deg F for the entire temperature range from 400 to 3200 psia. Thus a film temperature of only 5 to 9 deg F above that of the main body of boiler water would be necessary to produce Δts, or a saturated solution. If the film temperature exceeds this, the solution will go to dryness, or, in this case, result in hide-out of sodium phosphate. With solo solutions of potassium phosphate, a Δt of several hundred degrees would be required before saturation and hide-out could occur. Mixtures of sodium and potassium phosphates show intermediate behavior, with an increasing Δts as the ratio of potassium to sodium is increased.

Fig. 6 shows the vapor pressures for a number of solo solutions compared to those of water at various temperatures. It will be noted from Fig. 6 that many of the sodium salts such as sodium phosphate, sodium sulphate, and sodium silicate have very low Δts values, or would go to dryness at a film boiler temperature of 10 deg or less in excess of the temperature of the saturated steam. A considerably larger Δts value is indicated for sodium chloride and even greater values are obtained for potassium chloride. As mentioned in connection with Fig. 5, the Δts of potassium phosphate is so large that it would seem almost impossible to obtain a film temperature sufficiently high to precipitate potassium phosphate out of solution unless actual overheating of a tube occurs to a considerable degree. With either sodium or potassium hydroxides, concentration of the solution occurs without going to dryness. In other words, in a boiler, or in a water-hydroxide system, Δts is practically nonexistent for sodium or potassium hydroxides.

As pointed out in connection with Fig. 1, concentration of hydroxide, such as obtained by only a few degrees elevation in temperature due to film boiling, can produce conditions decidedly corrosive to boiler metal. Therefore in thinking in terms of the concentrated solution which can develop, it is desirable to introduce other salts of sufficient Δts to remain in solution in case of film boiling, and thereby reduce the concentration of caustic which can result. In order to accomplish this, the joint means were used of decreasing the range of alkali to be maintained in the boiler water and increasing the potassium chloride concentration. The effectiveness of this was checked in the laboratory by means of accelerated tests. Bombs were charged with 250 g of solids (anhydrous) and 30 g of water. The temperature within the bomb was raised to approximately 1022 F in a period of 3 hr, after which the heating was discontinued and the closed bomb allowed to cool to room temperature. The residual pressure due to the hydrogen generated during this test was measured after cooling. The results obtained for mixtures of potassium chloride and potassium hydroxide, potassium phosphate and potassium hydroxide, and mixtures of both potassium chloride and potassium phosphate with potassium hydroxide are plotted in Fig. 7. It will be noted from this figure that the amount of hydrogen formed, which is a direct indication of the amount of attack on iron, dropped very rapidly as the molar ratio decreases below 0.2 for mols KOH over the total mols of chemicals present. Thus for benefit to be obtained from this source it is indicated that the chloride concentration, in equivalents, should be at least 5 times that of the hydroxide concentration, and for added safety in this respect a ratio of 10 to 1 chloride to alkalinity was

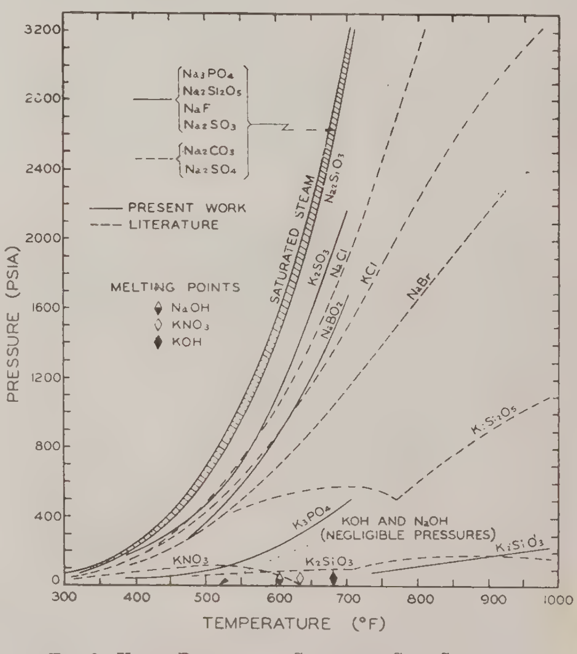

Fig. 6 Vapor Pressure of Saturated Solo Solutions

[9] "The Behaviour of Highly Concentrated Boiler Water," by C. E. Kaufman, V. M. Marcy, and W. H. Trautman, Proceedings of the Sixth Annual Water Conference, Engineers Society of Western Pennsylvania, October, 1945.

established as a minimum for the chemical control of the Montaup boiler water.

The detailed control limits which were established and have been maintained since January 1, 1944, are as follows:

pH value	9.8–10.4
Phenolphthalein alkalinity (ml, N/30 acid required for 100-ml sample)	0.5–1.6
Phosphate (PO_4), ppm	8–20
Chloride: hydroxide ratio, epm	Minimum = 10:1
Potassium: sodium ratio, epm	Minimum = 3:1
Total solids, ppm	Maximum = 1000

Actually, the control has worked out so that the chloride to hydroxide ratio, in equivalents, is seldom below 50:1. Thus in a film-boiling solution with Δt of 5 deg F, instead of obtaining a caustic concentration of 4.5 per cent, this concentration will be only about 0.09 per cent (900 ppm or 22.5 epm), or still within

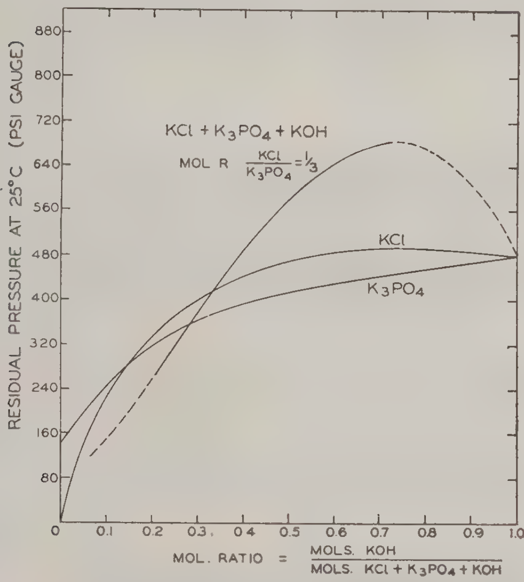

Fig. 7 Residual Hydrogen Pressure Developed by Action of KCl-K_3PO_4-KOH Mixtures

the protective range of minimum attack by hydroxide on steel at high-pressure-boiler temperatures, as indicated by the data of Berl and van Taack plotted in Fig. 1.

High-Pressure-Boiler Feedwater

The nature of the boiler feedwater is also a factor which cannot be ignored, especially in the operation of high-pressure boilers.

The boiler feedwater at Montaup is obtained from the turbine condensers plus a small amount of evaporated make-up water. Control to maintain good feedwater conditions is normally maintained at the plant, as proved by some 15 years' operation of the 400-psi boilers without difficulty in the preboiler equipment. However, with the advent of the early difficulties encountered in the operation of the high-pressure boiler, steps were taken further to improve the quality of the feedwater wherever possible. Operation of the two deaerators was adjusted so that they would always be under positive pressure to assure good elimination of dissolved oxygen. The turbine condensers were also retubed in 1944, to assure minimum contamination by the tidewater used for condenser cooling.

These steps have resulted in feedwater which generally shows zero values for dissolved oxygen. Carbon dioxide in the system is also very low, due to the feedwater to the evaporators being a sulphate rather than a carbonate water. Tests made on the steam indicate that the carbon-dioxide content is of the order of 0.01 ppm. Measurement by means of a Leeds & Northrup pH meter on flowing cooled samples, right at the sampling points after the deaerators, generally shows pH values of about 8.5.

Condenser leakage is immediately indicated on the condensate-conductivity recorders, and if this becomes at all high, the condenser is taken out of service as soon as possible and the leaking tubes located and plugged. As a result of this control the turbine condensate used for feedwater has averaged less than 5 micromhos per cm conductivity, since the summer of 1944.

Examination of Boiler-Tube Sections

The removal of tube sections for examination rather than merely examination and analysis of such deposits as are found in the wet-steam drum, has greatly facilitated the determination of internal conditions of the Montaup boiler. We have thus been able to study the distribution of constituents of the deposit between the fire and cold sides of the tubes, as well as between the surface of the deposit and the area next to the metal. Examples of this variation are the presence of acmite ($Na_2O.Fe_2O_3.4SiO_2$) on the fire side of some tubes in a thin layer next to the metal. In some instances this layer was so thin that it would never have been detected had the tube section not been pickled. The bulk of the deposits was iron oxide and contained little or no acmite. Another example is the presence of a considerably higher percentage of phosphate sludge on the cold side of some tubes rather than on the fire side. A third example of variation is found in the appearance of the internal surfaces of some tubes. Many of these specimens examined showed smooth continuous films of magnetic iron oxide, while others exhibited considerable roughness and thicker surface deposit. Pickling of the specimens showed that those tubes which exhibited a rough surface very frequently showed evidence of metal attack.

The first set of specimens examined by us was removed from the boiler on January 13, 1943, at the time of failure in the No. 2 roof tube. The general condition of these tubes has already been reported in the paper by Parks.[3] Also in this paper were presented for comparison photographs of tubes examined after the boiler had been on potassium-silicate treatment. In both of these sets of tubes a hard dense deposit, consisting chiefly of magnetic iron oxide, was found on the fire side of the specimens examined. This was, at least in the specimens removed after potassium-silicate treatment, found to overlie a very thin film of acmite ($Na_2O.Fe_2O_3.4SiO_2$). The specimens removed after sodium treatment were not pickled to determine if a layer of acmite adjacent to the metal was present. The cold side of the tubes, while showing a relatively rough surface, did not exhibit the hard, dense iron oxide found on the fire side in either of these sets of specimens. The material on the cold side of the tube was soft and powdery, as was the surface layer on the fire side which covered the hard, dense material.

Appreciable roughening of the metal surface of a number of the tubes was evident. This roughening was believed due in part, at least, to small tears produced in the tubes during cold-drawing. A specimen of this sort of tubing, carefully polished to remove the tears before installation, did not show as much attack on the metal surface although this tube section was not in operation as long as the unpolished tube. It is not known whether acid-cleaning of the boiler contributed to this roughening.

The first set of specimens removed after the discontinuance of silica feed still showed some patches of the dense iron oxide, which patches were coated with metallic copper. Since these specimens had been in the boiler during silica feed and the acid-cleaning which was done following the silica treatment, it seems quite

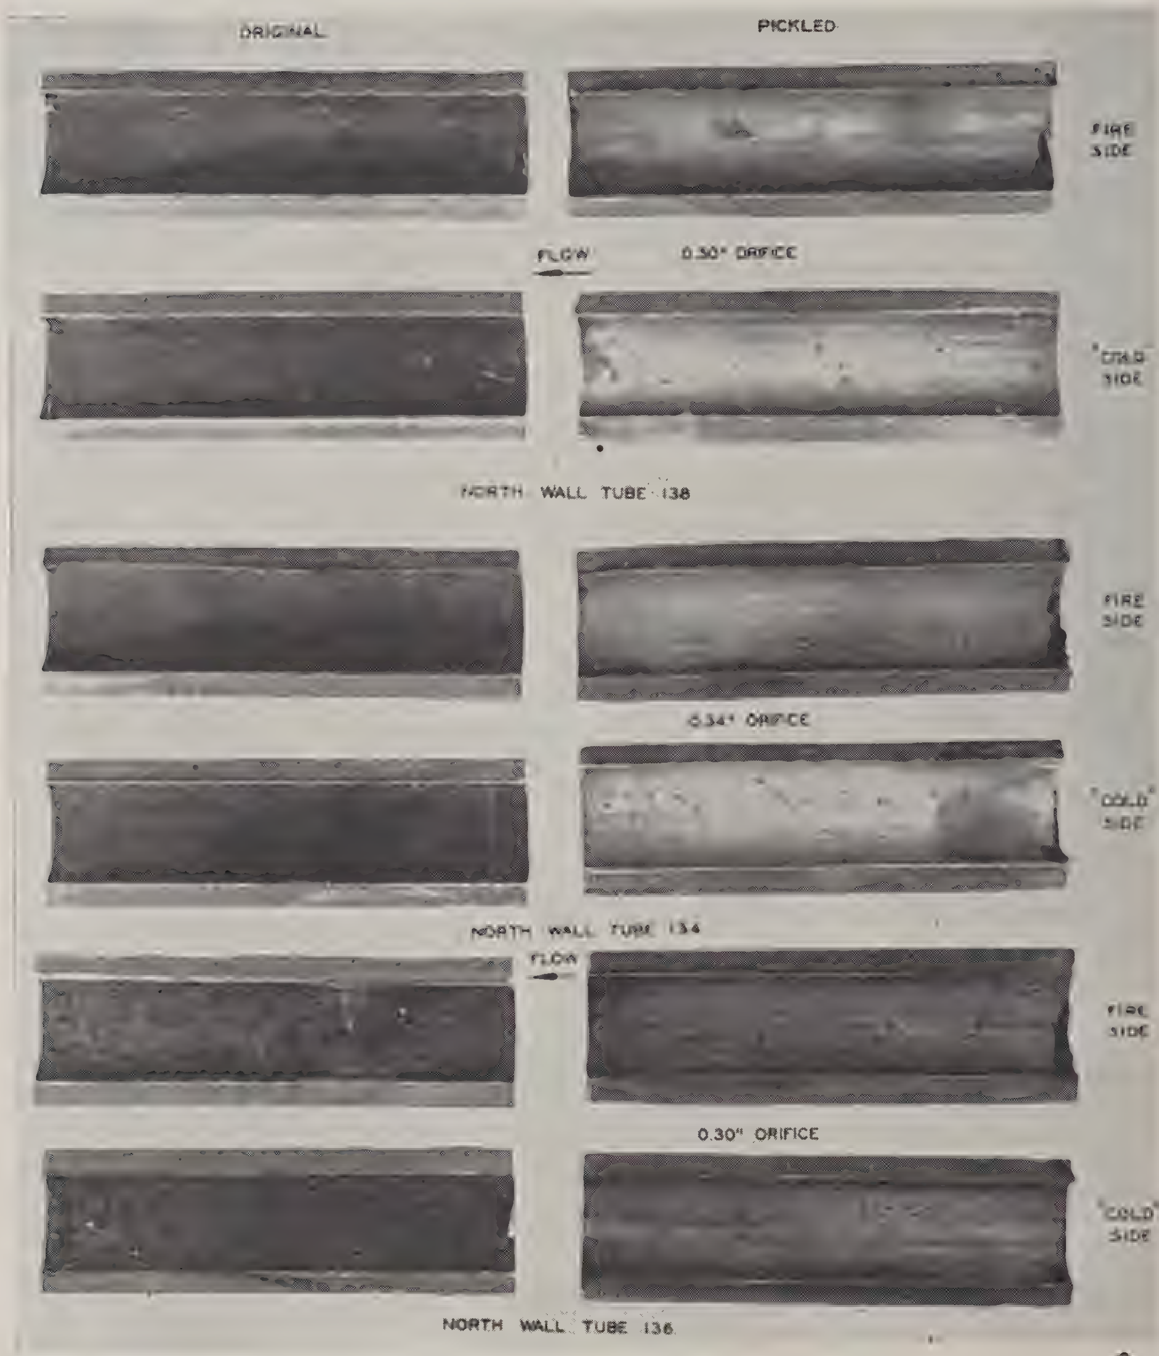

Fig. 8 Appearance of Boiler Tubes From Bifurcated Sections After 14 Months of Operation With Present Potassium Treatment

(Each tube is one of a pair of bifurcated tubes fed by a single orifice. Tube No. 138 is fed from a 0.50-in-diam orifice; tube No. 134 is fed from a 0.34-in-diam, or normal size orifice; tube No. 136 is fed from a 0.30-in-diam orifice.)

possible that the deposition of copper and even part of the pitting might have occurred during the acid-cleaning. Tube sections removed up to September, 1945, showed that none of the tubes which have been installed since the December, 1943, acid-cleaning contained any significant amount of this hard dense iron oxide. One or two localized patches of scale had developed, but this is believed due to restricted circulation from welding slag in the particular tube orifice, as will be explained later.

Since the surfaces of the tubes originally installed in the boiler were found quite rough, particularly on the fire side, it was decided, in order really to evaluate the present method of treatment, to examine only specimens which have been installed since the December, 1943, acid-cleaning. Special orifices were installed in the strainers feeding six of the north-wall tubes. A fairly large section of these tubes, plus an adjacent pair, fed by the normal orifice, was replaced in June, 1944, with new tubing and we were therefore able to determine the general effect of treatment and also the effect of the special orifices on the same set of samples.

The specimens from this section examined during the latter part of 1944, contained considerably more calcium and magnesium phosphate than had previously been seen on the tubes since the institution of potassium treatment, although there was no evidence of marked attack on the tubes such as had been experienced with the tubes examined previously. It was found that much of the sludge and iron oxide could be removed from the boiler by operating for a 24-hr period at 400 psi and high blowdown. Until the October, 1945, failure of two rear-wall tubes, this treatment of the boiler indicated that accumulation of deposit was insignificant.

Prior to the use of tubes installed in 1944, for examination, it was almost impossible to tell from the condition of the metal surface or from the amount of sludge accumulation just what the extent of attack really was. This was because the amount of metal loss and consequent roughening of the surface seemed to be a function of the number of tears occurring in the metal surface during cold-drawing, as well as operating conditions. The accumulation of iron oxide and also the precipitation of phosphate sludge appeared to be proportional to the amount of roughening of the metal surface. Of particular interest along this line was the fact that the phosphate sludge tended to pile up on the downstream side of a high spot in the iron-oxide surface, especially behind a tubercle on the cold side of the tube. We are at a loss to explain why there should be more phosphate on the cold side, unless the increased turbulence on the fire side of the tube prevented it from settling out. The phenomenon has, however, been observed too frequently to be pure coincidence.

Fig. 8 shows portions of tubes removed from the north wall after approximately 15 months of the present potassium treatment. Tube No. 134 is one of a pair of tubes being fed through a normal 0.34-in. orifice. It will be noted that the surface of the

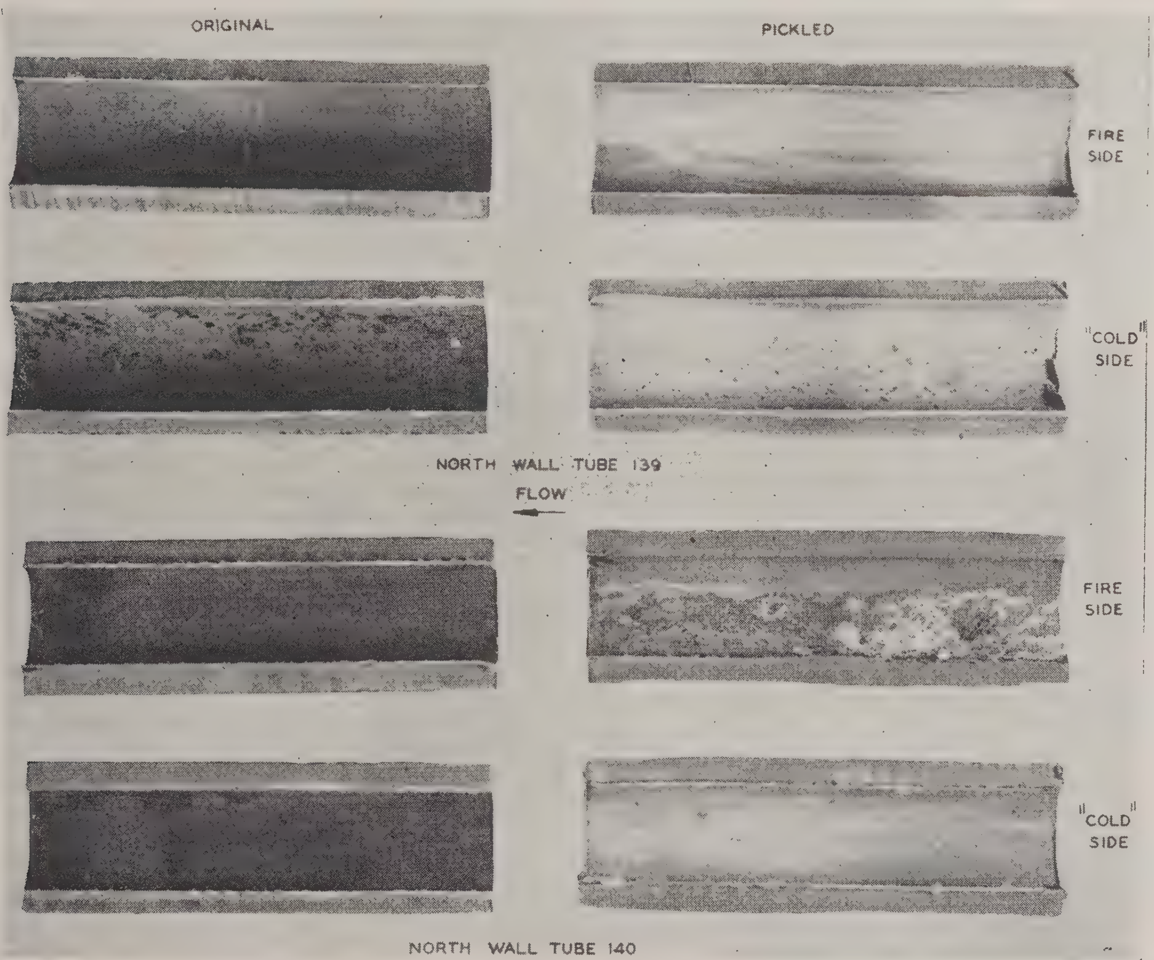

Fig. 9 Appearance of Boiler Tubes Fed by Single, Separate, 0.25-In-Diam Orifices After 14 Months of Operation With Present Potassium Treatment

oxide film is fairly smooth and that there is no evidence of significant attack on the metal in the pickled specimen, either on the fire or cold side. Tube No. 138 is one of a pair of tubes being fed by a special 0.50-in. orifice and is similar in appearance to No. 134 tube with the normal orifice. Tube No. 136 is one of a pair of tubes being fed by a reduced-sized orifice, 0.30 in. In the original specimen from this tube the definite roughening of the surface of the deposit can be noted on both the fire and cold sides. In the pickled specimen there is a little more roughening of the surface on the fire side, Fig. 9.

Tubes Nos. 139 and 140, Fig. 9, normally a pair fed by a single 0.34-in. orifice, are fed by two separate 0.25-in. orifices. These two separate small orifices would transmit about the same total water flow as through a single 0.34-in. standard orifice. It will be noted that there is no more attack evident on the pickled specimens of tube No. 139 than in the normal tubes. The flaking off of deposits on the cold side of tube No. 139 is believed to be due purely to mechanical causes during shipment of the tube, since light tapping of the tube in the laboratory removed more of the deposit. The particular section of tube No. 140 shown was photographed because of the apparent difference in the nature of the deposit. This is the only hard patch on any of this set of tubes, and does not extend over the remainder of the specimens from this tube. The main constituent of this very thin, hard, scalelike material is still iron oxide, although there is considerably more hematite (Fe_2O_3) than magnetic iron oxide (Fe_3O_4) present. There is also some phosphate sludge, some form of silica which was not sufficiently crystalline or present in sufficient amount for identification by x ray, and a small amount of metallic copper. Traces of sodium and potassium salts were also found in the deposits, apparently trapped in the scale. The poor appearance of the fire side of tube No. 140 is not considered significant as this condition was probably produced as a result of the orifice restriction which caused the No. 139 tube failure in July, 1944, as discussed in the first paper of this series by Parks, Patterson, and Ryan.[4]

The freedom from sludge and general appearance of most of these tubes is encouraging. It should be remembered, however, that the amount of sludge or scale which would cause little if any difficulty in the average boiler would likely result in a large number of tube failures in a high-pressure boiler with high heat-absorption rates.

The two tubes which failed on October 26, 1945, and a number of other tubes as well, again showed considerable deposit formation. In view of the long period of operation with little in the way of deposits from January 1, 1944, to September 14, 1945, it appears that some unusual circumstance may have developed in the operation prior to October 26. On the other hand, this may simply indicate that inasmuch as only the tubes cut out can be inspected for internal conditions, it would be advisable to acid-clean the unit at regular intervals such as annual shutdowns, rather than to operate indefinitely without certain knowledge of boiler cleanliness.

Conclusions

Operation of the Montaup high-pressure boiler since April, 1943, when potassium treatment was first instituted, has been decidedly successful, with operation at full design pressure and generally near design load as required by the plant.

There have been only two forced boiler outages since April, 1943, associated with internal boiler deposit. This record for $2^1/_2$ years' operation can be equaled or bettered by very few boilers operating at 1950 psi or higher drum pressure, which is the operating pressure of the Montaup unit.

In arriving at the boiler-water control for high-pressure boilers, not only the over-all boiler-water conditions must be considered, but attention must also be focused on the type of water which will develop when abnormally high concentrations occur, such as follow with but a few degrees film-temperature increase above the over-all boiler water and saturated-steam temperatures.

It is felt that the advantages of potassium equilibrium in the boiler water have been definite contributing factors to the operating record of this boiler, similarly to a number of other boilers operating at pressures of 600 psi or above, where definite improvements in internal boiler conditions or maintenance of turbine capacities, or both, have resulted.

Discussion

T. J. Finnegan.[10] This paper describes the application of potassium treatment to the Somerset Station and presents curves which show that under that treatment hide-out did not occur, while under sodium treatment it was present. This is in agreement with our experience with three high-pressure natural-circulation boilers which operate at 1265 psia and 900 F at the turbine inlet and deliver 900,000 lb of steam per hr. In our experience, however, it has been found that hide-out of phosphate is absent only when the PO_4 content of the boiler water is kept at a low figure and consequently we do not allow it to exceed 10 ppm. There is probably a relation between boiler design and the amount of hide-out which will occur, and this must be considered along with the purely chemical features of the problem.

We can also support the statement regarding the decomposition of sulphite in the boiler water and can demonstrate that the condition which permits it to occur may be very delicately established and difficult to define. In one of two 900,000-lb per hr high-pressure boilers, which had been operated with about 15 ppm of excess SO_3, sufficient decomposition occurred so that hydrogen sulphide could be smelled easily in the steam, and copper sulphide deposits were found on the high-pressure heaters, while in the other boiler no evidence of sulphite decomposition was found. Both boilers were operated under similar conditions of loading.

Reports have been received of good results in the treatment of high magnesium boiler water with silicates in order to avoid magnesium-phosphate deposits and to precipitate magnesium as silicate sludge. The boilers which are given this treatment are generally operated at low pressure and with high make-up. It seems risky to extend this treatment to boilers which operate in the pressure range which has been associated with silica deposits in the turbine. Silicate treatment was discontinued in the Somerset boiler because a small amount of silica scale had been found but an equally important consideration would be the internal condition of the turbine.

In spite of the fact that the three high-pressure units mentioned operate with less than 1 per cent make-up, at one time severe silica deposits had been found in the turbine. At present the silica deposits are light enough so that they can generally be disregarded in scheduling the regular outages of these machines, and this has been effected by reducing the boiler-water silica to as low a value as it is possible to obtain; it is usually of the order of 2 to 3 ppm of silica.

Authors' Closure

Mr. Finnegan's comments in regard to actions observed with phosphate and sulphite contribute to the information obtained from operating results.

The extent to which phosphate hide-out will occur, or be eliminated, when using potassium chemicals, will be affected by

[10] Chemical Engineer, Buffalo, Niagara Electric Corporation, Buffalo, N. Y. Mem. A.S.M.E.

the ratio of potassium to sodium present, and the Δt as illustrated by Figs. 2 and 5 of the reference paper.

The use of silica, properly controlled, has been of decided benefit in reducing the amount of adherent sludge in many boilers. Successful experiences in this respect include boilers operating at as high as 750-psi drum pressure, with no increase in the turbine deposition. The precipitation of residual magnesium entering the boiler as the silicate, instead of the hydroxide or phosphate, produces the most favorable conditions for the prevention of adherent sludges.

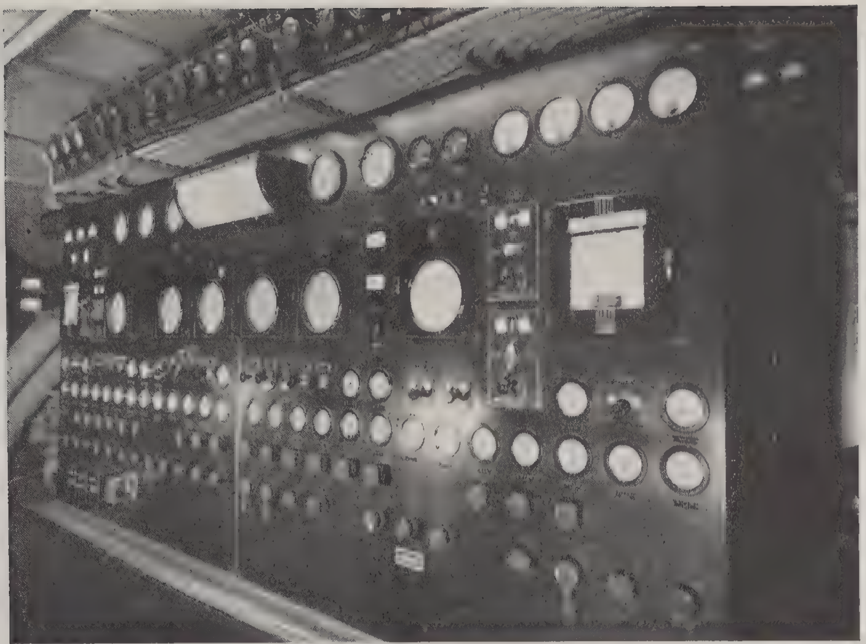

Fig. 1 Main Control Board 2000-Psi Boiler 6; Gr. 137

Experience With Instruments and Control Equipment for 2000-Psi Boiler at Somerset Station of Montaup Electric Company

By W. D. BISSELL[1] and E. B. POWELL[2]

This paper presents comprehensive descriptions and operating experiences with the instruments and control equipment as applied to the high-pressure high-capacity boiler of the Somerset Station. Details are given not only of the completely automatic operating and control equipment but also of the indicating and recording instruments which enable the operators to follow constantly the operating conditions of the boiler and thus permit immediate manual adjustment when the need is indicated.

The 2000-psi boiler at Somerset Station is numbered 6 from location and sequence of installation in the station and, for brevity, will be referred to as boiler 6 in this discussion. The instruments and automatic regulating devices which serve for operation control on the boiler are conveniently considered in three groups. In group (1) is classed equipment serving primarily for stabilization of output and efficiency of combustion; in group (2), equipment for maintenance of water conditions. For ready identification of equipment associated with the distinguishing characteristic of the boiler, a third grouping is employed for permanent instruments and controls installed to meet the special needs of forced circulation.

Control of Boiler Operation and Combustion Efficiency

The functions served by the instruments and control equipment of group (1), as classified in the preceding paragraph, are essentially those to be met in the operation of any modern boiler of equal capacity, i.e., pressure gages for steam, water, and air; flowmeters for steam, water, and fuel oil; feeder speed indicators for pulverized coal; instruments for evaluation of combustion efficiency; boiler-drum water-level recorder and drum water-level indicators; combustion and steam-pressure control; steam-temperature control; feedwater-pressure and flow-control devices. Interest in experience with this equipment is found chiefly in the instances where pioneering has been involved. Other equipment will be sketched merely for perspective.

Main Control Board. The main control board, mounting in-

struments and controls primarily of group (1), is shown in Fig. 1. The operating signal lights for the boiler circulating pumps at the extreme left near the top of the board are the only equipment of this figure not classed as of group (1). At right and left of the board are independently mounted primary-air pressure gages. Above the board are fuel-oil pressure gages and coal-stream temperature indicators. On the board proper the top row includes coal-feeder tachometers at the extreme left, and fan-motor ammeters at the extreme right, multipoint draft gages in the middle, with water- and steam-pressure gages. The row of recording instruments includes recorders for temperature of steam and boiler feedwater at the extreme left, and temperature of flue gases and air for combustion at the extreme right, with boiler-feedwater flow and pressure, and steam pressure, boiler-drum water level, main steam flow - air flow, reheater steam flow, fuel-oil pressure, and flue-gas oxygen in sequence in intermediate positions. At left and right of the feedwater flow recorder are mounted, respectively, controls for feedwater regulation and one of the drum water-level indicators. Similarly, at the sides of the flue-gas oxygen recorder are mounted, respectively, induced-draft-fan motor-exciter voltmeter and the steam-pressure reducing-valve controls. The lower half of the board is devoted almost exclusively to combustion and steam-pressure control, providing for manual control of the combustion system as a whole or for selective use of manual or automatic control as desired on the different elements of the system.

The flue gas-oxygen recorder is one of the highly informative instruments of the board. However, this instrument had barely passed the experimental development stage when purchased. As to be expected with novel equipment, a number of difficulties have been encountered from those frailties which it seems experience alone can fully bring to light. Experience has also proved the value of the instrument as a guide in control of combustion, giving more definite and precise indication of furnace conditions than the steam flow - air flow recorder which it serves to supplement. The flue-gas oxygen recorder is now to be extensively rebuilt.

Mounted on a hinged panel at the left of the recorder row are indicating pyrometers for main superheated-steam and reheated-steam temperatures. Mounted on a separate panel on the opposite side of the aisle, facing the main control board and not shown in the figure, is a group of instruments serving primarily to place control of the temperature of 375 psi superheated steam, delivered to the turbine throttle, in the hands of the high-pressure-boiler operator. This temperature control is effected by regulation of water supply to the desuperheater preceding the steam reheater normally, to the by-pass desuperheaters when the latter are in operation. The equipment of the panel includes two temperature indicators and recorders, one for each of the low-pressure-turbine throttles, an indicator for temperature of steam from the reheater, and water controls for the 4-in. by-pass desuperheater. Control valves for the desuperheating station ahead of the reheater, while not operated from the panel, are readily accessible at the rear of the boiler at the same grade. Controls for the 10-in. by-pass pressure-reducing and desuperheating station and for pressure reduction ahead of the 4-in. desuperheater are on the main board.

Variations in superheated-steam temperature on the low-pressure system are caused usually by variations in loading of low-pressure boilers which take up all load swings within the limits of their operating capacity. The throttle steam temperature on the low-pressure turbines must be held within close limits. Obviously, maintenance of mere constancy of reheated-steam temperature would not meet the requirements. Accordingly, manual adjustments are made in desuperheating the low-pressure steam prior to reheating, or in automatically controlled temperature of pressure-reduced steam, or in both, as required to give substantially constant temperature at the low-pressure-turbine throttles. The indicating pyrometers on reheated steam and the temperature indicators and recorders on steam at the throttles of the two low-pressure turbines give the operator clearly readable and closely concurrent values at these points at all times.

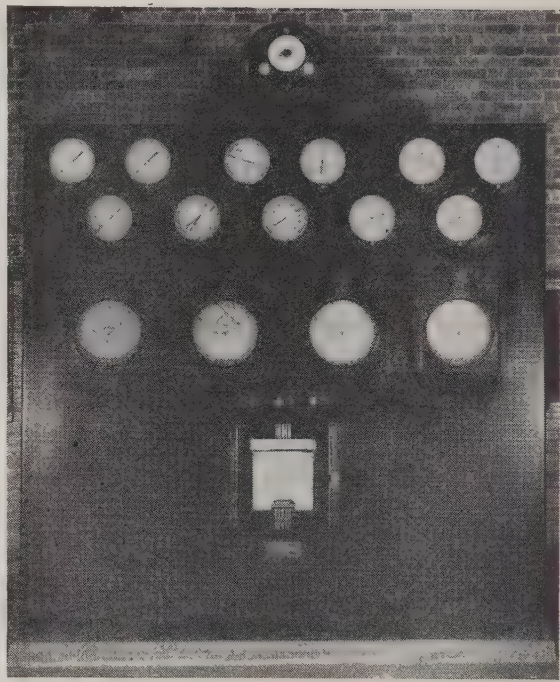

Fig. 2 Boiler-Feed-Pump Instrument Panel; Gr.137

Adjacent to the low-pressure-system steam-temperature control panel is a 12-point potentiometer indicator for checking recorders and for reading instantaneous temperatures. With multipoint recorders, several minutes may elapse between temperature measurements for a particular point. The indicators bridge the gap and give values instantly or continuously as desired.

Boiler-Feed-Pump Instruments. Fig. 2 shows the boiler-feed-pump instrument panel on the main operating floor, Gr. 137, on which are mounted a recorder for steam flow to turbine-driven feed pumps and for high-pressure-boiler feedwater flow and pressure, and a recording pyrometer for feedwater temperature at several stages of heating, as well as indicating gages for individual pump suction and discharge pressures, pump-turbine-drive exhaust and extraction pressures, and pressure differential between boiler drum and main feedwater header. Additional feedwater-system pressures and temperatures are indicated on the gages of the feedwater-heater instrument panel shown in Fig. 3. On this panel are also mounted controls for motor-operated feed-line valves at the high-pressure heaters and alarms for water levels in the shells of closed-type heaters. This panel is located on the ground floor, Gr. 118.

Regulation of Boiler-Feedwater Flow and Feed-Line Pressure. The feedwater flow recorder on the main board records the total of the separate flows in the two feedwater lines to the boiler economizer. The feedwater-regulator controls mounted adjacent to this recorder provide for adjustment of water-level position in the drum, for changes from automatic control from the corresponding drum-end thermostat to manual control, and

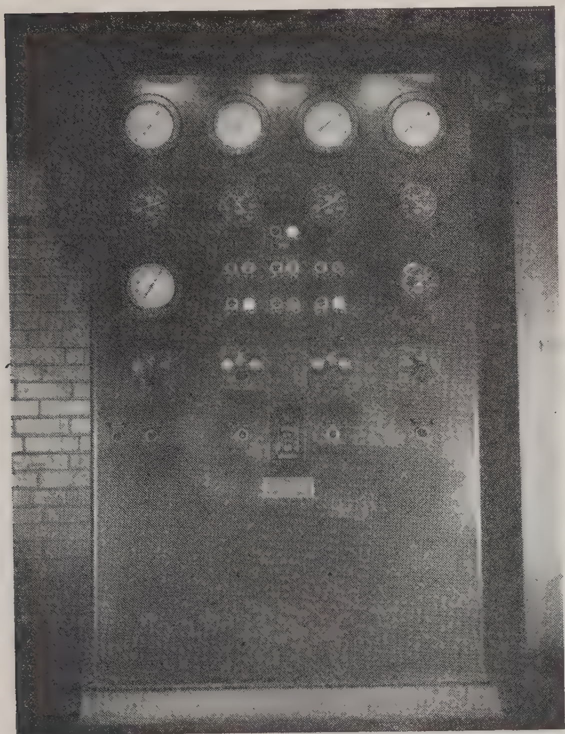

Fig. 3 Feedwater-Heater Instrument Panel; Gr. 118

vice versa on either or both feed-line flow regulators, and for the manual control of feed-line flow through either or both regulators. Valve position indicators immediately above the controls show at all times the degree of opening of each regulator. Separate line flow indicators, which are of value in equalizing regulator operation, are mounted adjacent to the respective individual metering orifices. The master controller, which functions to maintain the required head differential on the feedwater regulating valves and a definite pressure excess in the feedwater line for sealing the glands of the boiler circulating pumps, is mounted at the rear of the boiler and, as its adjustments are of relative permanence, is not arranged for control from the main board.

Transmission of the primary impulses from the drum end thermostats to the receiving diaphragms on the feedwater regulators, and from the feed-line excess-pressure master controller to the receiving diaphragms for adjusting the speed settings of the boiler feed pump turbine governors, has been accomplished eminently satisfactorily with compressed air. For the actual motivating fluid on the feedwater-regulator pistons, water was found during preliminary operation to give a smoother and more precise control and, accordingly, was adopted. On failure of the motivating water supply, the feed-regulating valve is automatically locked in position. Shifts back and forth between automatic and manual controls are effected easily and smoothly and, since the change in motivating fluid on the water-flow-regulator pistons, the functioning of the system has creditably met all demands, positively controlling the water level in the drum over the full capacity range of feed-line flow down to the condition of complete feedwater supply through circulating-pump gland leakage. Maintenance, aside from wear on the feed-pump low-load flow-recirculating valves, has called for little more than routine of inspection, cleaning, and lubrication of parts.

The feed-line pressure-control system provides not merely for high-pressure feed-pump speed adjustment but also for automatic spilling of the high-pressure feed-pump-drive turbine exhaust to the 15-psig exhaust system, and to atmosphere if required in the emergency of failure of one of the normally two such pumps in operation.[3] As there has been no high-pressure boiler-feed pump service failure, this last provision has not been called into operation.

The automatic control of recirculation of feedwater, required at low loads on the high-pressure boiler-feed pumps,[3] is also one of the functions of the high-pressure boiler-feed regulating system. The recirculating valve is operated by air impulse from the feed-pump-governor speed-setting control. As commented above, wear on the valve parts from the 2150-psi to 500-psi pressure reduction taken in the valve has been about the only source of significant replacement called for in maintenance of the high-pressure-feed regulating system. It is now believed that the life of these parts can be increased by change in design.

Combustion Control. Combustion control is of course initiated by change in steam pressure, with auxiliary adjustments from the accompanying steam flow and gas flow. The measurements of steam pressure and steam flow are usually direct and accomplished with adequate precision without regard to boiler design. On the other hand, for the modern boiler with heating surface almost exclusively of the radiant type, especially where the superheater is under gas by-pass control as in boiler 6, inherent sources of draft loss appropriate for the measurement of combustion-gas flow or combustion air flow become not so obvious. Control equipment and certain instruments used for giving a running check on control efficiency are dependent upon the precision of this measurement. The problem of providing the essentials for this measurement adequately and economically may well receive the careful attention of both boiler manufacturer and plant designer.

Before going into the experiences in measurement of combustion-gas flow on boiler 6, it should be pointed out that superheated-steam temperature is controlled by diverting through the upper economizer a part of the combustion gas flow which would otherwise make full travel of the convection bank of the superheater. The diversion of gas flow is accomplished by adjustment of main and by-pass dampers at the gas outlet of the economizer, shown diagrammatically in Fig. 4. Steam temperature is held very closely, swings in temperature rarely exceeding 5 F even during operation of soot blowers.

As first arranged, air flow for combustion was evaluated by summation of straight-line functions of gas pressure drops across the two parts of the economizer, utilizing connections at points about as indicated by C and D and E and F in Fig. 4. For recording steam flow - air flow relations, the combustion-gas flow initially was to be based upon the differential across the steam reheater between points indicated by A and B, also in Fig. 4. It early became evident, however, that the normal gas resistance of the reheater was not great enough to give consistent measurement of gas flow, and connections were made to provide for summation of straight-line functions of economizer-draft drops, paralleling the corresponding arrangements for combustion control. For metering purposes, however, an effort was made to compensate for variations in gas density by making the two pressure connections on the flue at the same level and extending the trailing pressure lead to the outlet of the economizer within the gas stream.

Attempts toward close co-ordination in combustion control en-

[3] "1825-Lb-Pressure Topping Unit With Special Reference to Forced-Circulation Boiler," by F. S. Clark, F. H. Rosencrants, and W. H. Armacost, Trans. A.S.M.E., vol. 65, 1943, pp. 461–477.

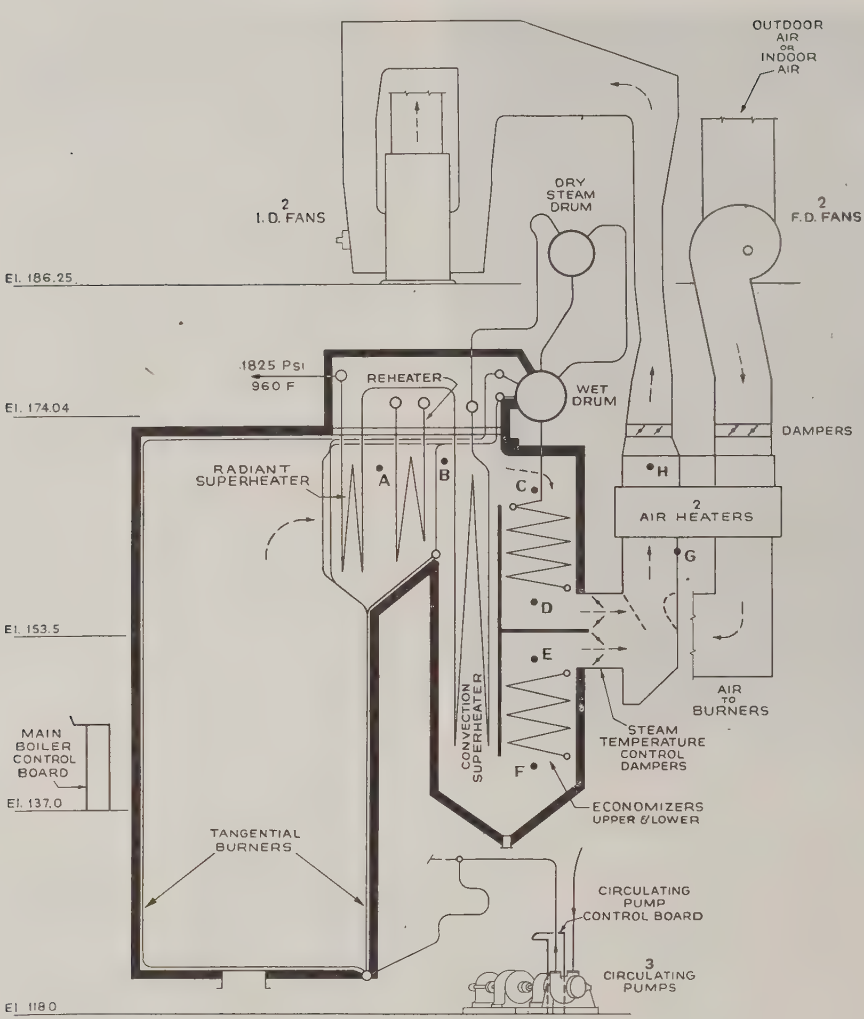

Fig. 4 Diagrammatic Section Boiler 6

countered the situation that pressures measured at the downstream connections in the economizer casings were seriously influenced by flow disturbances varying with the positions of main and by-pass dampers. In addition, during the first few months of operation, apparently the economizer gas-pressure differentials were affected by accumulating deposits on economizer surfaces and by flow disturbances from slag and ash accumulations in the superheater and reheater ahead of the economizer. These factors gave an annoying lack of consistency in gas-pressure differential in relation to actual rate of gas flow. After exhaustive efforts to improve performance, it was decided to abandon use of the steam-generating equipment proper as a source of gas-pressure differential and install restricting baffles to form an orifice in the short length of flue between the economizer-outlet dampers and the air heater, as indicated in Fig. 4. Observations with this arrangement, however, demonstrated that the pressure loss, as measured across the restricting baffles, was also influenced by the position of the dampers.

Air heaters of the rotating type are generally regarded as too unstable in draft characteristics for evaluating rates of gas flow, their variations in leakage and in resistance of path being thought too great to permit use of a device of that kind in the control of combustion and the metering of gas flow. However, use of the air-heater pressure differentials was adopted as a last resort. Connections for metering gas flow and the gas-flow factor in combustion control were shifted to G and H, Fig. 4. The results have been very promising. The arrangement has now been in operation more than 6 months, and combustion control and air-flow measurement have been found to respond satisfactorily not only to normal fluctuations but in meeting severe sudden changes in load.

Protective devices associated with the combustion control are arranged to give instant stoppage of fuel, coal or oil, on loss of primary air, on excessive back pressure in the furnace, or on failure of both induced-draft fans and, under this last condition, forced-draft and primary-air fans will be tripped out. The use of controlled circulation requires also that all fuel be instantly cut off on failure of circulation, which in this case is effected by the pressure differential across the circulating pumps on dropping to 20 psi.

Although not news to many associated with power-plant opera-

tion, it still cannot be too strongly stressed that successful operation of automatic controls is inescapably dependent upon their conscientious routine inspection and maintenance and, where compressed air is the control-impulse fluid as on boiler 6, absolute cleanliness and dryness of air and reliability of air supply are of vital importance. Control service compressors are provided in duplicate, each of capacity for full requirements, with the station compressed-air system as emergency reserve, each brought in automatically on predetermined fall in control-line pressure.

Control of Boiler Circulation

The control and instrument equipment of group (3), having to do primarily with control of the boiler circulation, are of the general type of group (1). Aside from the signal lights and emergency cutoff for fuel supply mentioned in discussing the equipment of group (1), and certain gages mounted directly on the circulating pumps, the present control equipment of group (3) is identified on the boiler-circulating-pump panel, Fig. 5, which is

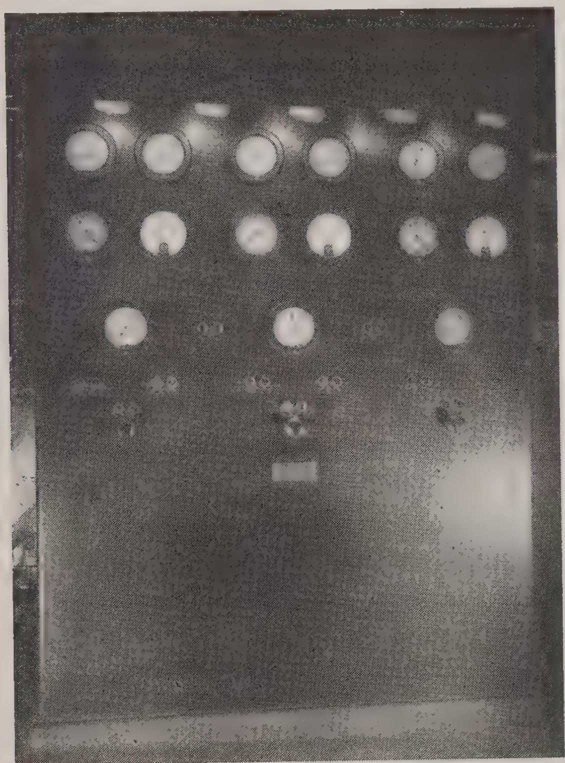

Fig. 5 Circulating-Pump Panel; Gr. 118

set up immediately beside the pumps as indicated in Fig. 4. There are three pumps, one motor-driven and two with combined motor-and-turbine drives. The gages of the two upper rows on the panel are arranged in three groups, showing for each pump labyrinth-seal injection and leak-off pressures and pump-drive-motor amperes.

Rise in labyrinth leak-off pressure, indicating an increase in sealing-water requirements, has served to give warning of wear in the labyrinth gland. The three gages of the next row below are for pump suction and discharge header pressures and steam pressure available at the pump-drive-turbine throttles. Operating signal lights for the two turbines are mounted in intermediate positions in this row. Below are, first a row of signal lights to indicate the position of the individual pump suction and discharge valves, whether open or closed and, below these, the motor-circuit-breaker controls and their open and closed position signal lights. For convenience of the pump operator for close observation while the boiler is being brought up to pressure or taken off pressure, injection pressure gages are mounted close to the injection control valves at the individual pumps.

In addition to the control facilities at present in use, three differential-pressure recorders have been provided and are now mounted in place, but not yet connected, on a separate panel near the main operating board of boiler 6 on Gr. 137. These recorders will give, for each of the three pumps, continuous record of pressure differentials between suction and discharge and between discharge and labyrinth-gland-seal injection. As pointed out in a paper by Parks, Patterson, and Ryan,[4] in the original sealing arrangement the breakdown from the operating pressure of the circulating pump to the final leak-off pressure of approximately 125 psi was effected by labyrinth exclusively. Water flow for sealing purposes and required boiler-feed line pressure, however, proved considerably higher than anticipated. With this condition corrected, the purpose of the new recorders is both to give continuous record of circulating-pump over-all performance and to permit taking full advantage of the gland-seal improvement in lowered feed-line pressure and feed-pump power consumption.

Control of Water Conditioning

As is to be inferred from the other papers of this series, experience with the instruments of group (2) has been of major interest at the station. Preliminary operation of the high-pressure unit early demonstrated that the simple routine of daily tests which had served for the older 375-psi plant was far from meeting the needs of close control of water conditions for boiler 6. More observations and more frequent observations were necessary to avoid too long continuance of contamination or too wide discrepancy between coincident chemical requirements and actual chemical concentrations. Specific factors determined as commonly contributing to upsets of water conditions and found calling for more prompt detection have included condenser leakage; evaporator carry-over; chemical-feed variations; change in continuous-blowdown recirculation; change in continuous blowdown to waste; contamination of stored condensate; subatmospheric pressure in deaerators; carry-over by steam from low-pressure boilers.

Hazards associated with condenser leakage in a seaboard plant hardly need comment. Evaporator carry-over at Somerset Station presented a greater than usual problem because the make-up feed is drawn from a surface supply subject to seasonal organic contamination of a sort which markedly affects the boiling properties of the water. The severe foaming which, prior to the installation of supplemental washing scrubbers on the evaporator vapor lines in the summer of 1944, was liable to occur at unexpectedly low evaporator concentration, was also very liable to pass undetected by any usual spot-sampling routine. The other factors mentioned have recognizable counterparts in most power stations. Factors less usual and less liable to occasional occurrence have also come to attention. All have important potentialities in any high-pressure-boiler plant.

Inspection following the overheating of a furnace-roof tube on January 13, 1943, had shown incipient pitting on tube interior surfaces with corrosion products constituting the major part of the

[4] "Operating History and Performance of 2000-Psi Forced-Circulation Boiler at Somerset Station of Montaup Electric Company," by G. U. Parks, W. S. Patterson, and W. F. Ryan, published on pages 411–427 of this issue of the Transactions.

deposited material within the tubes. It appeared that temperature rise in the metal from the insulating effect of a solid deposit on the interior surface of the tube might be promoting corrosion and so adding to the build-up of solid material with accelerating effects. Recording instruments to reveal and identify corrosive and other unfavorable conditions as they occurred seemed of pressing importance.

Hydrogen evolution at the steel surface was believed to give a reliable index of the rate of metal loss in the absence of free oxygen in the system. Consequently, among the first of the new instruments selected was a two-point hydrogen single-point oxygen recorder, its commercial development and possibilities having been brought to the attention of one of the authors by Sheppard T. Powell. Also, for the utmost promptness in detection and identification of departures from scheduled conditions, so as to minimize the continuance and effects of water variables, recorders were provided to cover continuously the highly informative test values of high-pressure feedwater and boiler-water pH and conductivity, and high-pressure steam and evaporator vapor conductivity. It was further recognized that instruments of this class should be under practically constant surveillance of operators who would themselves take any indicated corrective measures or would be in a position promptly to give proper instructions to others. In setting up the permanent installation, the hydrogen-and-oxygen recorder, the high-pressure feedwater and boiler-water continuous-blowdown pH recorder, the high-pressure feedwater and superheated-steam conductivity recorder, and the high-pressure boiler-water continuous-blowdown conductivity recorder were mounted on the high-pressure turbine-room main operating control board shown in Fig. 6, and the evaporator vapor-conductivity recorder was installed in the low-pressure station pump and evaporator room.

The high-pressure-turbine operator makes an hourly log of chemical-pump operation and continuous-blowdown valve settings; also, of recorded high-pressure feedwater oxygen and hydrogen concentrations, conductivity, and pH; boiler-water conductivity; and superheated-steam hydrogen concentration and conductivity. In logging these values entry is made of the temperature of the samples to the different recorders. Because of the importance of stability of water conditions in boiler 6, the operator makes hourly tests of the high-pressure continuous-blowdown water for alkalinity, phosphate concentration, and pH value as running checks on the recorders. With the close observation of water conditions so maintained in such comprehensive scope, even a slight change is quickly detected and usually its source rather promptly identified so that, in general, correction can be made before any serious effects have resulted. Nevertheless, much more in this direction can still be done. Meanwhile the broadened and heightened interest of the turbine operators, and their conscientious follow-up of irregularities observed in water conditions, are worthy of note and of emulation.

The more complete daily analysis of high-pressure-boiler water and boiler feedwater is made once daily by the plant laboratory and the results of these analyses are used as the over-all check on the hourly tests for basic control of water conditioning. The extremely low values to which contamination from hardness-producing salts is held in the condensate of this tidewater station make it practicable to recirculate boiler blowdown water to assist in stabilizing feedwater alkalinity and deliver the normal dosage of all water-conditioning chemicals continuously at the outlet of the deaerators to be carried through all high-temperature heat-exchange equipment to the boiler. A high-pressure chemical pump is available for delivery of chemicals directly to the boiler drum as special conditions may require.

Notwithstanding the generally small values of feedwater contamination, the recording instruments give very practical demonstration of the importance of continuity and uniformity in chemical feed. With intermittent delivery of chemicals, if there is serious condenser leakage or evaporator priming during an interval between periods of chemical introduction, there are prompt reflections in phosphate concentration and pH value, followed by increase in hydrogen evolution shown by the sample streams of both steam and feedwater. It is an almost invariable observation that serious upset in water conditions causes response in at least some discernible degree in the three feedwater test recorders. On this account, if one instrument shows an unusual in-

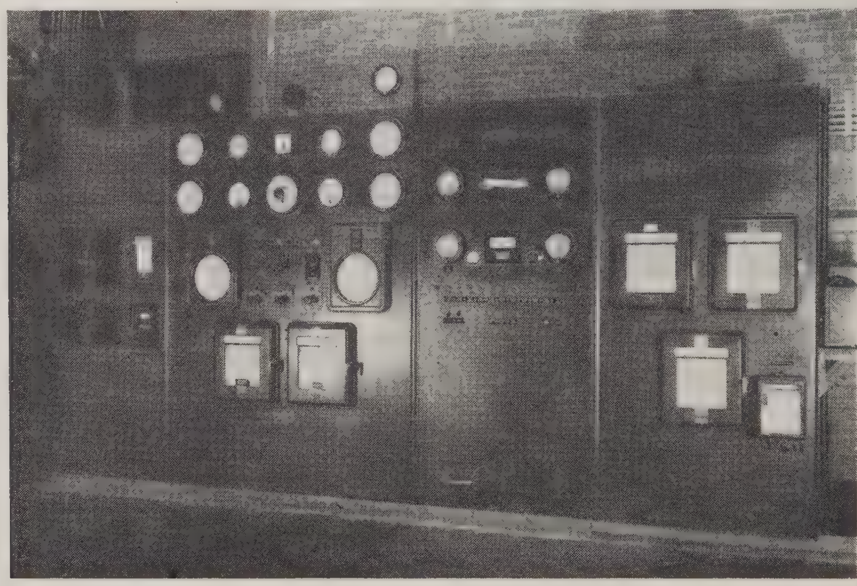

Fig. 6 Main Control Board High-Pressure Turbine; Gr. 137

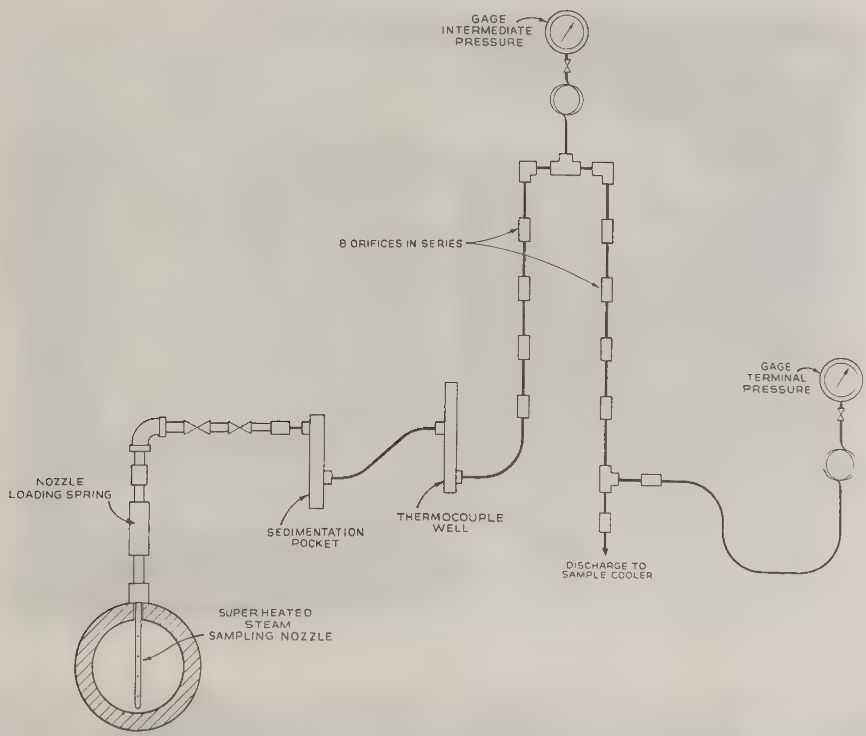

Fig. 7 Diagram of High-Pressure Superheated-Steam-Sampling Connection

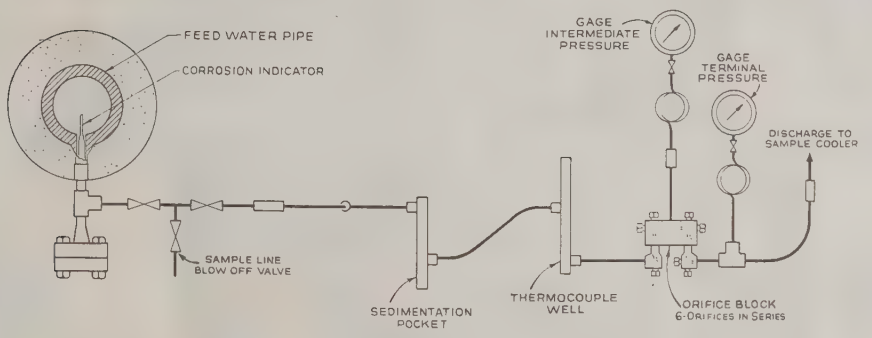

Fig. 8 Diagram of Boiler-Feedwater-Sampling Connection

dication without response of any sort in the records of the others, the condition and accuracy of that instrument are investigated.

Initial sampling connections and piping to the analyzing blocks of the hydrogen and oxygen recorder were temporary in anticipation of exploratory studies to be conducted. With the aid of degassing and sampling apparatus made available in March, 1944, through the courtesy of the American Gas and Electric Service Corporation and Beech Bottom Power Company, several weeks were spent in calibration of the hydrogen equipment and the potential accuracy and dependability of the analyzer and recorder demonstrated. After considerable preliminary investigation of sources of hydrogen liberation in the high-pressure system, permanent connections for sampling were established, and the installation was completed early in 1945. The oxygen-analyzing block of the recorder was connected to the high-pressure feedwater line immediately ahead of the boiler 6 economizer. One of the hydrogen-analyzing blocks receives its sample from the same point. The second hydrogen-analyzing-block connection was made to the high-pressure superheated-steam lead of the 1800-psi 950 F topping turbine.

Steam- and Water-Sampling Arrangements. General arrangements of the high-pressure steam- and feedwater-sampling connections are shown in Figs. 7 and 8. Fig. 9 is from a photograph of the feedwater-sampling connection immediately ahead of the economizer. The steam-sampling nozzle is stabilized stainless steel, and to avoid complexities associated with welding to the carbon-molybdenum steel of the adjacent outer fittings, this nozzle is held to seated position by a special alloy spring. The initial pressure of the steam sample is broken down through a series of eight orifices to about 100 psig. The sample is then led through stainless steel to cooling coils in which it is condensed and the temperature brought to approximately 120 F or some-

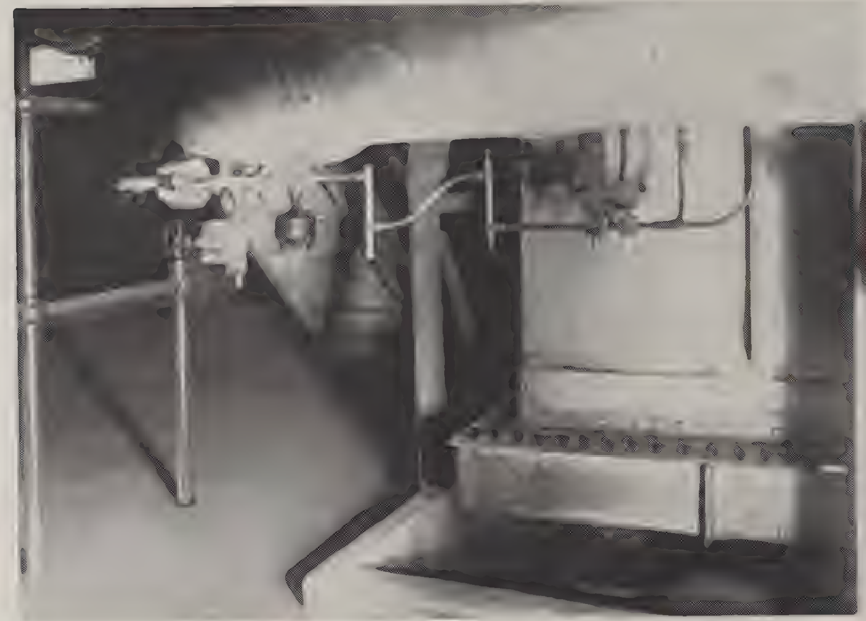

Fig. 9 View of Boiler-Feedwater-Sampling Connection

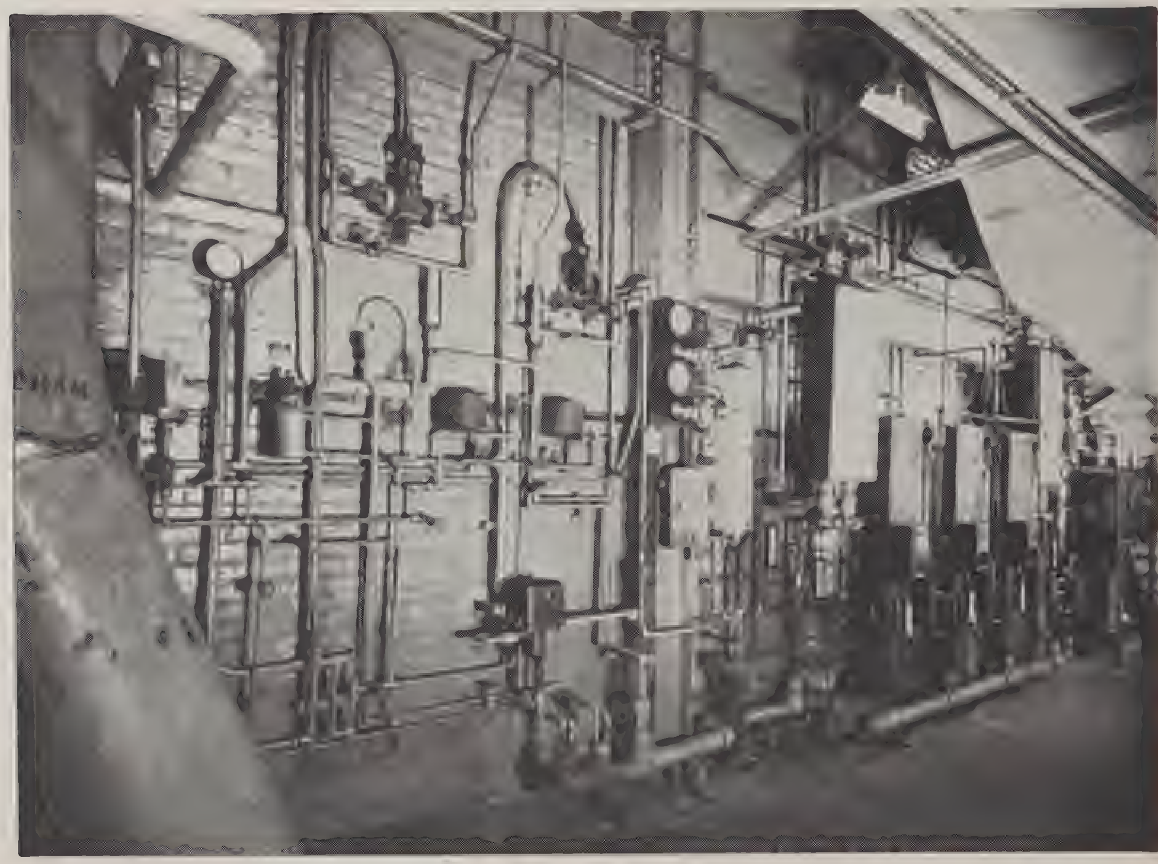

Fig. 10 Hydrogen-Analyzing Blocks, pH, and Conductivity Cells and Accessories

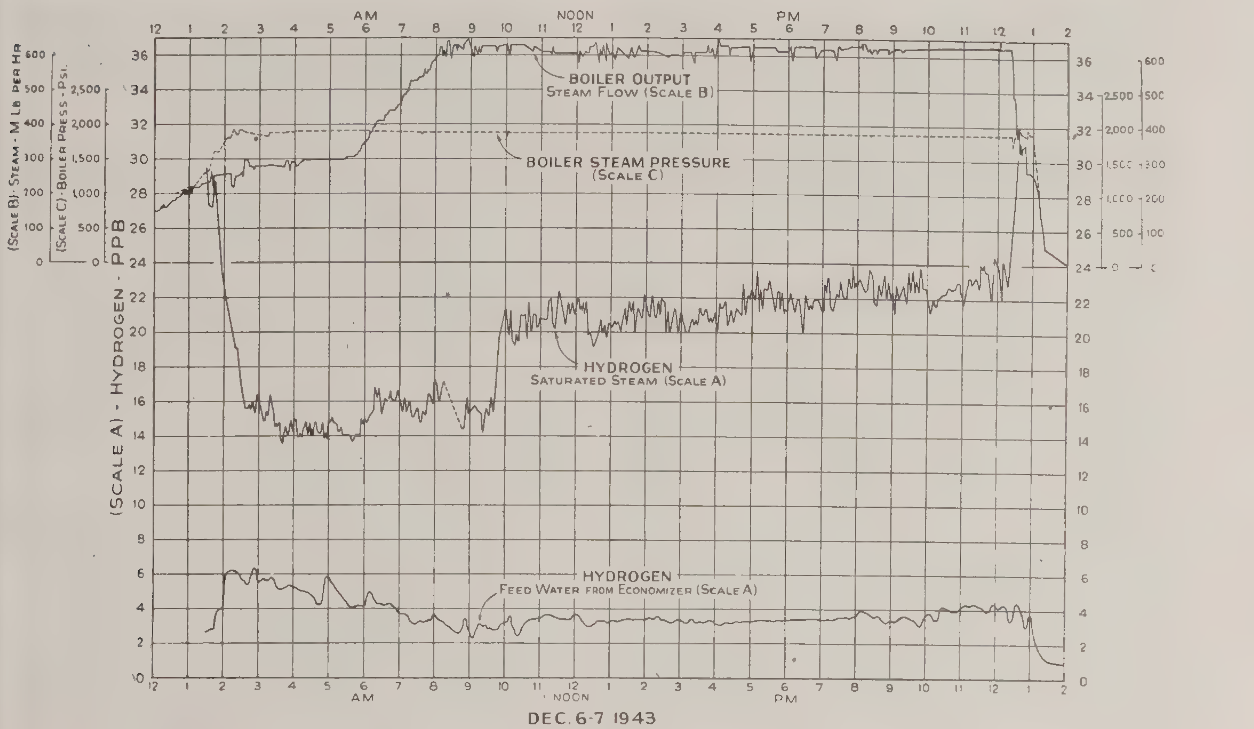

Fig. 11 Graphic Log: December 6 and 7, 1943

what higher for the hydrogen-analyzing block, and for degassing when a precise measure of steam conductivity is desired.

A part of the condensed sample is cooled further, to about 100 F, for purposes of the routine conductivity record. The high-pressure feedwater sample passes first over the corrosion-indicating specimen mentioned in a current paper by Bissell, Cross, and White,[5] then flows through a six-orifice stainless-steel pressure-reducing block in which the pressure is brought down to somewhat under 300 psig. The feedwater sample is also cooled to 120 F or somewhat higher, for the oxygen and hydrogen analyzing blocks, and parts are cooled further to 90 F, approximately, for conductivity and pH measurement. As in the case of the condensed sample of high-pressure steam, the tubing used to convey the feedwater sample is of stainless steel. Intermediate and terminal pressure connections are provided for the series of orifices on each sampling line.

Although used initially for checking the flow capacities of the orifices, the gages are part of the permanent installation to give warning of change in flow characteristics from accumulation of iron oxide in the orifices or from wear. The iron oxide present in the feedwater and steam, which is an important topic of another paper of this series,[5] deposits in the orifices of the feedwater-sampling system but apparently has had no effect on steam sampling. It has so far rather frequently proved necessary to clean the orifices of the feedwater system when returning the boiler to service after an outage. Similarly, at the end of approximately 1 year, the steam-sample flow rate through the orifice series was unchanged and the water-sample flow rate had been increased by roughly 40 per cent. The sample cooling coils and analyzing elements for the group (2) recorders mounted on the high-pressure-turbine operating board are shown in Fig. 10.

Records of Operation. Under current normal operating conditions, oxygen concentration recorded is "zero," expressed in parts per million (ppm), and the approximately full-load concentrations of hydrogen are close to 2 parts per billion (ppb) in the feedwater at the boiler 6 economizer entrance and below 3 ppb in the superheated steam as delivered to the high-pressure turbine. Other full-load characteristics recorded by the instruments of group (2) are conductivity of steam about 1.5 micromhos as sampled, varying with the seasons, and 0.6–0.7 micromho degassed; conductivity of chemically treated feedwater about 5 micromhos; conductivity of boiler water about 1000 micromhos; pH value of feedwater 8.3; and pH value of boiler water 10.3.

To illustrate the potential value of instruments of this general class it has seemed advantageous to select records of important departure from the characteristic performance. Figs. 11, 12, 13, and 14 have been prepared with this in view.

The hydrogen-and-oxygen recorder had been placed in operation November 7, 1943. The manufacturer's field calibration was undertaken within the next 10 days. On placing the instrument in service, the points of sampling at that time being at the economizer outlet and the dry drum of boiler 6, recorded hydrogen concentrations in the saturated steam seemed high, 10 ppb to 18 ppb at times, and showing progressive increase.

On November 27, 1943, the boiler was taken out of service for low-pressure blowdown, and on December 5, 1943, for complete change of water and cleaning of the main drum. Eleven pounds of solids, approximately 45 per cent magnetic oxide of iron from the analysis, were removed from the drum and the boiler was

[5] "Special Studies of the Feedwater-Steam System of the 2000-Psi Boiler at Somerset Station of Montaup Electric Company," by W. D. Bissell, B. J. Cross, and H. E. White, published on pages 429–442 of this issue of the Transactions.

returned to service, attaining full rated pressure and an output of 620,000 lb per hr shortly after 8 a.m. on Monday, December 6.

Values shown in Fig. 11 for hydrogen in feedwater and steam are probably not very significant prior to 12:30 or 1:00 a.m. when the boiler pressure had passed above 1000 psi. Full designed pressure was attained shortly after 2:00 a.m. The progressive fall in hydrogen concentration of the saturated steam shown prior to about 3:30 a.m. is probably due to dilution accompanying the increasing rate of steam generation which at 3:30 was approximately 375,000 lb per hr.

There had been a period of leakage in one of the condensers between midnight and 1:00 a.m. and this was probably, at least in part, responsible for the relatively high evolution of hydrogen in the feed system during the early morning hours. Feedwater make-up at the time was being drawn from the distilled-water storage tank and may have been not entirely free from solids contamination. It will be noted that instead of a fall in hydrogen concentration of the steam which is a usual accompaniment of an increase in rate of steam generation, the increase in boiler loading between 5:30 a.m. and 8:30 a.m. brought a small rise in hydrogen concentration of the steam.

Without much further change in loading, this was followed at 9:30 a.m. by rapid increase in rate of hydrogen evolution in the boiler by about 6 ppb, attaining a concentration in the saturated steam of 20–22 ppb at 10:00 a.m. With this substantially full-rated-load operation continuing the balance of the day, there was gradual progressive increase in rate of hydrogen evolution in the system until at 12:25 a.m., December 7, with the hydrogen concentration in the steam having reached 24 ppb, one of the roof tubes ruptured and the boiler was thereupon promptly taken off the line. The increases in hydrogen evolution in the feedwater system, raising the hydrogen concentration of the feedwater to 4 ppb at 8:00 to 8:20 p.m., and to a maximum of 4.4 ppb after 10:00 p.m., may have been due to leakage of one of the condensers. Records are not complete for the period.

In the light of subsequent experience it is of course perfectly obvious that on at least part of the boiler surface, temperatures had been excessive throughout the full period of operation prior to December 7, during which the hydrogen-and-oxygen recorder had been in service but at the time there was still much doubt regarding the interpretation to be placed upon the indications of the instrument.

As stated in the first paper of the series,[4] there have been two subsequent failures from overheating of furnace tubes in boiler 6. At the time of the first of these failures, discovered on taking the boiler off the line on July 16, 1944, the analyzing block for hydrogen concentration in steam had been out of order for several days, so depriving the operators of the possibility of a warning indication. The circumstances of the second failure October 26, 1945, are discussed later in the present paper under "Value and Limitations of Hydrogen Recorder."

Fig. 12 was prepared primarily to show by means of 6-hr averages immediate and cumulative effects of continued tube leakage in a service water heater. It will be noted, however, that the records show other features of interest. The steam condensed in the service heater was returned at intervals to the boiler-feed system by a trap. The water being heated was from the same surface supply from which water for the boiler-feed make-up evaporators is taken and is very low in dissolved inorganic solids but carries small and somewhat varying proportions of

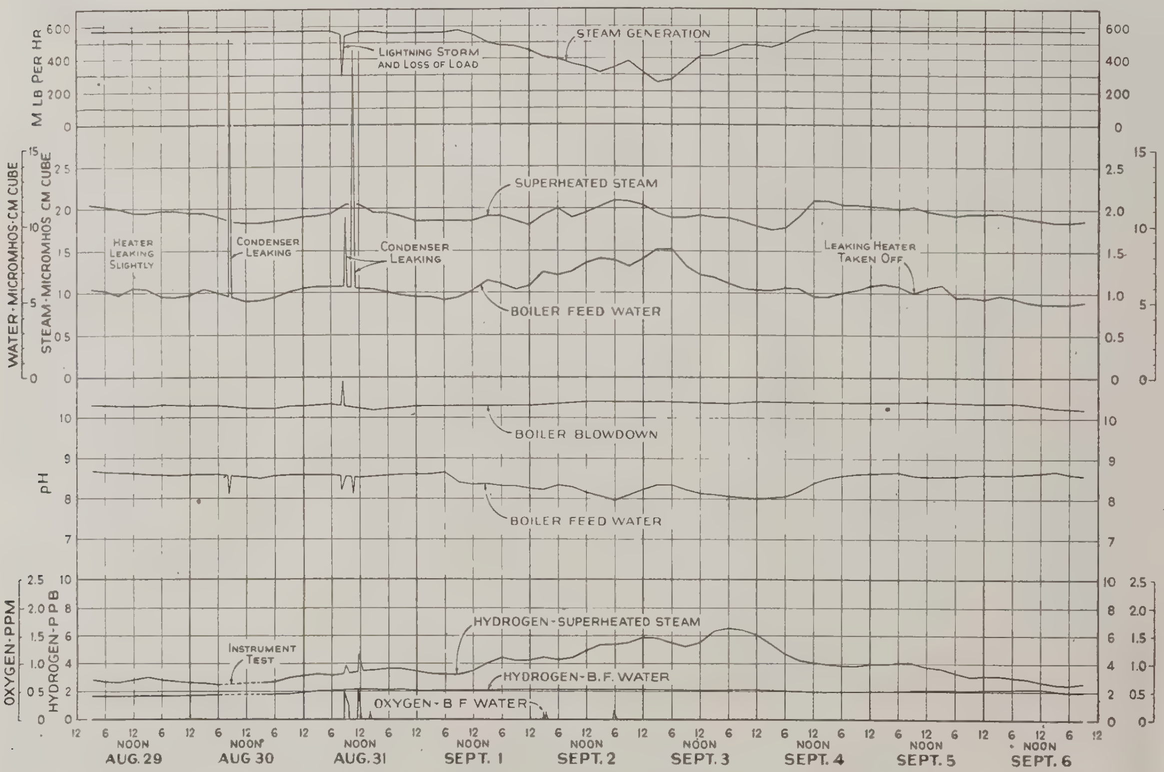

Fig. 12 Graphic Log: August 29 to September 6, 1945, Inclusive

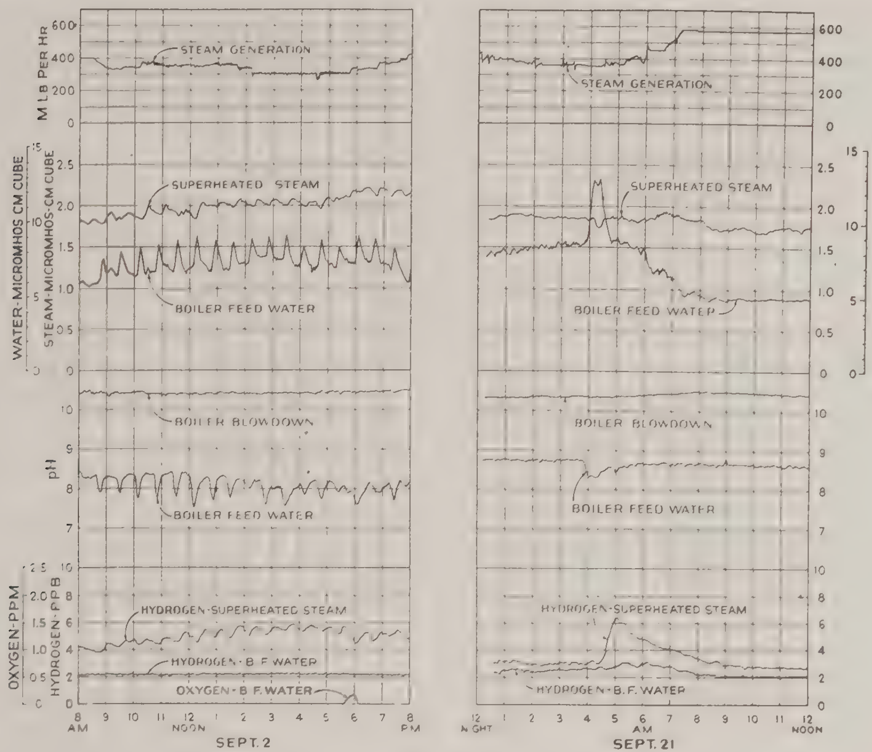

Fig. 13 Graphic Logs: September 2 and September 21, 1945

carbon dioxide and ammonia. Instantaneous effects of the operation of the trap during the height of the heater leakage are shown in some detail in Fig. 13.

Apparently the service-heater leakage on August 29, 1945, was comparatively slight and the irregularities in feedwater characteristics were not immediately sufficient to attract the attention of the operators. However, after the swings in feedwater conductivity became noticeable, it was some time before the source of contamination could be identified, on the evening of September 3, and then it was not found feasible to take the heater out of service for repair until September 5.

The rise in average feedwater conductivity over the period of September 1 to September 3, inclusive, is probably all to be accounted for as a reflection of the week-end and Labor Day holiday sag in load. The sag in feedwater pH average over the same period is believed similarly accountable as due to decrease and absence of low-pressure-boiler blow-down recirculation.

On the other hand, it seems that the high-pressure superheated-steam hydrogen concentration may be reflecting the effects of feedwater contamination to some extent and, on September 2 and 3, was also influenced by the low feedwater pH occurring on those days. As to be inferred from Fig. 13, the gas content of the raw water entering the system through the leaking heater causes increase in the conductivity of the superheated steam. The main cause of the higher-than-usual average conductivity of the steam was probably a high proportion of make-up coupled with seasonal increase in gas content of the raw make-up water.

On August 30 and on August 31 the effects of the service-heater tube leakage were augmented by main-condenser-tube leakage. Shortly after 8:00 a.m. on August 30 leakage of one of the surface condensers caused a brief rise in high-pressure-boiler feedwater conductivity from about 5 micromhos to 22 micromhos. The leakage was rather promptly corrected. The effect on pH value of feedwater was recorded by coincident drop from pH 8.6 to pH 8.1. Any effect on the rate of hydrogen evolution in either boiler-feed system or high-pressure boiler was masked by the test on the instrument begun shortly thereafter.

At about 8:20 a.m. on August 31 a severe lightning storm took out transmission lines which caused an abrupt drop in boiler load equivalent to about 275,000 lb steam generation per hr. The resulting temperature stresses in the condensers caused tube-joint leakage which was reflected in rise of feedwater conductivity from 5–6 micromhos to over 10 micromhos, drop in feedwater pH value from pH 8.6 to pH 8.2, and rise in hydrogen concentration in the superheated steam from 2.7 ppb to 3.5 ppb, the last mentioned being doubtless in part a simple reflection of loss of load. At the same time apparently the abrupt temperature change in the boiler-furnace tubes was sufficient to cause some release of "hide-out" alkalinity, as reflected by the abrupt rise in pH value of boiler water from around pH 10.35 to pH 10.9.

The initial stoppage of the condenser leakage was only temporary, and further leakage was registered about 10:30 a.m. which caused an abrupt and very brief increase in feedwater conductivity from about 6 micromhos to 20.5 micromhos with accompanying drop in pH value of boiler feedwater from pH 8.6 to pH 8.15 and somewhat marked increase in rate of hydrogen evolution in the high-pressure boiler, raising the concentration in the superheated steam from about 3 ppb to 4.4 ppb. The loss of load and leakage of condensers were both accompanied by oxygen contamination of the boiler feedwater. Whether this was due to unbalance of steam supply to the deaerators at the time is uncertain. There was further appearance of dissolved oxygen in

the feedwater on September 2 which is mentioned in the following discussion of Fig. 13.

Eight hours of chart records for Sunday loading on September 2 have been plotted at the left in Fig. 13 to show more clearly the response of the high-pressure-boiler feedwater steam system to the leakage in the service heater. As to be expected, the effects of the discharge of the heater drain trap are most acutely reflected in the conductivity and pH value of the boiler feedwater. The intermittent contamination, probably chiefly from the gaseous content, also appears in the conductivity of the superheated steam. The rate of hydrogen evolution in the boiler-feedwater system seems not to have been influenced, continuing practically constant at around 2.2 ppb as measured at the entrance to the boiler 6 economizer. The effect on hydrogen evolution in the boiler is, however, only slightly less noticeable than that on boiler-feedwater conductivity and pH value. It will be noted that in their general trend, the values for conductivity of superheated steam and boiler feedwater, the pH value of boiler feedwater, and the hydrogen evolution in the boiler are all responsive to the rate of steam generation.

The appearance of dissolved oxygen in the boiler feedwater beginning about 5:40 p.m. and reaching a value of about 0.2 ppm at 6:00 p.m., may have been due either to unbalance of steam supply to the deaerators resulting from the accompanying increase in boiler load or to admission of air-contaminated water in preparing one of the boiler feed pumps for return to service, actually put on the line about 6:50 p.m.

The graphs at the right in Fig. 13, for 12 hours of the morning of September 21, are intended primarily to show the recording of an instance of severe condenser leakage occurring shortly before 4 a.m., and so further illustrating the sensitivity of the feedwater line and boiler system to corrosive and otherwise adversely reactive constituents in the feedwater. The trends of the several values also reflect effects of change in rate of steam generation. Boiler 6 was carrying the entire station load up to 7:15 a.m.

The relatively high conductivity shown by the boiler feedwater prior to the development of the condenser leakage was probably the result of continuing the chemical-feed delivery at the average rate which had been adjusted for the higher load conditions of the previous day. The condenser leakage brought a rather abrupt rise in feedwater conductivity from about 8.5 micromhos to 12.5 micromhos and was effectively checked about one-half hour later, as will be noted from the rapid fall in feedwater conductivity to a value governed essentially by the rate of feedwater flow.

The conductivity of the superheated steam responded in a brief fall of about 0.1 micromhos, suggesting either a fixation of a part of the ammonia or carbon dioxide by dissolved solids of the contaminating harbor water or stabilizing effects of the chloride content of the harbor water. The pH value of the boiler feedwater dropped substantially simultaneously with the increase in conductivity. The recovery of pH value was more gradual. The trend of the dissolved-hydrogen values recorded for the boiler feedwater would suggest a somewhat delayed response. The response in rate of hydrogen evolution in the boiler, however, was quite marked and prolonged, the increase in concentration in the superheated steam being approximately 3.4 ppb, requiring a full 4 hours for recovery.

An item, possibly of interest in connection with the detection of condenser leakage, was met in the early investigation of potential sources of contamination which would affect the operation of boiler 6 when it was found that salt in considerable quantity could be added at the condenser hot well without effect upon the recorded condensate conductivity although appropriately increasing the feedwater conductivity. The hot-well conductivity cells drew their sample from the top of the condensate line ahead of the hot-well pump. Dispersion in the condensate line evidently was not sufficiently rapid.

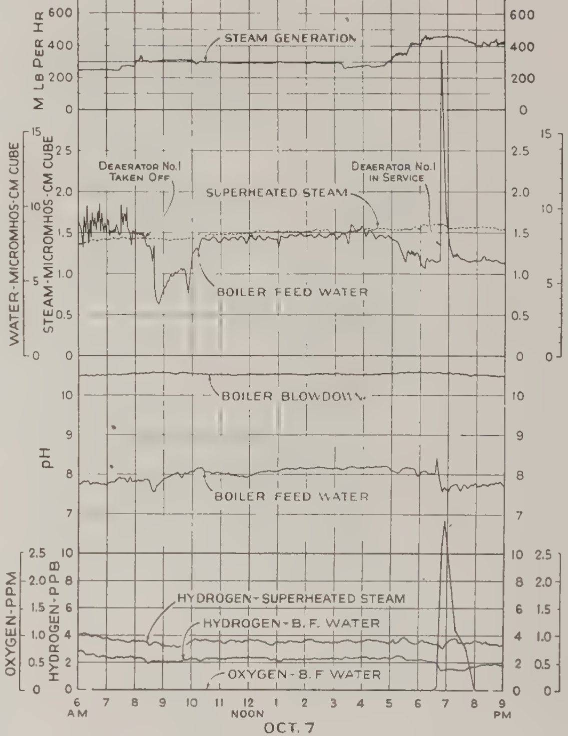

Fig. 14 Graphic Log: October 7, 1945

Fig. 14 shows recorded effects associated with taking one of the station deaerators out of service, and its return, on Sunday, October 7, 1945. The graphs give a 15-hr record. It seems probable that with the light loading of the early morning, there were sufficient differences in deaerator pressures to cause fluctuations in chemical-feed distribution between the two deaerators, resulting in the fluctuations in feedwater conductivity and pH noticeable between 6:00 a.m. and 8:00 a.m. Around 8:30 a.m. steps were taken to cut deaerator No. 1 out of service. The chemical feed to that deaerator was not immediately shut off. With the falling pressure in the first deaerator, chemical feed to the other deaerator was automatically discontinued.

The absence of chemical feed caused immediate drop in conductivity of feedwater from about 8.0 to 3.5 micromhos, accompanied by a drop in pH value of feedwater of about 0.3. On returning the deaerator to service shortly after 6:30 p.m., the abrupt delivery to the feed line of the chemical solution earlier accumulated in the deaerator brought a brief increase in feedwater conductivity from a value of approximately 6 micromhos to somewhat over 20 micromhos, with an accompanying increase in feedwater pH value from about pH 7.8 to pH 8.25. The water first delivered to the feed system from the deaerator returned to service also contained sufficient dissolved oxygen to cause the high-pressure-boiler feedwater to register concentration in excess of 3 ppm, and dissolved oxygen in considerable concentration was not entirely out of the high-pressure-boiler-feed system until more than 1 hour later.

Apparently a part of the oxygen in the feed system was consumed in reaction with the hydrogen evolved in that system. The rate of hydrogen evolution in the boiler shows increase as

an effect of the sudden introduction of the chemical charge but the hydrogen in the feedwater fell appreciably. A corresponding effect on the hydrogen concentration in the boiler feedwater, but of lesser magnitude, is noticeable when the deaerator was taken out of service, although the recorded rise in dissolved-oxygen content at that time was exceedingly brief and reached a maximum of only about 2 ppm. It would seem likely that in this latter instance the effect on rate of hydrogen evolution recorded for the feedwater system was due more to the marked decrease in feedwater conductivity without great loss in pH value than to reaction of evolved hydrogen with oxygen.

Value and Limitations of Hydrogen Recorder. It had of course been recognized that hydrogen evolved in the feedwater system or boiler might combine to some extent with oxygen where found dissolved in the water in contact with the metal surface. A contingency overlooked was that an oxide of copper might function in the system as a source of oxygen. The practical importance of chemical action of that sort was brought strongly to attention by the October 26, 1945, furnace-tube failures taking place without marked increase in recorded rate of hydrogen evolution in the boiler.

One of the low-pressure-turbine stage heaters, temporarily operated as an evaporator condenser with feedwater entering at 215–218 F and condensing vapor of about 16 psig pressure, corresponding to about 250 F, had been returned to this vapor-condensing service October 10, in the midst of the season of maximum organic contamination of the evaporator water supply and immediately following installation of 468 new tubes of Admiralty alloy. Apparently the copper carried into the feedwater system in oxidized form from the corrosion of the new Admiralty alloy tubes was sufficient to cause practically complete disposal of the hydrogen evolved from the overheating of the boiler tubes. Although the boiler had been in operation less than 6 weeks following an inspection when the drum had been cleaned, considerably in excess of the quantity of metallic sludge to be expected from 6 months of operation was found to have accumulated in this brief period, and the sludge was approximately two-thirds copper, which is one and one-half times the maximum proportion of that metal previously found.

A factor which will be recognized as commonly responsible for hydrogen concentrations out of step with temperature or other corrosive influences normally to be associated with concurrent operation is the abnormally high chemical activity of the metal surface following an acid-cleaning of the boiler. The rate of hydrogen evolution which occurs during the first few weeks of operation of an acid-cleaned boiler may be so high as to mask any increase in rate of hydrogen evolution which might result in the boiler from other than extreme contamination or actual overheating.

Notwithstanding such interfering factors as mentioned, hydrogen evolution in a boiler gives the best known indication of corrosion or solution of the boiler metal and the measurement of the rate of this evolution affords the only feasible basis for judging the extent of corrosion taking place while the boiler is in operation. Means for minimizing the effects of interfering factors are being studied.

Conclusions

It will be obvious from the experience in operation of boiler 6 that on modern steam-generating equipment, instruments appropriate to the requirements, especially recording instruments, can be not merely informative but of tremendous instructive value and sources of heightened interest in operating personnel. The importance and the potentialities of such instruments doubtless increase with the degree of operating efficiency which it is desired to maintain, and for a base-load unit of the capacity and type of boiler 6, become essential. To fulfill their potentialities, in fact to avoid real hazard from their presence, the instruments must be rugged by the station environment standard rather than by that of the laboratory and must be followed with definitely scheduled routine inspection, calibration, and maintenance of frequency and thoroughness that will assure precision of indication within acceptable limits at all times.

Comment on the importance of control-equipment maintenance is given earlier in the paper, and should not need repetition. High standard of upkeep in instruments is hardly less vital and, from the point of view of subsequent analysis of operating events, dependable instrument charts can contribute invaluably to the continuity of informative records.

Acknowledgments

The authors desire to record their appreciation of valuable suggestions on the text of the paper made by Mr. G. U. Parks, and of his permission for use of the station data, and of the assistance of Mr. H. E. White in arrangement of these data. They would also record their appreciation of the very constructive criticism of the text by Mr. W. S. Patterson.

The authors take this occasion to express appreciation of the very generous co-operation afforded them by Mr. Philip Sporn, and Mr. W. L. Webb of the American Gas and Electric Service Corporation, and Mr. J. R. McDermet of the Elliott Corporation, which aided greatly the studies conducted in preliminary exploration of hydrogen evolution in the high-pressure system at Somerset Station. Appreciation is also expressed of the very exceptional patience shown by Mr. G. U. Parks and his operating organization and their co-operation in adapting their plant operation to the needs of this investigation.

Discussion

W. W. Cerna.[6] The authors have gone to considerable pains to present complete descriptions and operating experiences of useful instrumentation and control equipment applied to the operation of a high-pressure high-capacity boiler. These descriptions and operating experiences cover not only completely automatically operating and control equipment, but also indicating and recording equipment to enable the operators to have constant knowledge of conditions, and thus provide for ready manual adjustments when the need is indicated.

The authors refer to the log of operations maintained and hourly simple control tests conducted by the high-pressure-turbine operator, in connection with chemical feed, blowdown, etc., for the No. 6 boiler. It has been of particular interest and satisfaction to note that a few minutes spent each hour on these readings and control, plus the daily complete check and establishment of the expected chemical-feed requirements for the next 24 hours by the chemical laboratory, have resulted in boiler-water conditions of unusual uniformity. This is of particular significance when one considers the fact that the Somerset Station is a tide-water plant, using salt water for condenser cooling. The significance of "close control" of boiler-water conditions at this plant will be particularly apparent by referring to the control ranges of various chemicals and salts maintained in the No. 6 boiler water, as given in another paper of this Montaup series by Scott and the writer.[7]

In discussing both the value and limitation of the hydrogen recorder, the authors also point out that copper oxide in the water

[6] Hall Laboratories, Inc., Pittsburgh, Pa.

[7] "Water Conditioning for the 2000-Psi Boiler at the Somerset Station of Montaup Electric Company," by W. W. Cerna and R. K. Scott, published on pages 443–451 of this issue of the Transactions.

system might serve as a means of combining with hydrogen to prevent the indication of hydrogen formation. That this mechanism can and does occur has been confirmed by some laboratory work carried out by Messrs. Kaufman and Trautman of our research department. The tests were conducted in laboratory bombs. One test, using a synthetic but highly concentrated boiler water with considerable alkali present to insure the formation of hydrogen at the test temperature, showed, as expected, considerable hydrogen formation. In another test synthetic boiler water of the same composition was used to which some solid copper oxide was added. The test conditions were repeated, with the result that very little free hydrogen was found and considerable of the copper oxide had been reduced to metallic copper.

Under similar boiler conditions copper salts or compounds would be effective in preventing hydrogen indication and recording by the recording instrument, as illustrated by the following reactions:

$$CuO + H_2 \rightarrow Cu + H_2O$$

$$Cu_2Cl_2 + H_2 + 2KOH \rightarrow 2Cu + 2KCl + 2H_2O$$

R. R. Donaldson.[8] Automatic combustion control, which started out as a convenient accessory for holding constant steam pressure, today has virtually the status of an integral part of the boiler plant. It is depended upon to perform the twin functions of regulating the operation of the boiler so as to satisfy the load demands in a desired manner and of automatically maintaining optimum controlled fuel-air ratios.

In accomplishing the latter function, that of production of proper fuel-air ratios, the ability to measure fuel input and air input is paramount in the present state of the art. It is fair to state that for the present, the production of desired fuel-air ratios by flow proportioning of fuel Btu and air represents the most advanced engineering solution. While someday we may reasonably expect to have gas-analyzing apparatus which is rapid and dependable enough to be used for automatic control of combustion, we have not yet reached that point.

The authors found that it was necessary to do considerable experimental work on their boiler before a satisfactory location for measurement of products of combustion or air flow could be obtained. Their final use of the Ljungström preheater drop gave them a satisfactory solution for this installation.

The difficulties encountered in measurement of air flow for boiler control are not unique with Montaup. There are many installations where perfection of results is limited chiefly by ability to measure air flow satisfactorily.

Admittedly, the problem of metering the products of combustion or the air supply to a large steam-generating unit is far more difficult than the ordinary metering of fluid flows. If, however, in the inception of every new steam-generating installation, the purchaser and the manufacturer of the equipment would spotlight this feature of the boiler design, there is no doubt that better operating installations from the standpoint of maintained furnace efficiencies would result.

The present paper will serve as a stimulus and spearhead to a concerted program for investigating and improving the metering characteristics of modern steam-generating equipment.

[8] Hagan Corporation, Pittsburgh, Pa. Mem. A.S.M.E.

Authors' Closure

Mr. Cerna has contributed valuably in presenting results from bomb tests conducted by Hall Laboratories, Incorporated, in studying the possibilities of reduction of copper oxide in high-pressure boiler water by hydrogen evolved from the boiler metal. Through the courtesy of the Laboratories we learn that similar tests more recently conducted in continuing their investigation have demonstrated that, by increasing the proportion of copper oxide added to the bomb solution, actual evolution of hydrogen may be practically prevented and that the same general effects are observed to occur in the bomb at the temperature with which we are concerned whether or not alkali other than from the boiler metal is present.

Mr. Finnegan's pressing emphasis[9] on the need for more fundamental work on the pure chemistry of the water-metal systems, especially throughout the high-temperature range, is very gratifying. Lack of fundamental information on the reactions of both iron and copper in the range of temperature and other environmental conditions met in the feedwater-boiler water-steam circuits of the high-pressure unit has been a serious handicap throughout the operation of boiler 6 to date.

Mr. Donaldson underscores very aptly the present necessity for dependable, instantaneous, mechanical evaluation of combustion air-flow from the standpoint of the control-equipment designer and manufacturer. The authors concur fully that provisions for evaluation for air-flow rate should be made one of the elementary considerations in design of the modern fuel-burning steam-generating unit.

The improvement work on the flue-gas oxygen-recording equipment and on the boiler-feed-pump flow recirculating valves, mentioned in the paper as to be undertaken, is going ahead promisingly but has not in either case progressed sufficiently to warrant further comment now. The installation of the boiler-circulating-pump pressure differential recorder also is not yet complete. In regard to the last-mentioned equipment however, such brief preliminary observations as have been made have brought to attention valuable data on pressure conditions during periods of boiler start-up and shutdown which would not otherwise have been noted and present impressions are that the information made available by the graphic record will prove even more useful than initially contemplated.

The Supply of Air to Coal-Fired Steam Locomotives

By R. A. SHERMAN,[1] W. H. BROWNE,[2] and R. B. ENGDAHL[2]

As part of the program of research for Bituminous Coal Research, Inc., means by which the performance of coal-fired steam locomotives can be improved are being investigated. Because of the importance of the method and of the rate of supply of air in any combustion process, an analysis has been made of the factors that govern the supply of air to the locomotive by its unique method of discharge of the exhaust steam to the stack through the front-end nozzle. The analysis shows that for any given front-end arrangement and locomotive, there is a definite upper limit of output of the locomotive at which the weight of air supplied will equal that required for the fuel burned. A similar but lower limit applies on the basis of fuel fired. Below these limits the percentage of excess air will increase with decreasing output of the locomotive; above the limits there will be a deficiency of air. The position of the limits is determined by the performance characteristics of the engine, of the boiler, and of the front-end arrangement. A program of research is outlined which is aimed to supply information (*a*) on the design of front ends for maximum combustion efficiency through proper excess air and minimum carry-over of cinders, and for maximum power output through reduction in back pressure on the cylinders, and (*b*) on the merits of overfire air in improving combustion efficiency through reduction in carry-over of cinders.

The method of supplying air to steam locomotives is unique. Whereas the stationary boiler plant has a high stack or, more commonly, fans to provide the pressure difference necessary to force the air through the fuel bed and the combustion gases over the heat-absorbing surfaces of the boiler, the steam locomotive has only a short stack that barely projects above the boiler shell. The pressure difference, usually called draft, is provided by discharging the steam exhausted from the cylinders through a nozzle at the base of the stack.

Furthermore, whereas the stationary boiler is equipped with dampers or other means by which the rate of air supply can be closely adjusted to the requirements of the load or of the fuel, the locomotive has, practically without exception, no independent control of the air supply. As the output of the engine increases, the amount of steam admitted to and exhausted from the engine increases, and the rate of supply of air for combustion of the fuel increases.

This simple method of supplying the air also serves to a considerable degree to decrease the objectionable noise of the exhaust steam. It was for this purpose that Trevithick and Stephenson, to whom first use of the method is variously credited, originally turned the exhaust steam into the stack. However, although the steam must be exhausted from the engines, the movement of air in this way is, obviously, not without expenditure of energy. The increase in back pressure on the cylinders, necessitated by the restriction of the nozzle, materially decreases the horsepower output of the locomotive.

This paper analyzes the available data on the performance of the air-supply system of locomotives to determine its relation to the efficiency of combustion and to that of the engine at various power outputs. The particular purpose is to determine what information on the problem of air supply is lacking that might be obtained by research, that the performance of coal-fired locomotives may be improved.

Previous Work

Few parts of the locomotive lend themselves to such ease of trials of changes as the exhaust nozzle and its arrangement with relation to the stack. Hence much cut-and-try work has gone on and has been reported in the literature. The International Railway Fuel Association and its successor, the Railway Fuel and Traveling Engineers Association, have long had a Standing Committee on Front Ends, Grates and Ash Pans, and the committee has, with few exceptions, had an annual report. No attempt will be made here to review completely these many reports.

One of the most thorough discussions of exhaust arrangements is that of Chapelon (1)[3] in his book on the steam locomotive, but this has not been generally available in this country. MacFarland (2) presented a discussion principally directed to a demonstration of the power loss through high back pressures because of restricted nozzles and made a plea for induced-draft fans. Jackson (3) recently gave a review of the problem of drafting locomotives with a discussion of the attempts at variable-exhaust nozzles.

Young (4) has presented a complete analysis of the early work on the drafting problem as an introduction to the report of his exhaustive experimental investigation of the performance of various types of nozzles. His work was done on a one-fourth-scale model of a locomotive.

Fry (25) has recently shown that the performance of the front end affects the efficiency of combustion and sets the maximum output of the locomotive.

Methods for Evaluation of Exhaust Arrangements

Despite the long use of the steam nozzle to move air and gases in the locomotive and its extended use in other applications as the boiler-feedwater injector, the steam-jet ejector for air-conditioning systems, and the steam jet for blowing air in overfire-air applications, the action of the nozzle is not wholly understood. The ability of the jet to entrain and to move air is apparently a function not only of the kinetic energy of the steam, but is also related to the exposed surface of the steam. Because of the importance of the latter factor the steam is often divided into multiple streams as in the pepperbox nozzle, or the surface is in-

Contributed by the Fuels and Railroad Divisions and presented at the Annual Meeting, New York, N. Y., Nov. 26–29, 1945, of The American Society of Mechanical Engineers.

[3] Numbers in parentheses refer to the Bibliography at the end of the paper.

creased by a star-shaped section, or by bridges. It is interesting to note, however, that Young (4) found, as a result of his tests, a difference from the worst to the best no greater than 12 per cent in the performance of various nozzles as expressed by the ratio of the weight of air moved to the weight of steam exhausted through the nozzle.

Because of the obvious necessity of high differences of pressure, or draft to move the gases through the restricted area of the long fire tubes of the locomotive boiler, and also the obvious undesirability of high back pressures on the engine cylinders, the number of inches of water draft in the front end per pound of back pressure has long been used as the criterion of the performance of front-end arrangements. Although this may apply for a given locomotive of fixed resistance to flow, an attempt to apply such a criterion to locomotives of different design and size is obviously in error. It is as incorrect as it would be to rate the capacity of fans by the static pressure that they develop, or to express the capacity of boilers by the pressure at which they operate.

Young (4, 5) clearly recognized that the value of a front-end arrangement should be measured by its ability to move air; this could not be measured by draft alone. In a discussion (6) of the paper by Jackson, he has made a good statement of the problem as follows:

"The actual problem of front-end design is to produce an arrangement which will pull an optimum weight of air through the fire for each pound of steam generated and discharged, maintaining at the same time, three mechanical conditions: 1 Minimum back pressure, 2 clearing the smokebox, and 3 lifting the smoke above the train. The greatest difficulties lie in the mutual incompatibility of these mechanical requirements."

Factors Affecting the Performance of Front Ends

Engdahl and Holton (7) in an investigation of steam-air jets for supplying overfire air have shown that with air tubes whose area is large relative to the area of the steam nozzle, ratios of the order of 200 to 500, as much as 15 to 20 lb of air could be moved per lb of steam used. They found, as others have shown, that the entrainment ratio increases as the steam pressure decreases and as the ratio of the area of the air tube to that of the steam nozzle increases. As they were interested in the jets as blowers to move air at high velocities against small differences in pressure, they did not investigate the effect of resistance to flow, but this should, obviously, affect the performance of jets. The temperature of the gases moved should also be important.

Effect of Steam Pressure at Nozzle. As the output of a locomotive increases, the weight of steam used and exhausted from the cylinders through the nozzle increases. The back pressure at the nozzle increases approximately as the square of the weight of steam discharged. Hence the range of back pressures at the nozzle is large.

Fig. 1 shows the variation of the entrainment ratio, the ratio of weight of gases to weight of steam, with back pressure for a typical locomotive. As expected, the air-steam ratio decreases with increase in back pressure. The ratio is much lower than those quoted from the work of Engdahl and Holton (7) on overfire-air jets because, as will be shown later, of the difference in area ratios of stack to nozzle, and because of the resistance to the flow of gases.

Effect of Ratio of Areas of Stack and Nozzle. As previously noted, almost every steam locomotive has been the subject of experiments on the exhaust nozzle and front-end arrangements and thus has had the ratio of the area of the stack to the nozzle changed. In these experiments, however, facilities have not been available to measure the air flow as well as the steam flow.

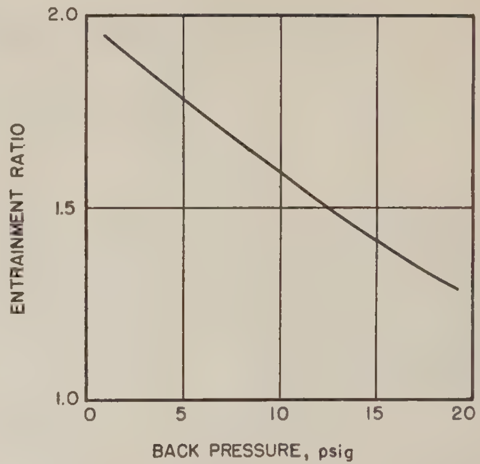

Fig. 1 Relation of Entrainment Ratio to Back Pressure on Nozzle for Typical Locomotive
(Ratio, area of stack to nozzle, 6.2. Resistance ratio, 4.5×10^{-5}.)

For data on the effect of this variable the work of Young (4) is used.

Fig. 2 shows the relation derived from Young's data of the entrainment ratio to the ratio of areas of stack and nozzle. As his data were obtained on a quarter-scale model, the original data have been corrected by the factors that he derived from principles of similarity. The pressures and dimensions are multiplied by 4, the reciprocal of the scale of the model, and weights of air and steam by $4^{5/2}$ or 32.

The curves show the increase of the entrainment ratio as the ratio of the area of stack to that of the nozzle increases. Curves for two steam pressures, 8 and 32 psig, are included. Again, the reduction of the entrainment ratio with increase in pressure is shown.

Effect of Resistance Against Which Gas Is Moved. A third factor which governs the performance of a locomotive front end is the resistance against which the gases must be moved. The resistance is determined by the path of the gases in the front end, the area and length of the tubes and flues of the boiler, the area of the throat back of the arch, the thickness of the fuel bed, the area of the air openings in the grate, and of the air openings into the ashpan.

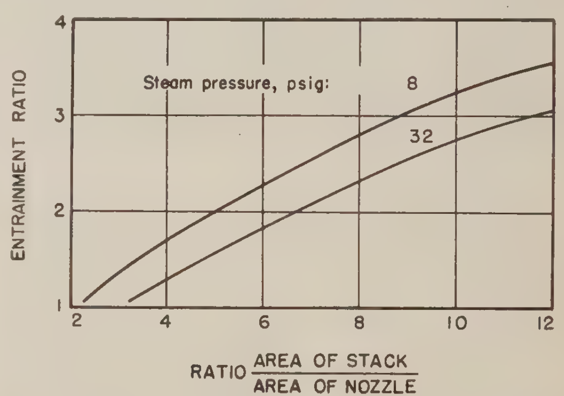

Fig. 2 Relation of Entrainment Ratio to Ratio of Area of Stack to Nozzle
(Resistance ratio, 2.8 to 3.0×10^{-5}. Data from Young (4) corrected for size ratio.)

The data in Fig. 2, as were most of the data presented by Young (4, 5), were taken with a fixed resistance made up of that of the locomotive model and an orifice of fixed area. The resistance was so chosen by Young as to simulate that of a full-scale locomotive.

Fig. 3 presents data obtained by Young in a series of tests in which the area of the orifice in the system was changed to vary the resistance. The solid portion of the curves covers the range of data given by Young; the dashed portion was drawn from data taken at Battelle on a $^1/_{16}$-scale model. Each curve represents one constant steam pressure on the nozzle.

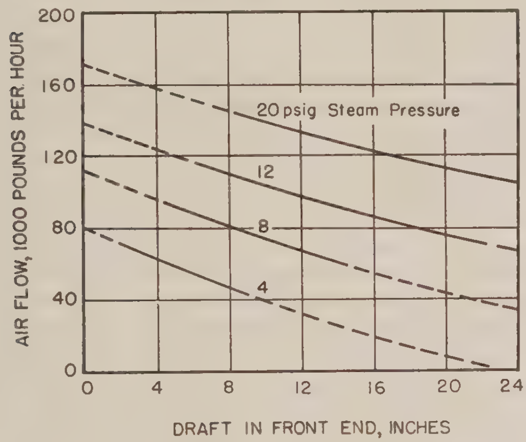

Fig. 3 Relation of Air Flow to Draft in Front End and to Steam Pressure

(Ratio of area of stack to nozzle, 11.1. Data from Young (4) corrected for size ratio.)

The curves in Fig. 3 show the way in which the rate of air flow decreases as the resistance, as indicated by the draft, increases. This figure demonstrates clearly the inadequacy of the draft as a criterion of the performance of front ends. By increase of resistance the draft obtained with a given nozzle and steam pressure can be increased, but the air supplied, which is the true measure of the performance, decreases.

Concept of Resistance to Gas Flow. In consideration of the flow of electricity, we have a concept of three definite measures; current, voltage, and resistance, and the familiar relation that

$$\text{Current} = \frac{\text{Voltage drop}}{\text{Resistance}}$$

In the flow of fluids we have, corresponding to current, the volume or weight of the fluid, and to voltage, the pressure drop, but no term for resistance is in common use. As a result the pressure against which the pump, fan, or ejector moves the fluid is often used as a measure of the resistance. In locomotives the pressure is less than atmospheric and is termed draft.

Unfortunately, also, the term draft is often confusedly used not only as a measure of pressure drop and resistance, but also of rate of flow of gas as well; that is, a high draft is often assumed to be synonymous with a high rate of flow of gas. As just shown in Fig. 3, this is far from necessarily true.

The general relation of the rate of flow of gases to the pressure difference in turbulent flow is

$$Wa = K\sqrt{d}$$

where

Wa = rate of flow in pounds per hour

K = a constant coefficient involving a number of physical factors in the system of flow

d = pressure difference or draft in inches of water

Legein (8) introduced the conception of a factor of temperament, T, in his studies of locomotive drafting, and Chapelon (1) and Young (5) have also used it, but otherwise it has not been used in this country. The temperament is equivalent to the constant coefficient K in the foregoing equation. Thus we have

$$Wa = T\sqrt{d}$$

$$T = \frac{Wa}{\sqrt{d}}$$

Compared with the flow of electricity, the temperament T corresponds to the conductivity.

The reciprocal of the conductivity can, however, be as conveniently used, and we have

$$Wa = \frac{\sqrt{d}}{R}$$

$$R = \frac{\sqrt{d}}{Wa}$$

This expression considers both the pressure difference or draft and the rate of flow of gas and thus permits proper comparison of different locomotives or parts of the gas-flow system of a given locomotive.

Fig. 4 presents Young's data used for Fig. 3 in which the ratios of weights of air and steam are plotted against the resistances to flow. The curves show a sharp decrease in the entrainment ratio with an increase in the resistance. The curves emphasize again the impossibility of accurate comparison of the performance of front ends of locomotives without consideration of the resistance of the gas-flow system.

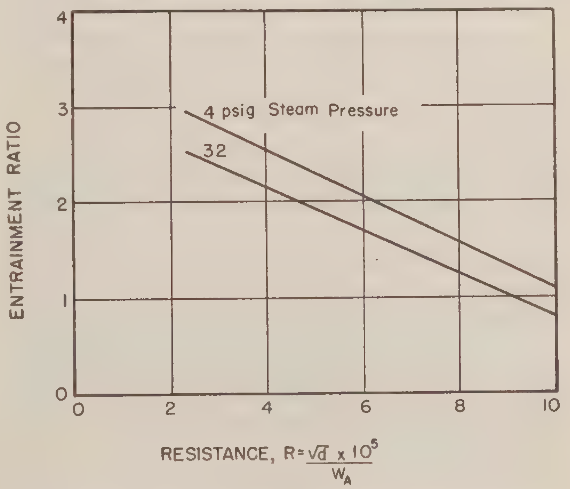

Fig. 4 Relation of Entrainment Ratio to Resistance to Air Flow

(Ratio of area of stack to area of nozzle, 11.1. Data from Young (4) corrected for size ratio.)

Effect of Temperature of Gas. The data of Young that have been used are for the movement of air at atmospheric temperatures, for which most of his tests were run. He did, however, investigate the effect of temperature, and Fig. 5 shows the relation that he found. The reduction in the entrainment ratio was as

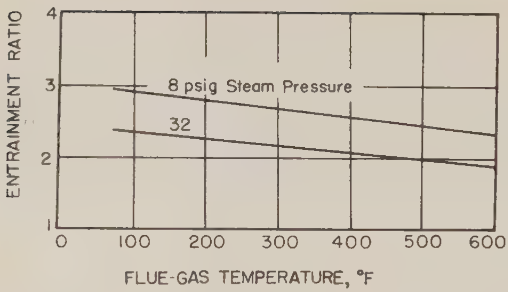

Fig. 5 Relation of Entrainment Ratio to Flue-Gas Temperature

(Ratio of area of stack to area of nozzle, 8.5; resistance ratio, 2.8 to 3.0 × 10^{-5}. Data from Young (4) corrected for size ratio.)

great as 25 per cent for gas at 600 F as compared to gas at room temperature.

The percentage reduction in entrainment ratio by increase in the flue-gas temperature increased as the rate of flow of gases increased. Hence it may be concluded that the effect of temperature in full-scale locomotives would probably be greater than found by Young. His model did not include a boiler, although it did have flues, and thus the temperature gradient in the gases was obviously lower than in a locomotive.

Summary of Factors Affecting Front-End Performance. The data that have been presented show that all four factors, steam pressure, ratio of area of stack to nozzle, resistance of the gas-flow system, and the flue-gas temperature are of major importance in determining the performance of the locomotive front end. Other factors, as the distance between the nozzle and base of stack, and length and taper of stack, also affect the performance but are of less importance. The data also show that it should be possible to predict the performance of a front end and to eliminate the cut-and-try methods that have been so largely used.

That Young's data are applicable to full-scale locomotives may not be apparent at once. Fig. 1 showed entrainment ratios of the order of 1.25 to 2, while the figures prepared from the model tests showed entrainment ratios of the order of 2 to 3. However, we note in Fig. 2 that the entrainment ratio for a steam pressure of 32 psig and a stack- to nozzle-area ratio of 6.2, which is that of the locomotive in Fig. 1, is slightly less than 2. If we apply that point to Fig. 4 at the resistance ratio of about 3 × 10^{-5}, the resistance for the locomotive of Fig. 1, an entrainment ratio of the order of 1.5, or within the range of Fig. 1 will result, even without correction for temperature.

Hence Young's data provide an excellent basis for the development of basic design data for front ends. They require supplementary and confirming tests on full-scale locomotives where care is taken to obtain accurately the weight of gases moved. More data are also required on the resistance of the gas-flow system in locomotives. This, again, requires accurate information on the weight of gas moved.

Relation of Front-End Performance to Air-Fuel Ratio

Now that we have established the general effect of the several pertinent factors on the amount of gas moved by the front end, let us examine how it satisfies the air requirements of a locomotive at various power outputs.

Fig. 6 presents six plots that develop the relation for a typical locomotive between the requirements and the supply of air. Plot (A) shows the relation between the hourly steam output of the boiler and the locomotive output in drawbar horsepower. This is a straight-line relation because the cylinder efficiency and the mechanical efficiency were practically constant over the range of outputs.

Plot (B) shows the relation between the heat-liberation requirements expressed in pounds of coal per hour and the steam output. This is essentially a straight line as the efficiency of heat absorption is practically constant. Note that this is the heat liberated from the coal burned and not the coal fired. As is well known and as will be discussed later, there is a large loss of heating value of the coal fired at high rates because of the solid combustible matter that passes out of the firebox unburned. Combustible matter that does not burn does not use air and is thus not here considered.

Plot (C) shows the relation of the weight of air required per hour to the coal burned. As a definite weight of air is required per pound of coal, this relation, too, is obviously a straight line. Plot (D) shows the relation between the entrainment ratio, weight of air per pound of steam, and the output of steam. Because the back pressure on the cylinders increases as the rate of steam output increases, and because the entrainment ratio decreases with increase of pressure, we have the relation shown.

Plot (E) shows the relation of the air requirements and the air supplied to the drawbar-horsepower output of the locomotive. Combining relations shown in plots (A), (B), and (C) gives us the curve of air required, which is a straight line. Combining (A), (B), and (D) gives us the curve of air supplied. The nozzle in this particular locomotive gave such entrainment ratios that the rate of air supply first increased at a faster rate than the rate of

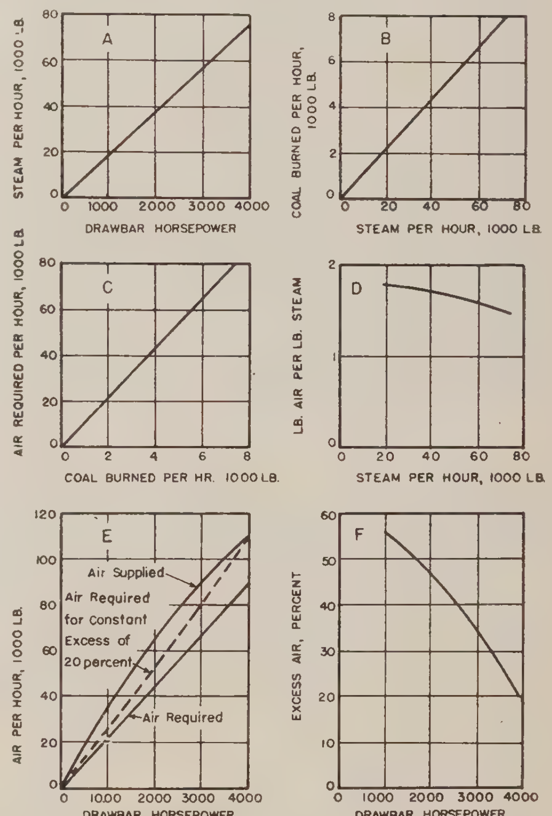

Fig. 6 Development of Relation Between Air Requirements of Locomotive at Different Rates of Power Output and Air Supplied by Front End

air requirements but, because of the decrease of the entrainment rate with increase in back pressure, the rate of increase dropped off at high power outputs.

Combustion of any fuel requires a certain amount of excess air, either to avoid losses in unburned gaseous combustible matter, or to avoid excessively high temperatures. This excess, for good efficiency in heat transfer, should be at a minimum. Whether the excess should be constant over the range of rates of operation, or whether it should increase or decrease with the rate cannot be definitely and generally answered; it depends upon the design of the combustion device.

However, it can be stated with assurance that the amount of air supplied should never be less than required. If it were, although by firing more fuel, the output of the boiler and engine would continue to increase, the unburned combustible losses would become excessive, and the over-all efficiency would be low.

Plot (F) in Fig. 6 shows the relation of the excess air as calculated from the curves of air required and air supplied in plot (E). It can be seen that the percentage excess was rapidly decreasing; if the locomotive had been carried to higher outputs there would have been an actual deficiency of air.

If the front end of the locomotive had been so designed as to follow exactly the air requirements at low outputs the drooping characteristics of the air-supplied curve would have resulted in a deficiency of air at a much lower power output.

The dashed curve in plot (E) shows the correct characteristic for a constant excess of 20 per cent for this locomotive.

Calculations of Conditions for Equilibrium of Requirements and Supply of Air. The relations established by curves as in Fig. 6 can also be worked out by simple mathematical relations. The following expressions give the relations between the weights of air supplied and required:

$$\left[\frac{\textit{Locomotive}}{\textit{Performance}}\right]\left[\frac{\textit{Boiler}}{\textit{Performance}}\right]$$

$$\frac{\text{Lb air req'd}}{\text{Dhp}} = \frac{\text{Lb steam}}{\text{Dhp}} \times \frac{\text{Lb coal}}{\text{Lb steam}} \times \frac{\text{Lb air req'd}}{\text{Lb coal}} \ldots [1]$$

$$\left[\frac{\textit{Locomotive}}{\textit{Performance}}\right]\left[\frac{\textit{Nozzle}}{\textit{Performance}}\right]$$

$$\frac{\text{Lb air supplied}}{\text{Dhp}} = \frac{\text{Lb steam}}{\text{Dhp}} \times \frac{\text{Lb air entrained}}{\text{Lb steam}} \ldots . [2]$$

But in Equation [1]

$$\frac{\text{Lb coal}}{\text{Lb steam}} = \frac{\dfrac{\text{Btu}}{\text{Lb steam}}}{\dfrac{\text{Btu absorbed}}{\text{Btu liberated}} \times \dfrac{\text{Btu}}{\text{Lb coal}}}$$

$$= \frac{\text{Btu}}{\text{Lb steam}} \times \frac{\text{Btu liberated}}{\text{Btu absorbed}} \times \frac{\text{Lb coal}}{\text{Btu}} \ldots\ldots\ldots [3]$$

and

$$\frac{\text{Lb air req'd}}{\text{Lb coal}} = \frac{\text{Lb air req'd}}{\text{Btu}} \times \frac{\text{Btu}}{\text{Lb coal}}$$

It is well established, although not so widely recognized as it should be, that the weight of air required per Btu is practically constant for solid, liquid, and most gaseous fuels. The value is 7.56 lb of air per 10,000 Btu or 7.56×10^{-4} per Btu. Hence we have

$$\frac{\text{Lb air req'd}}{\text{Lb coal}} = 7.56 \times 10^{-4} \times \frac{\text{Btu}}{\text{Lb coal}} \ldots\ldots\ldots [4]$$

Substituting values in Equations [3] and [4] in [1],

$$\frac{\text{Lb air req'd}}{\text{Dhp}} = \frac{\text{Lb steam}}{\text{Dhp}} \times \frac{\text{Btu}}{\text{Lb steam}} \times \frac{\text{Btu liberated}}{\text{Btu absorbed}} \times \frac{\text{Lb coal}}{\text{Btu}} \times 7.56 \times 10^{-4} \times \frac{\text{Btu}}{\text{Lb coal}}$$

which becomes

$$\frac{\text{Lb air req'd}}{\text{Dhp}} = \frac{\text{Lb steam}}{\text{Dhp}} \times \frac{\text{Btu}}{\text{Lb steam}} \times \frac{\text{Btu liberated}}{\text{Btu absorbed}} \times 7.56 \times 10^{-4} \ldots\ldots [5]$$

The factor of calorific value of the coal cancels out and the weight of air per drawbar horsepower is dependent only on the efficiency of the locomotive in the use of steam, the enthalpy of the steam, and the absorption efficiency of the boiler, and is independent of the calorific value of the coal.

This proves that if the not infrequent statement that a locomotive was correctly drafted for one coal, but not for another, is correct, it is not so because of differing air requirements based upon calorific value. It may, however, have a basis in the fact that one coal may require a higher excess of air, either to avoid losses in unburned gaseous combustible, or to avoid clinkering and slagging difficulties because of the fusion characteristics of its ash.

Returning to Equations [2] and [5] for the air supplied and required, it can be seen that in equating them the factor of locomotive performance is eliminated and we have

$$\frac{\text{Lb air entrained}}{\text{Lb steam}} = \frac{\text{Btu}}{\text{Lb steam}} \times \frac{\text{Btu liberated}}{\text{Btu absorbed}} \times 7.56 \times 10^{-4} \ldots\ldots [6]$$

Using Equation [6], we can calculate the entrainment ratio we must have under given conditions. For example, if the Btu per pound of steam, its enthalpy, is 1300, and if the boiler absorption efficiency is 80 per cent

$$\frac{\text{Lb air entrained}}{\text{Lb steam}} = 1300 \times \frac{100}{80} \times 7.56 \times 10^{-4}$$

$$= 1.23$$

The entrainment ratio of the front end must be 1.23 if the theoretical air requirements of the coal burned are to be met. If an excess of 20 per cent is required, the entrainment ratio must be $1.20 \times 1.23 = 1.48$.

Thus as has also been shown by Fry (25) the calculation of the required entrainment ratio for the front end reduces to an extremely simple basis. If we knew accurately the values of the several variables that fix the entrainment ratio, the design of a front end could be reduced to an exact engineering operation.

Relation of Excess Air to Power Output. Relations similar to those in Fig. 6 have been worked out for several locomotives from data from testing plant tests of the Pennsylvania Railroad and the University of Illinois. They all show similar relations to those presented and it is needless to burden this report with them.

The percentage excess air can, of course, be calculated from the composition of the flue gases and it is usually a standard item in the report of a locomotive test. The excess air calculated from the flue-gas composition gives, it must be recalled, the excess on the basis of the fuel burned and not on the basis of the fuel fired. Hence the values obtained are comparable with those presented in Fig. 6.

Fig. 7 presents the relation of the percentage excess air to the output for four locomotives: a Mikado 2-8-2 tested at the Uni-

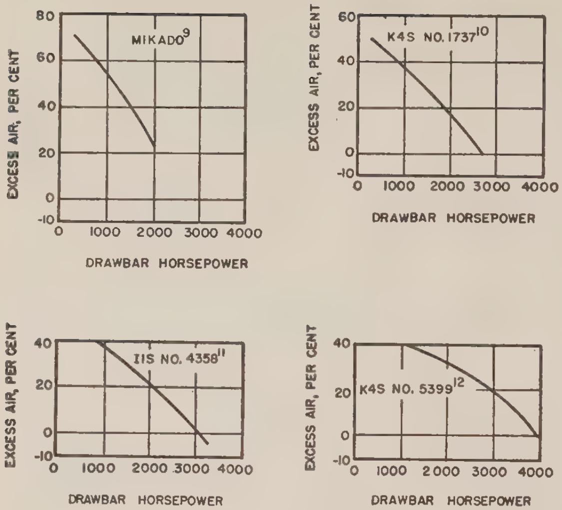

Fig. 7 Relation of Excess Air to Power Output for Four Locomotives

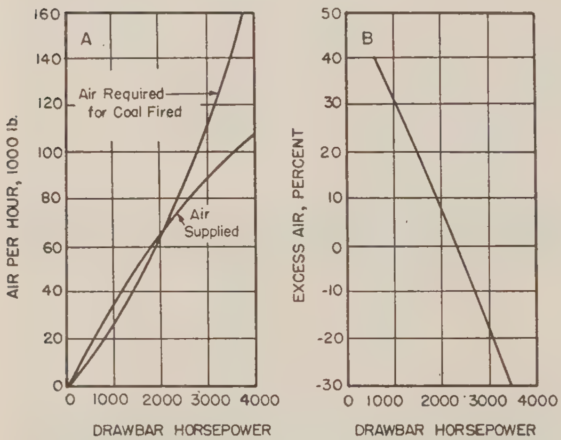

Fig. 8 Relation of Weight of Air Required and Supplied, and of Percentage Excess Air to Power Output of Locomotive on Basis of Coal Fired

versity of Illinois (9); a K-4-S No. 1737 (10); an I-1-S No. 4358 (11); and a K-4-S No. 5399 (12); all tested at the Altoona testing plant of the Pennsylvania Railroad.

The four curves have the same characteristic shape. Two of them reached zero excess air, and one showed an actual deficiency, at the maximum output at which they were tested.

Relation of Air Supplied by Front End to Air Required for Coal Fired. The calculations and considerations up to this point have been on the basis of the coal burned or heat liberated. It is more customary, however, in locomotive practice, to consider the over-all performance on the basis of the coal fired to the grate.

Fig. 8 shows on this basis the relation of the air required and supplied for the same locomotive used as an example in Fig. 6. The method of development was the same as for the former figure, but only the curves for the air required, and the air supplied, and the curve of percentage excess air are shown in plots (A) and (B), respectively.

Above an output of 2200 drawbar horsepower (dhp), the amount of air supplied by the front end was less than that required for the coal fired, and the deficiency amounted to 30 per cent at an output of 3500 dhp. On the basis of the heat liberated from the coal burned, plot (F) in Fig. 6 showed that there was still an excess of 28 per cent at that power output.

Fig. 8 shows that at an output of 3500 dhp the air required for the coal fired was 142,000 lb per hr. At this output, as shown in Fig. 6, the steam generated and exhausted through the nozzle was 65,000 lb per hr. For the front end to have supplied the air required, each pound of steam would have had to have entrained 2.18 lb of air. Actually, the entrainment ratio at this output was 1.50.

The data on locomotive performance which have been examined in this study have shown no front ends that had entrainment ratios of over 2 at high outputs, although conceivably, one might be designed for such performance.

If, however, the front end did supply enough air for the coal fired at an output of 3200 dhp and if, as it must, the performance curve was the same as shown in Fig. 8, plot (A), then it is obvious that the percentage excess air at all lower outputs would have been very great.

General Law of Front-End Performance. From the foregoing considerations one can draw the following generalization or law on the performance of front ends relative to their function of moving the air and combustion gases:

For any given front-end arrangement and locomotive there is a definite upper limit of output of the locomotive at which the weight of air supplied will equal that required for the fuel burned. A similar but lower limit applies on the basis of fuel fired. Below these limits the percentage of excess air will increase with decreasing output of the locomotive; above the limits there will be a deficiency of air. The position of the limits is determined by the performance characteristics of the engine, of the boiler, and of the front-end arrangements.

To use terms common in locomotive practice, this law means that if a locomotive is correctly drafted at a given output it will be overdrafted at all lower outputs and underdrafted at higher outputs. It does not follow, necessarily, that all locomotives are correctly drafted at the maximum output at which they are designed to operate. They may be either underdrafted or overdrafted at that point, but it follows that the trend will be toward overdrafting at lower rates and underdrafting at higher rates. The possibility of manual or automatic controls to maintain a constant excess of air will be discussed later.

Relation of Performance of Front End to Loss of Heat in Cinders

Fig. 9 shows the relation of the percentage heat loss in cinders, together with that of the excess air, on the basis of the coal fired as in plot (B) Fig. 8, to the power output of a locomotive. The rather rapid rise of the loss in cinders at the power outputs in which the air supplied drops below the air required would seem to indicate that the cause of the rise in cinder loss might be the deficiency of air.

This can best be analyzed, perhaps, by comparison of the cinder loss in locomotives where the rate of air supply is a variable, dependent upon the rate of steam generation, and in stationary boilers where the rate of air supply is a variable, independent of the rate of steaming or rate of firing, and is controlled by dampers or fans.

Fig. 10 shows a comparison of the relation of the cinder loss to the rate of firing in pounds of coal per square foot for a locomotive fired by a stoker, and for a stationary boiler fired by underfeed stokers. Data on a stationary boiler fired by spreader stokers would have been preferred, but they were not found. The locomotive data are from the tests by Collins (13) of a J-1-b; the

stationary-boiler data are those given by Driscoll and Sperr (14).

Two facts stand out in these data, as follows: (*a*) At low rates of firing of the locomotive when there is an ample excess of air, the cinder loss is higher than for the stationary boiler; (*b*) at a rate of approximately 75 lb of coal per sq ft per hr, the loss of cinders from the stationary boiler equals that of the locomotive and the direction of the curve is steeply upward.

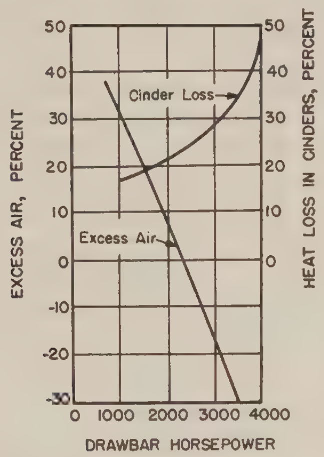

Fig. 9 Relation of Excess Air on Basis of Coal Fired and Cinder Loss to Power Output of Locomotive

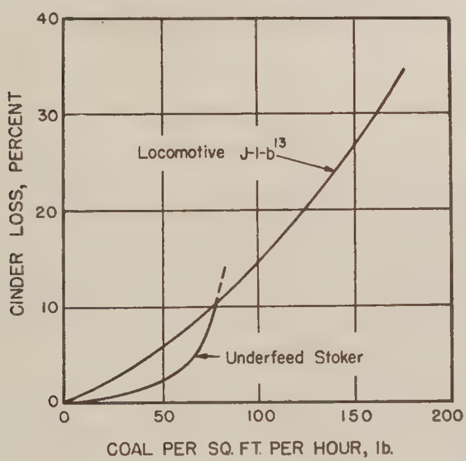

Fig. 10 Comparison of Relation of Cinder Loss to Rate of Firing in Locomotives and Stationary Boilers Fired With Underfeed Stokers

As there was no question of deficiency of air supply in the stationary boiler, the conclusion to be drawn is that the deficiency in air supply, on the basis of the coal fired, is not the major cause of the high cinder loss at high rates of firing in the locomotive. Rather, the high cinder loss is the result of the high carrying power of the gases for solids at the high velocity with which they move through the combustion chamber at high rates of operation. Coal is both carried out of the bed and is swept out of the stream of coal being fired before it reaches the fuel bed.

The probability is that the loss might be somewhat lower if an excess of air were present because the rate of burning in suspension is affected by the amount of oxygen present in the gas. But because the time is so short only the smaller particles would have an opportunity to burn.

Effect of Back Pressure on Power Output

As mentioned in the introduction of the paper, the back pressure on the cylinders which is required to discharge the steam through the nozzle, both increases the amount of steam required for a given output and reduces the maximum power developed. This has always been well recognized, and MacFarland (2) presented extensive data on the back-pressure power loss as calculated from indicator diagrams. Hence but one example will be required to demonstrate the magnitude of the loss of power.

Fig. 11 shows the relation of the horsepower loss by back pressure for locomotive No. 4358 of Class I-1-S (11) to the output. The back-pressure horsepower was calculated as the difference

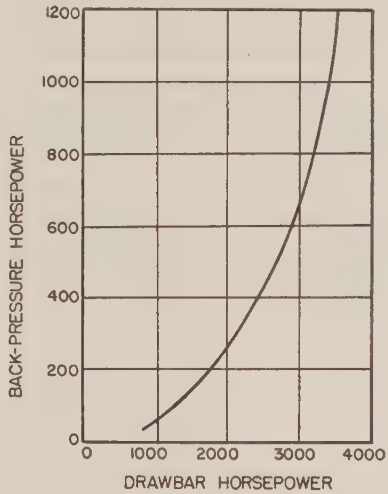

Fig. 11 Horsepower Loss by Back Pressure on Locomotive I-1-S, No. 4358 (Reference 11)

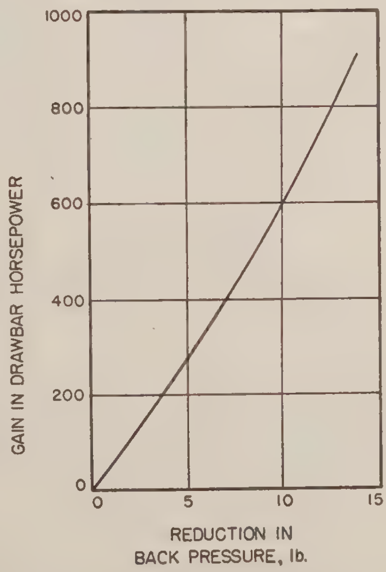

Fig. 12 Gain in Power Output of Locomotive I-1-S, No. 4358, by Reduction in Back Pressure From 14 Psig

in the horsepower actually developed and that which would have been developed if the steam had been expanded to one tenth of the gage back pressure. Although this degree of reduction in pressure was arbitrarily selected, it is satisfactory to illustrate the order of the power loss.

The loss in power increases rapidly with the increase in the net power output and amounts to about 1200 hp or one third of the net maximum output of the locomotive. The desirability of reduction of this loss is obvious.

Fig. 12 presents one further demonstration of the gain in power output by decrease in back pressure. This shows, for the same locomotive as Fig. 11, the gain in output for the same steam consumption by reduction in the back pressure at an output of 2930 dhp, and a back pressure of 14 psig. The gain is slightly more than directly proportional to the reduction in pressure, but for this locomotive each 1-lb reduction means a gain of approximately 60 dhp.

Efficiency of Front End

Fig. 13 shows the power required to supply the air and move the combustion gases through the boiler for the same locomotive used in the example, Fig. 11. The air horsepower was calculated in the usual manner from the rate of flow of the gases, with correction for temperature, and the pressure against which the gases were moved.

Also shown in Fig. 13 is the ratio of the power required to move the gases to the power lost by the back pressure. Above an output of 1000 dhp the ratio is about constant at $^{1}/_{10}$, that is,

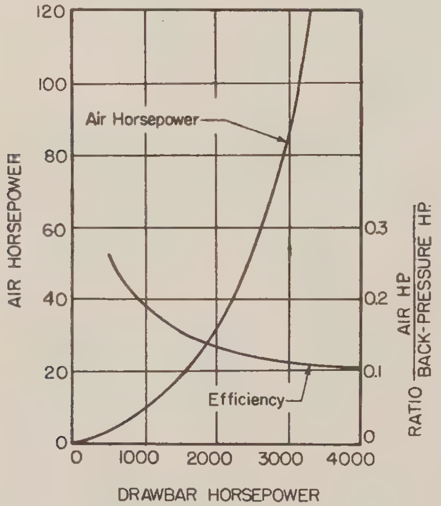

Fig. 13 Relation of Air Horsepower Required to Move Air and Gases and of Ratio of Air Horsepower to Back-Pressure Horsepower to Output of Locomotive

the efficiency of the front end, by this method of calculation, is 10 to 20 per cent.

Young (4) has shown that on the basis of the kinetic energies in the gases and in the steam at the nozzle, the efficiency of the front end is of the order of 5 per cent, but it is considered that the foregoing calculation is of greater significance.

Possibilities of Improvement in Design and Performance of Locomotive Air-Supply Systems

The lines along which efforts to improve the combustion efficiency and over-all performance of the coal-fired locomotive should proceed become clear from the analysis that has been presented. They are as follows: (*a*) To control the drafting appliance that the percentage excess of air for the coal burned will be essentially constant at all rates of operation; and (*b*) to move the air and combustion gases with the minimum back pressure on the cylinders.

With these objectives in mind we shall review the various methods of improvement that have been tried in the past. These include the following: (*a*) Change in area or shape of the nozzle; (*b*) change in area of stack; (*c*) change in resistance to air flow; (*d*) manually and automatically variable nozzles; and (*e*) induced- and forced-draft fans.

Change in Area and Shape of Nozzle. Probably the most common method of changing the locomotive to improve its "drafting" is to change the diameter of the nozzle or to change to one of

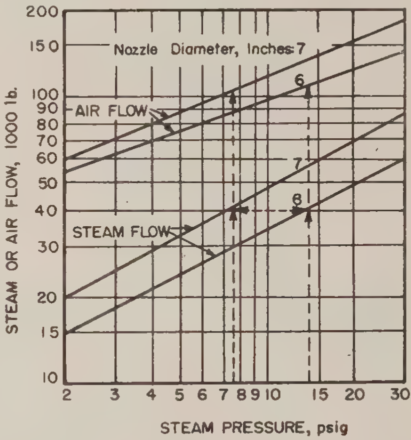

Fig. 14 Relation of Steam Pressure at Nozzle to Rate of Flow of Air and Steam
(Data from Young, reference 4, corrected for size ratio.)

special shape. If the engine does not "steam" properly the usual step is to insert a small nozzle. If it seems wasteful of fuel or emits excessive cinders, a larger nozzle is put in.

Fig. 14 presents curves from Young's work (4) which permit an analysis of what happens when the size of the nozzle is changed. The relations between the steam pressure on the nozzle and the rate of steam and of air flow are plotted on logarithmic paper on which they assume straight lines.

Let us assume first that the locomotive has a 7-in-diam nozzle and is found not to steam properly. A 6-in. nozzle is installed. The dashed lines indicate, as an example, that when the pressure at the nozzle was 7.6 psi, the rate of flow of steam was 40,000 lb per hr, and the rate of flow of air was 105,000 lb per hr. If the flow of steam remains the same, the back pressure with the 6-in. nozzle will be 14 psi; the air flow will be 109,000 lb per hr. The increase is only 4 per cent and is caused, it is to be noted, not because of the increased steam pressure, as we have seen that this decreases the entrainment ratio; instead, it is because of the increase in the ratio of area of stack to nozzle because of decrease in the area of the latter.

Actually, to maintain the same power output from the locomotive with the smaller nozzle would necessitate an increase in steam flow because of the increased loss in power by increase in back pressure. The cutoff would have to be increased, the rate of flow of steam and the back pressure would increase, and the flow of air would increase. A greater net output will be obtained from the engine but at a lower engine efficiency.

Conversely, it can be seen that if a change was made from a 6-

in. to a 7-in. nozzle, the cutoff could be decreased to obtain the same output and the steam flow and air flow would decrease more than shown by the dashed lines.

The size of the nozzle must be of course that which will give the design output of the locomotive, but data should be made available which would make unnecessary a trial-and-error method to establish the correct size. As for special designs and shapes, some have merit, but Young's findings have already been recalled; namely, that among all that he tried the best was only 12 per cent better than the poorest.

Although the size of the nozzle may be varied, we have seen that the laws of flow are such that the percentage excess air supplied will decrease with increase in rate of output of the locomotive, and a fixed nozzle cannot change this fundamental relation.

Change of Area of Stack. The dimensions of the stack of a locomotive once built are not susceptible of simple change and less experimenting has been done with the stack.

For maximum performance of any given combination of stack and nozzle, the distance from the nozzle to the top of the stack must be such that the steam will fill or "seal" the stack. Because the height of the stack is limited by the clearances of the right of way, there is a limit to the stack diameter that can be used.

Furthermore, as the stack diameter is increased, the velocity of discharge of the gases is decreased and trailing smoke that obscures vision may result. European locomotives have often used "wings" to lift the gases above the train. They have also been used to some extent in this country.

Change of Resistance to Air Flow. The analysis in the earlier part of the paper showed that the resistance against which the air and gases are moved is one of the principal factors that determine the entrainment ratio of an exhaust nozzle. The expression for resistance

$$R = \frac{\sqrt{d}}{Wa}$$

was suggested.

Table 1 gives some of the data on five locomotives, the average over-all resistance calculated from the draft in the front end, the resistance of the tubes from the pressure drop across them, and the ratio of the two resistances.

Resistance values from individual tests of each locomotive showed no general trend with locomotive output but were, with few exceptions, nearly constant at the average value shown. When it is seen that the resistance of the tubes is 67 to 75 per cent as large as the total resistance, it is not surprising that the over-all resistance should not change with a change in the thickness of the fuel bed or other variables in the course of tests at various rates of output.

Table 2 gives the pressure drop across various parts of the air- and gas-flow system of a locomotive, the resistance of each section, and the ratio of each to the over-all resistance.

The last column of Table 2 gives the ratio of the resistance of each of the several parts of the system to the over-all resistance. It must be remembered that the sum of the resistances is not equal to the total resistance; instead, the total resistance equals the square root of the sum of the squares of the resistances of the separate parts..

Resistance of Diaphragm and Tubes. The two largest single resistances in the system are those of the diaphragm and tubes. They are, respectively, 59 and 51 per cent of the over-all resistance or together

$$\frac{100\sqrt{2.3^2 + 2.0^2}}{3.9} = 78 \text{ per cent of the total}$$

Hence it would seem that here lies the greatest opportunity for reduction in the resistance and thus the improvement in the performance of the exhaust system.

The function of the diaphragm is to break up and extinguish cinders that they may be discharged freely and harmlessly from the stack. Many variations, such as so-called cyclone front ends, have been tried. A review of all suggested designs and an experimental program on new designs would now be in order.

The resistance of the tubes is high because of the high velocity with which the gases are passed through them. This high velocity results in excellent heat transfer but, as previously pointed out, at the expense of a loss of efficiency of the engine because of the high back pressure.

The over-all efficiency of the locomotive in its use of the heat liberated from the coal is the product of the efficiency of the engine and that of the boiler. As the efficiency of the engine decreases and that of the boiler increases, as the area of the tubes is decreased or their length is increased, there is a value for area and length at which the over-all efficiency is at an optimum.

An analysis to establish whether the values now used in locomotive design are the optimum should be made. If not, experimental research to establish the optimum should be carried out.

Resistance of the Arch. The resistance to the flow of gases backward to the throat of the arch and then by a hairpin turn forward is an important part of the resistance, but the gain in combustion efficiency by this turbulence and in absorption efficiency by the surface of the tubes is large and cannot be sacrificed. It is possible, however, that in the locomotive used as an example, and others, the throat is too small and should be increased.

Resistance of Fuel Bed and Grate. What part of the resistance of the fuel bed and grate is caused by the fuel bed and what by the grate separately is not known. They must be considered together. The total is the smallest of the four resistances so far considered. Even if the resistance could be removed entirely, the flow through the system would not be greatly increased.

For example, the over-all pressure drop would be reduced from

TABLE 1 AVERAGE RESISTANCE TO FLOW OF GAS FOR FIVE LOCOMOTIVES

Locomotive	Max dhp	Grate air openings, per cent	Areas, sq in. Nozzle	Areas, sq in. Stack	Ratio, (Area of stack)/(Area of nozzle)	Resistance Total	Resistance Tubes	Ratio, R(tubes)/R(total)
I-1-S 4358(11)	3334	32	35.9	314	8.8	5.0	3.7	0.74

TABLE 2 DRAFT, PRESSURE DROPS, AND RESISTANCE TO GAS FLOW IN LOCOMOTIVE[a]

Position	Draft, in. water	Pressure drop, in. water	R, $\frac{\sqrt{d}}{Wa} \times 10^5$	Ratio to over-all resistance
Front end	20.1	...	3.9	1.00
Across diaphragm	..	6.9	2.3	0.59
Back of diaphragm	13.2	...	...	..
Across tubes	..	5.3	2.0	0.51
At flue sheet	7.9	...	...	..
Across arch	..	4.2	1.8	0.46
Firebox	3.7	...	...	..
Across fuel bed	..	3.0	1.5	0.38
Ashpan	0.7	...	...	..
To atmosphere	..	0.7	0.7	0.18

[a] Drawbar horsepower = 3839. Air flow = 114,600 lb per hr.

20.1 to 17.1 in. and the resistance would be as 20.1 to 17.1 or as 4.5 to 4.1. The rate of flow for a given draft varies inversely as the resistances. Hence for the same draft in the front end the rate of flow without the resistance of the fuel bed and grates would be $\frac{4.5}{4.1} = 110$ or 10 per cent greater.

This shows that the effect of reductions in the percentage air openings in the grates, which is often now as low as 7 to 10 per cent compared to 40 to 50 in earlier locomotives, is not that of so increasing the resistance that the ratio of air to fuel is decreased. Instead, the advantage of reduced air openings is that they improve the distribution of the air over the grate and prevent the passage of a large amount of air through a hole that may occur in the fuel bed.

Resistance of Ashpan. The resistance offered to the flow of air by the inlets to the ashpan is much the smallest of the several resistances, but the fact that there should be any resistance, as evidenced by a draft in the ashpan, has often been questioned by engineers.

Even if it were removed, the change in the over-all resistance would be small, of the order of

$$\frac{\sqrt{20.1 - 0.7}}{\sqrt{20.1}} = \frac{4.4}{4.5} = 0.98$$

that is, a 2 per cent decrease. This is small but a reduction would undoubtedly be desirable. The seemingly prevalent rule that the area of the inlets to the ashpan should be 15 per cent of the area of the grate may well be questioned.

Manually and Automatically Controlled Front Ends. Many suggestions have been made of variable nozzles, some controlled manually from the cab and some automatically. The history of the manually controlled nozzles has been that they were difficult to maintain in working order at the temperatures of the front end or that they were closed to their minimum at all times. Their acceptance in this country has not been great.

Lewis Nozzle. Of the several automatically controlled nozzles, the Lewis, described by Jackson (3), attained some use. It was a slot-type nozzle in which two vanes were mounted on shafts which were geared together and connected to a weighted loading arm damped by a dashpot. The vanes "pumped" at low engine speeds as the back pressure varied, but at high speeds they rode at balance, opening further as the pressure increased. The desired functioning was never clearly described in terms of rate of air flow at various outputs. One statement was made that a constant draft was obtained. This is obviously impossible and undesirable as the draft must increase as the rate of output increases.

The action must have been that by opening with increased pressure, the back pressure was held down but because the ratio of area of stack to nozzle was decreased, the rate of air supply was less than it would have been with a fixed nozzle. The reverse has been shown to be the desirable action.

Bertram Automatic Drafting. A device for automatic control of the draft on a locomotive is covered by two patents (16, 17) to Bertram, and some results have been described. It consists of several spring-opposed (18) valves in a line leading from the exhaust pipe to the atmosphere. The valves start to open at a pressure of 5 to 6 lb, and by by-passing part of the steam from the exhaust nozzle the back pressure is reduced. Also, it must reduce the amount of air moved by a nozzle of the same size; whereas we have seen that the need is for a greater amount of air at high rates and a reduction at low rates.

If a smaller nozzle than normal for a nonautomatic nozzle were used and the spring-loaded valves opened early to by-pass a part of the steam at low rates, some measure of the desired action might be attained, but neither the patents nor descriptive literature clarify the exact action. The article states that 59 locomotives of the Lehigh Valley were equipped with the device from 1938 to 1941, but it is understood that all have now been removed.

The Clemac Front End. Another automatically controlled front end has been recently developed by W. H. Clegg, general superintendent, Motive Power and Car Equipment, and R. R. McIntosh, mechanical engineer, Grand Trunk Western Railroad. Only a short discussion has been published (19), but Messrs. Clegg and McIntosh have kindly made all details available to the authors. The development is also well described in two patents (20, 21).

The essential features are as follows:

1 Back-pressure relief valves of the weighted poppet type to govern back pressure on the cylinders by exhaust of steam to the atmosphere.

2 A draft-relief valve that opens to admit air to the front end and thus limits the draft. The draft at which the valve opens increases as the output of the locomotive increases because the valve is loaded by the pressure of the steam at the nozzle through a piston on the upper end of the stem of the valve.

3 A cinder ejector which consists of a pipe that extends from the point of maximum draft inside the skirt of the stack to the bottom of the front end.

4 The elimination of the diaphragm, table plate, draft sheet, and netting from the front end.

The action of the back-pressure relief valve is not essentially different from that of the Bertram, and the same objections apply.

The draft-relief valve may have merit in that it should be possible to maintain the air-fuel ratio constant or to vary it as desired over the range of outputs.

The elimination of the diaphragm, table plate, draft sheet, and netting should decrease the over-all resistance to the flow of gases, permit a larger nozzle, and thus reduce the back pressure on the cylinders. Why these supposedly essential features can be eliminated by the inclusion of the back-pressure and draft-relief valves is not clear. However, the two locomotives equipped with the device have been approved from the standpoint of danger of forest fires for operation in Michigan by the Conservation Department, and in Canada for operation on the associated lines of the Canadian National Railways.

Admittedly, there is much that is not known about the factors that control the pickup and carry-over of cinders. If the carry-over varies as some power, greater than 1, of the rate of flow of gases, the carry-over will undoubtedly be high at the instant the exhaust valve on the engine cylinder opens, when the rate of discharge of steam is at a maximum. Thus it is conceivable that the carry-over would be considerably less for the same total flow if the rate of flow of gases were continuously at the average value than if the rate varies widely, as it must with the intermittent exhaust of steam at widely varying pressure.

Correct Principles of Automatic Control of Air Supply. The automatic devices described appear to have been designed in the belief that a locomotive is overdrafted at high rates and underdrafted at low rates, whereas we have seen that the reverse is true. The correct principle is to install a nozzle of the correct size to give the required output of the locomotive and the desired excess air at that output and to open the nozzle, to by-pass steam, or to relieve the front-end draft at lower outputs to maintain a constant excess of air.

If this were manually controlled an indicator in the cab would be required as a guide to the proper setting. A dual gage, one pointer indicating flow of steam by pressure drop across a nozzle, the other indicating flow of gas by pressure drop across the tubes

with such adjustment of the linkages that when the pointers were together the rate of air supply was correct, would be suitable. This is the principle of the Bailey boiler meter, widely used on stationary boilers and adaptable to automatic control. The difficulties of application to locomotives with widely varying pressures, particularly at low speeds, are apparent.

Induced- and Forced-Draft Fans. The possibility of the application of either forced- or induced-draft fans to the locomotive has occurred to many. MacFarland (2) as the result of his studies of the power losses because of back pressure, designed an induced-draft fan operated by high-pressure steam. The design was applied to one switcher and three road locomotives of the Atcheson, Topeka and Santa Fe Railroad from 1912 to 1914. From 1920 to 1927 Dr. W. F. M. Goss experimented with a turbine-driven induced-draft fan using exhaust steam.

Jackson (3) reports that both of these failed because of the impossibility of maintenance of the blades against the erosion by slag particles and cinders.

The Committee on Front Ends, Grates, and Ash Pans of the International Railway Fuel Association (22) has described a forced-draft installation on a locomotive of the Texas and Pacific, burning both Texas lignite and bituminous coal. Although the first results were promising, no further application seems to have been made. The fan was operated by a turbine, presumably on exhaust steam, although this was not definitely stated. The exhaust of the turbine passed through a nozzle to the stack. Both the nozzle and stack were considerably enlarged as compared to normal practice.

The difficulties of forced draft are obvious. The firebox will be under pressure greater than atmospheric, and the firing door cannot be opened unless the fan is shut off.

Overfire Air. The use of overfire-air jets to decrease the loss by unburned combustible gases and to decrease the smoke has long been practiced and is now coming into greater favor because of the work of Bituminous Coal Research, Inc. (7, 23, 24). This work has given the correct principles of design of steam and fan-driven jets and has shown how the noise which so often prevented their use, can largely be eliminated by a simple silencer. More than 600 locomotives on 24 railroads have now been equipped with jets based on the BCR design.

If 10 or 20 per cent of overfire air is desirable, the question arises whether the supply of 30 to 50 per cent of the air would not be more desirable.

The introduction of the air over the fire would do little to relieve the work on the front-end nozzle and thus reduce the back pressure because the gases would still have to be moved around the arch, through the tubes, and around the diaphragm. We have seen that these constitute the bulk of the resistance of the system.

Whether the use of large proportions of overfire air would reduce the large losses in cinder at high rates depends upon the amount of this carry-over that comes from the fuel bed and the amount that is carried from the coal thrown from the stoker and thus never reaches the bed. Only experimental research will determine the value of overfire air, but as the possible gains are great, a thorough research is warranted.

Conclusions and Recommendations for a Program of Research

This analysis of the problem of the supply of air to coal-fired locomotives by means of the "front-end" system of exhausting the steam from the cylinders into the stack through a fixed nozzle shows the following:

1 That the design of the front end definitely establishes at all rates the efficiency of combustion of the coal, as measured by the excess of air, and the efficiency of the cylinders except for some modification possible by the engineer by position of the throttle and cutoff.

2 That the front end does not increase the rate of supply of air proportionately to the rate of output of the locomotive but leads to a decreasing excess or even a deficiency of air at high rates.

3 That the loss of heat in cinders carried out of the combustion chamber at high rates is not necessarily the result of the deficiency of air supply by the front end.

4 That the high back pressures on the cylinders at high rates lead to large losses of power output.

5 That one of the principal reasons why high back pressures are required is the high resistance offered to gas flow by the diaphragm and the tubes.

6 That most attempts at manually or automatically controlled front ends have been based on the assumption that locomotives are overdrafted at high rates of output and underdrafted at low rates, whereas the reverse is true.

A program of research to improve the performance of the coal-fired steam locomotive by improvement of the air-supply system should include the following:

1 A program of tests on a full-scale locomotive to fix definitely the value of the factors, ratio of area of stack to nozzle, steam pressure, temperature of the gas, and resistance to gas flow that determine the entrainment ratio of a nozzle.

This information can be obtained on standing tests using throttled desuperheated steam. Of particular importance is that the weight of gases moved be accurately measured. This is preferably obtained by movement of the gases with a fan and measurement by means of a nozzle or a Pitot tube.

With this information and with knowledge of the resistance to gas flow and of the consumption of steam of a given locomotive, the proper size of nozzle for a given performance could be established by calculation, and cut-and-try methods of adjustment of the front end would be eliminated.

2 Review of design of front ends and experimental research to develop a design with the minimum resistance to the flow of gas consistent with proper self-cleaning characteristics.

3 Review of the problem of heat transfer in the boiler tubes to fix the area and length to make the over-all efficiency of the locomotive an optimum.

4 Conduct a thorough program of experimental research to determine the value of overfire air in elimination of smoke, reduction of losses in gaseous combustible, and of losses in cinders.

Discussion

E. D. Benton.[4] While investigations and testing of various combinations and arrangement of front-end parts have been carried on for many years, no one, heretofore, has clearly set forth the principles so that the ability of the front end to move air could be rationalized. Had this been done previously many of the misconceptions of its inherent characteristics would have been known, and much time and effort saved in attempts to design and patent ideas which were doomed to disappointment. The apparently simple fact that steam-air entrainment ratios decrease with either an increase in steam flow at the nozzle or increase in draft, and therefore at maximum output there is no surplus steam exhausted, has not been appreciated except by a few people. This has resulted in many attempts to improve the front end by the application of principles which, in effect, did just the reverse.

The development of a simple formula for calculating entrainment ratios, based upon the fact that both the air rate per Btu in the coal and boiler-absorption efficiency are essentially constant thus leaving only one variable, that of total heat or enthalpy of the steam, is particularly valuable. It, of course, assumes that all of the steam generated is exhausted through the nozzle or absorbed by the boiler feedwater. However, a sizable percentage of the steam generated by the boiler does not pass through the exhaust nozzle, such as the heat lost from continuous boiler blowdown, the steam-air pump, cab and headlight generator, stoker engine and jets, train heating, etc. Obviously, a factor representing this should be included in Equation [6].

The paper, by inference, brings out an interesting but seldom appreciated point, that exhaust pressures must be higher for modern high-pressure high-superheat engines than for older or saturated-steam engines. Assume two engines with the best possible front-end arrangement, but one engine producing steam having an enthalpy of 1200 Btu per lb, and the other engines with steam conditions giving 1395 Btu per lb. Then the engine with the greater enthalpy must entrain $\frac{1395 - 1200}{1200} \times 100$ or 16 per cent more air per lb of steam exhausted. If Young, in his investigations at the University of Illinois, was able to measure a difference of only 12 per cent between the best and the worst front-end nozzle-stack arrangement, it becomes apparent that the engine having the highest enthalpy must have a well-designed front end, and particular attention must be given the resistance offered to the flow of gases from the ashpan to the front end. It would appear that Young's statement, "the mutual incompatability of the mechanical requirements of the front end," has another difficulty, i.e., that of enthalpy.

The concept of resistance and resistance ratios as presented in the paper should prove helpful to anyone experiencing drafting difficulties, particularly when attempting to compare front-end proportions between engines having substantial differences in enthalpy of the steam generated. That grate and fuel-bed resistance is only about 15 per cent of the total will surprise many stationary-power-plant men who usually consider the fuel bed as the major resistance to the flow of air. It is for this reason that engines appear to steam equally well with a fuel and ash bed free of clinkers of 14 in. in thickness as with one only 6 in. thick.

If the steam turbine is to enjoy the success it justly deserves, considerable attention must be given the optimum "resistance train" in order to lower back pressure and improve water rates, since an increase in enthalpy of the steam is handicapped by an increase in exhaust pressure.

J. R. Jackson.[5] In the main, the writer follows the analysis and subscribes to the points advanced by the authors, particularly that "draft," as expressed in pressure differential, is not the proper basis for the study of the flow of heat through the locomotive boiler, and that the composition, weight, and temperature of the gases moved, at various locations in progression through the boiler, should be determined for different rates of power development. It is agreed with that in this respect there is a lack of information and a field for investigation which should yield a better understanding of the factors in the burning of solid fuels on grates throughout the normal range of power development of a steam locomotive boiler and possibly lead to an extension of the economic range over that heretofore obtainable.

However, there are two points made by the authors which the writer finds it difficult to subscribe to:

1 The evaluation of the resistances to flow through the boiler, particularly to the relatively small value attributed to the fuel bed.

2 The statement of "the correct principles of automatic control of air supply."

As to the first point, fire-bed resistance; the front-end plates and spark-arrester appliances, the tubes and flues, the arch, the grates, and the ashpan openings are the fixed resistances; the fire bed is the variable resistance and consequently the only means the locomotive fireman has to regulate and control air supply. While fire-bed resistance as the authors show, is of a relatively small magnitude as compared with the fixed resistances, it is a most important factor in the control of steam generation for any given rate of power development in any existing coal-

[4] Fuel Engineer, Louisville and Nashville Railroad Company, Louisville, Ky. Mem. A.S.M.E.

[5] Engineer of Tests, Missouri Pacific Railroad, St. Louis, Mo. Mem. A.S.M.E.

fired steam locomotive. The difference between a good fireman and a poor one is essentially the manner in which he regulates fire-bed resistance to control air supply.

As to point 2, i.e., automatic control of air supply. If by "correct size to give the required output of the locomotive" the authors mean maximum output, a nozzle of relatively large area is essential if the cylinder back-pressure horsepower loss is to be kept at the desired minimum for those conditions. However, in practice, with the relatively large nozzle desired for maximum output, it is too large for the lower rates of power development and the locomotive will "steam hard" or "fail for steam" as the rate of flow of exhaust steam through the nozzle is decreased by throttle or cutoff control. The universal remedy followed to improve steaming at the lighter loads under the conditions as just set forth is to reduce the nozzle area. This is directly the opposite procedure to the authors' statement of the correct principles of automatic control of the air supply and wherein the writer finds it difficult to agree. The case of a relatively large-nozzled locomotive in effect approaches the authors' concept for the automatic control of air supply, and yet it does not work out in practice.

It has been realized for many years that the back-pressure horsepower loss in the reciprocating steam locomotive is relatively high at the higher rates of power development. The writer has had considerable experience in attempts to bring about improvement in this direction and still believes that this angle requires further study and experimentation in any program of research looking to the improvement of the conventional reciprocating steam locomotive.

The control of air flow through the grates or above the fire in a coal-fired steam locomotive, throughout the relatively wide range of power development, is not a simple problem but it is believed that the approach, as suggested by the authors in this paper, should yield long-needed supplementary information and gives promise of realizing some worth-while improvements in the efficiency of the steam locomotive within the relatively narrow thermal-efficiency limitations attainable in this type of motive power.

In conclusion, the writer is thoroughly in sympathy with the authors' recommendations for a program of research employing a full-sized locomotive and hopes that it will be carried out along the general line as set forth in this paper.

R. R. McIntosh[6] and W. H. Clegg.[7] We note in the section, "Relation of Air Supplied by Front End to Air Required for Coal Fired," the authors refer to a locomotive developing 3500 dhp, at which output there was a deficiency of 30 per cent in excess air required for the coal fired, while actually for the coal burned, there was still an excess of 28 per cent at that power output. This fact seems to offer the most lucrative field for research in correcting the factors leading to such a tremendous loss in unburned fuel.

It is also noted in "Relation of Performance of Front End to Loss of Heat in Cinders," that the authors conclude that the high cinder loss is the result of the high carrying power of the gases for solids at the high velocity with which they move through the combustion chamber at high rates of operation, and that coal is both carried out of the bed and swept out of the stream of coal being fired before it reaches the fuel bed.

It is apparent that these undesirable conditions exist at high rates of output where they are influenced by the higher back pressure developed, which rapidly increases the ratio of the loss of back-pressure horsepower to the drawbar-horsepower output, as illustrated in Fig. 11. The small percentage of increase of air flow obtained by large increases in back pressure is obtained only at a very high price and is entirely out of proportion. It is therefore reasonable to assume that much may be accomplished in this direction where both high values of back pressure and air flow are automatically controlled, especially where such permits the locomotive to develop its boiler and tractive-effort capacity by reducing materially the ratio of back pressure-horsepower loss to drawbar-horsepower output and maintaining a more satisfactory range of entrainment ratio in the movement of gases.

We heartily concur in the authors' conclusions and recommendations for a program of research which should embrace a careful study of past and present designs of air-flow control, and the effect of unburned fuel loss by the control of back pressure, especially in view of the high ratio of back pressure - horsepower loss to drawbar-horsepower output. It is obvious from the authors' conclusions that they regard high back pressure as a very important factor which should be minimized by reduction of resistance to air flow, and we believe this to be well within the bounds of possibility with automatic control.

Authors' Closure

Mr. Benton has correctly pointed out that an increase in enthalpy of steam, by increase in pressure or in superheat, or both, results in an increase in the required entrainment ratio of the front end. His conclusion that this means that an engine having higher enthalpy must have a well-designed front end is also sound as there is little purpose in increasing the energy in the steam at the high level if one must decrease the size of the nozzle and thus throw the energy away in increased back pressure.

Mr. Jackson questions the conclusion that the resistance of the fuel bed plays a small part in control of the flow of air through the system. His belief that the fireman can control the amount of air by the thickness of the bed is natural and it is true that if the pressure drop through the fuel bed is increased, the supply of air will decrease, but it is not true that it will decrease greatly for normally expected changes in resistance.

If we take, for an example, the conditions shown in Table 2, when the pressure drop across the entire system was 20.1 inches of water and that across the fuel bed was 3 inches, and assume that the drop across the bed is doubled, then the increase in resistance will be

$$\frac{\sqrt{23.1}}{\sqrt{20.1}} = 1.07$$

or seven per cent. That is, the air flow would be decreased by seven per cent, certainly not a large amount, for a doubling of the pressure drop across the fuel bed. The authors will certainly agree with Mr. Jackson that the difference between a good fireman and a poor one is the manner in which he maintains the uniformity of his fuel bed. For example, if the fireman fires too much coal and greatly increases the thickness of the bed, the result may be heavy smoke and loss due to carbon monoxide and unburned volatiles, not because the increased thickness of bed reduced the amount of air appreciably but because it changed the air-coal ratio by too much coal.

Conversely, a decreased rate of firing will lead to a thin fuel bed, low CO_2, and falling steam pressure, not because the air has increased a great deal but because the coal has decreased.

Mr. Jackson questions whether the authors mean maximum output in the statement, "correct size to give the required output

of the locomotive". The answer is that they mean the maximum output desired for the given locomotive, although this is usually the maximum that can be obtained. The authors recognize that as the size of the nozzle is decreased to give a higher entrainment ratio and more air, the cylinder output decreases because of the increased back pressure and the efficiency of the engine will decrease. Hence there should be an optimum size of nozzle for maximum output, but often a higher output can be obtained even at lower efficiency and this sacrifice is made.

The authors confess to lack of practical locomotive experience, but fail to see why, if a given nozzle gives satisfactory operation at high outputs, there should be "hard steaming" at lower outputs. The mathematical relations, fully confirmed by test data, show that the entrainment ratio of a nozzle increases as the flow of steam and thus the back pressure decreases. The "hard steaming" cannot be for lack of air. Could it be from too great an excess?

Messrs. McIntosh and Clegg appear to be in full accord with the conclusions of the paper and suggest that it is possible to obtain automatic control to avoid back pressures. The authors agree as to desirability, but point out again that the method of by-passing steam is wrong in principle because, when more air is needed, it can definitely not be obtained by not passing part of the steam through the nozzle.

Analysis of Special Electronic-Tube Tests

By J. H. Campbell[1] and C. G. Donsbach,[2] Schenectady, N. Y.

The complexity of manufacturing electronic tubes is such that professional groups normally associated with design and laboratory activities are called upon to work in the factory. These groups contribute considerably to the control of material assembly, test, and the outgoing quality of the product. In this industry many variables exist and because none of the tube parts can be tested electrically until the tube is completed, a system of "statistical quality control" is in order. This paper illustrates improvements which may be accomplished through special tests on tubes in the course of production, followed by statistical analysis of the results.

The complexity of the manufacture of many articles has been greatly increased in the past few years due to at least one or more of the following conditions:

1 The large number of new devices.
2 The relatively short period of time allowed for development.
3 The large quantities on order.
4 The precise quality and limitations imposed by critical wartime requirements.

There are probably few manufacturing processes more complex than the manufacture of electronic tubes. In order to cope with the situation many professional groups, normally associated with design and laboratory activities, must be called upon to work in the factory. The regular complement of production engineers in an electronic-tube factory must have the assistance of chemical and metallurgical engineers as well as glass technologists. This technical help in manufacturing contributes considerably to the control of material assembly, test, and the outgoing quality of the product.

Another important tool which is gaining in popularity and use in most industries is statistical quality control. In the electronic-tube industry the need for control of the many variables is especially acute since none of the parts can be tested for electrical characteristics until the tube is completely made. These variables start from the material composition of the parts and continue through all processing stations to the final test for electrical characteristics. When properly applied to manufacturing, statistical analysis becomes a library of information to help engineers, foremen, and operators make the right decision at the right time.

This paper is intended to illustrate what can be accomplished through the use of special tests in the production of electronic tubes, with particular emphasis on the need for statistical analysis of the results.

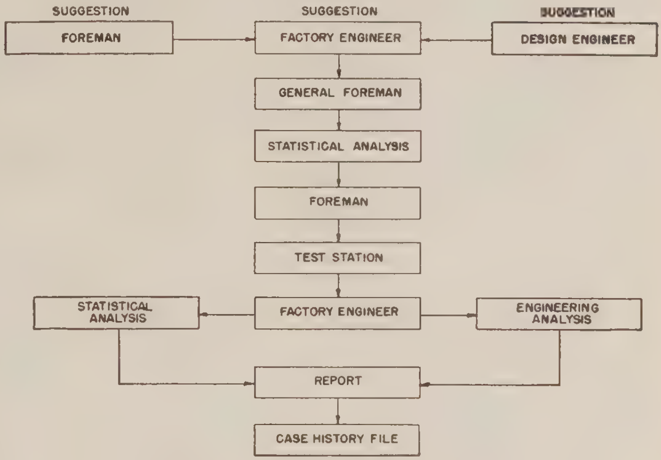

Fig. 1 Start and Finish of Special Test

"Special Tests" for Electronic Tubes

In order to avoid confusion in the term "special test," which will be referred to quite often, the following explanation is given:

The making of electronic tubes like many other manufacturing processes is accomplished by means of standard instructions. These instructions are the best known method of producing a particular tube type at the time the tube is considered developed and ready for manufacture. A special test usually has one variable which is not within the standard instructions. The engineer or person who suggests the test believes the one variable introduced in the manufacture of the tube will improve the quality and/or reduce manufacturing losses. If the test accomplishes either or both of the improvements, the corresponding change is made in the standard instructions.

It is therefore obvious that the special test is one of the most important tools for the factory to improve the quality of its product or reduce the losses in manufacture.

In order to utilize the test method to its fullest extent, complete co-ordination of all the groups in the factory must be obtained. Fig. 1 shows how this is accomplished. In general, the three groups who initiate a test are the engineers in the factory, the foremen, and the design engineers. The factory engineer's office serves as a clearing house for all technical information and the engineer accepts or rejects a special test based on the value of the information he expects may be gained by conducting it.

When a test is approved from a technical viewpoint, the general foreman is consulted regarding the priority the test should have in the production schedule. The written test form is then studied by the statistician to determine whether the method to be used will properly isolate the one variable being tested. The foreman then receives complete instructions and the tubes are assembled and tested. It then becomes the joint responsibility of the engineer and the statistician to analyze the data to determine whether the results are significant enough to require a change in standard instructions. A case history is then kept for future reference. The data are arranged by tube type and subject and made available to all who may have occasion to use them. When

this file is properly kept it serves to avoid duplication of effort as well as to provide information on past experience to help solve difficult problems in the future.

Production Flow Chart

To give an idea as to the number of variables encountered in the making of a tube, a typical flow chart of production is shown

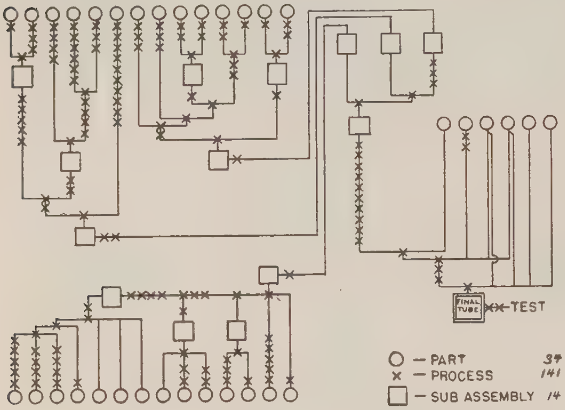

Fig. 2 Flow Chart Showing Possible Variables

in Fig. 2. It will be noted that this chart contains 34 parts, 141 manufacturing processes, and 14 subassemblies. In the manufacturing processes we have not included on the chart any subprocesses such as cleaning schedules of parts, exhaust schedules, etc. Likewise, Fig. 2 does not indicate the number of different machines, or operators, or test sets that may be in use at any one time. For ease of illustration these additional variables were omitted from the flow chart. It is important to note that practically any number of these variables or combinations of them may affect one or more of the electrical characteristics of the tube. The decision as to the total possible number of variables which can be encountered will be left to the reader's imagination.

Control over these variables is maintained statistically in many ways, a few of which may be listed as follows:

(*a*) Control over incoming material by sampling procedures.

(*b*) Control over processing stations by per cent defective, and variables control charts based upon 100 per cent and/or sampling inspection.

(*c*) Control at the test station by means of per cent defective, and variables control charts based upon 100 per cent and/or sampling tests. This may mean control over previous processing procedures since the results at test are, in many cases, directly or indirectly related to processing.

(*d*) Control by means of special tests.

In the remainder of the paper we will point out the method employed in analyzing special tests and some of the results obtained by the use of this system in an electronic-tube plant.

Procedures Followed in Special Tests

Fig. 3 is a flow chart which will give the general basis for the instigation, analysis, and disposition of such tests. An explanation of this chart follows:

The various reasons for running a test may arise from four general sources: 1 It may be the suggestion of a production worker, a foreman, or an engineer to change a certain processing procedure in the hope of improving the quality of the tube. 2 If a rise occurs in the per cent of defective tubes, it is the engineer's responsibility to isolate and correct the cause. This is often done by means of a special test where the suspected cause is the only variable. These troubles may in some cases be outstanding, as when the tubes suddenly become defective, or when per cent defective and/or variables control charts indicate trouble. 3 Another cause for which a special test may be run is to determine whether any differences exist among processing procedures such as among operators or machines. This source also uses special tests to compare test sets. 4 A special test may result from a necessity of control over certain incoming materials such as base metals, filaments, grids, etc., or from necessity of material control over certain processing materials, such as, emission-coating mixes, etc.

In general, regardless of the reason for conducting a special test, the procedure is to manufacture a small sample of tubes under prescribed conditions. Because of the large number of variables encountered it is absolutely necessary to send a control test along with the special test so that conclusions can be studied

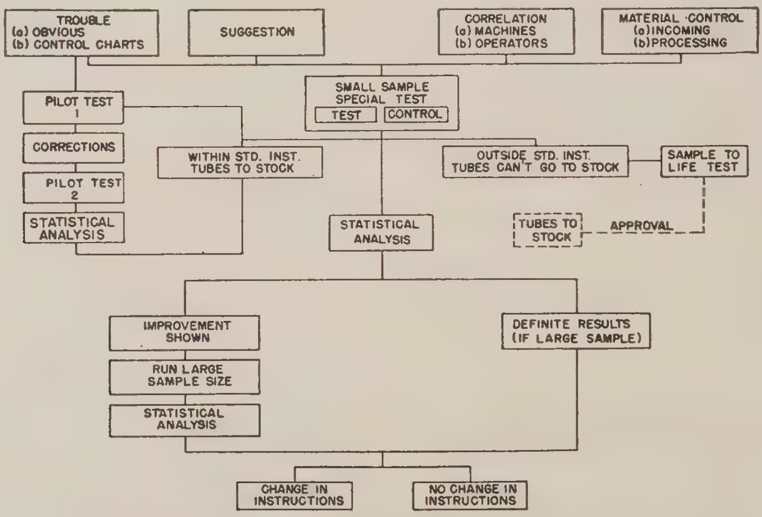

Fig 3 Flow Chart Showing Instigation and Procedures Involved in Special Tests

properly. This is the means used for reducing experimental error by holding constant all factors except the one under investigation. It means that the control test must be processed by exactly the same machines and same conditions (except for the one variable being tested) as the special test. Unless this is done, the results of the special test are not indicative.

These special tests may be further classified into two catagories, i.e., those in which the procedures are within standing instructions, and those which are outside standing instructions. In the case of the former the tubes may go directly to stock, but where the test is for tubes made under procedures which are outside standing instructions, the tubes cannot be stocked until the quality is determined by means of a life test or equivalent on a reasonable sample of the lot. If the tubes pass the additional prescribed test they may then go to stock.

As soon as the tubes are tested the results of the special test are compared with those of the control test. It is in this comparison that the use of the statistical analysis is applied. Fig. 4 shows the various statistical tests applied to determine whether the special-test results are different from normal production (control test). A brief explanation of each of these tests will be given, but for the basic theory the reader is referred to the Bibliography of this paper.

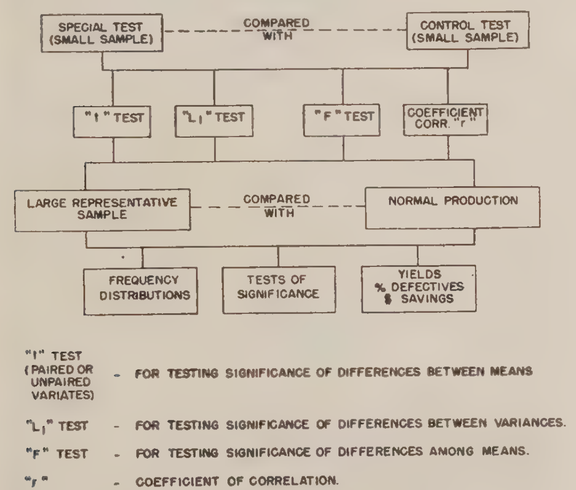

Fig. 4 Flow Chart Showing Methods of Statistical Analysis

Statistical Comparison of Test Results

In the statistical comparison of test results the usual procedure is to figure the mean and standard deviation of the individual electrical characteristics for both the special and control tests, and then be sure that a controlled process exists. The question which then arises is, "Are these means and variations statistically different between the special and the control tests?" In order to determine this, various statistical tests of significance are applied. One of these is the t test. This determines on the basis of the sample size whether the "averages" are significantly different from each other. The t test may be subdivided into two categories, i.e., that of paired, and that of unpaired variates. In all cases where control tests are run along with special tests, it is possible only to use the t test for unpaired variates. In other cases where partial special tests are run without control tests, such as in checking test equipment, the t test for paired variates is used. This is illustrated in Example 4.

The L_1 test is used to determine the significance of differences in "variance" between the special and control tests. The methods of computing the values of the t and L_1 are shown in examples 1 and 4, and the significance is determined from tables prepared for the purpose.[3]

Where there are more than two means and/or variances to be compared, the F test is generally used. Example 3 is an illustration of the use of this F test. Where correlation studies are indicated, the coefficient of correlation and line of regression are computed.

If the results of the special tests show fairly significant differences or are borderline cases, it is usually the procedure to send through a larger representative sample; perhaps a day's production or more. The control for this test is actually normal production before and after the large sample is run. In running this larger test care is taken to see that all parts and processes are randomized as is normal production. If three machines and three operators normally work on one of the tube processes, then this test is run so that the tubes are randomized among these machines and operators as they are in normal production.

After the tubes are tested for electrical characteristics, the results are statistically compared to normal production. The method of best presenting the results of this comparison has been found to be by cumulative frequency distributions, sometimes plotted on probability paper. This not only gives the shape of each distribution but enables one to estimate the average and standard deviation as well as per cent defective. This type of comparison is illustrated in examples 1 and 2. Where it is thought necessary, statistical tests of significance are also applied to these large sample sizes. However, in most cases a study of the curves together with the small-sample analysis are sufficient to determine whether or not to change normal production over to the new procedure.

Pilot Tests

As mentioned previously, there are instances where special tests are run in about the same manner as normal production. The cause for running this test (which is called a "pilot test") is to determine if the yield of percentage of good tubes can be increased. The principle used is first to observe every process in the production of the tube. During this observation period referred to as pilot test 1, no corrections are made but are merely noted. The results of the yield of this are tabulated with all possible discrepancies. Then pilot test 2 is run with all corrections applied. The corrections are decided upon by engineers who consult with foremen and test observers.

Fig. 5 shows the yield of a certain tube (not yet out of the developmental stage) plotted over a period of time. Note the yield of pilot test 1 and then note the upward trend resulting as corrections were applied. Pilot test 2 showed almost a 71 per cent increase in yield over pilot test 1. The yield on this tube has continued along the yield obtained by pilot test 2.

The examples given in the appendix are taken from case histories of recent special tests. They have been selected as representative cases of actual production and are believed to be self-explanatory. The number of these tests being run and the results obtained from them can be illustrated by the following figures for April, 1945:

Number of tests started	50
Number finished	34
Number of those completed showing improvements	16

The program, as explained in this paper, is being followed actively at the present time. It is helping to produce the highest-quality product. In the postwar period the ultimate consumer will derive benefits in the form of increasingly good quality.

[3] Tables are available in various texts on the subject. (Refer to Bibliography following.)

Appendix

EXAMPLE 1 SPECIAL TEST RUN AS RESULT OF SUGGESTION TO IMPROVE QUALITY

On one tube type the electrical characteristic "grid current" was the cause for a fairly large percentage of loss. The engineer decided that a change in the method of assembly would narrow the tube-to-tube variation and eliminate a considerable number of electrical defects.

After considering the daily production schedule and the number of possible variables present, it was decided to send through a special test of 50 tubes together with a control test of 50 tubes. For the control test, every part used came from the same lot of material and all processing operations were made by the same operators and on the same machines, under the same conditions as the special test, except for the one variable being tested.

The following results were tabulated for the grid characteristic:

	Test	Control
Sample size (n)	50	50
Average ($\bar{X}$), ma	37.4	42.0
Standard deviation (σ), ma	4.2	7.1

Were these results statistically different? The statistical t test was applied to determine the significance of the difference between the averages, and the L_1 test was applied to determine whether this difference in averages was due to inequality in variances.

For the t test, applying the formula

$$t = \frac{d}{\sqrt{\dfrac{\Sigma(X_t - \bar{X}_t)^2 + \Sigma(X_c - \bar{X}_c)^2}{n_t + n_c - 2}\left(\dfrac{1}{n_t} + \dfrac{1}{n_c}\right)}}$$

we have

$$t = \frac{4.6}{\sqrt{\dfrac{890 + 2518}{50+50-2}\left(\dfrac{1}{50} + \dfrac{1}{50}\right)}} = 3.9$$

which for 98 deg of freedom is significant.[4]

Applying the formula for the L_1 test

$$L_1 = \frac{s_t^2 s_c^2}{s_a^2 s_a^2}$$

where

$$s_a^2 = {}^1/_2(s_t^2 + s_c^2)$$

we have

$$L_1 = \frac{(17.8)(50.4)}{(34.1)(34.1)} = 0.78$$

$$+ s = {}^1/_2(17.8 + 50.4)$$

The value of L_1 for sample sizes of 50 is 0.9612, beyond which lie 5 per cent of all values of L_1. The value 0.78+ is far below this and indicates that the variances of the two assumed normal populations from which these samples were drawn differ significantly.

Because of the results in the special test of 50 tubes, it was decided to obtain a larger representative sample by running at least a day's production with the new assembly technique. In doing this the day's production was run with all shifts, all machines, and other variables that would be encountered in normal production. The distribution curves plotted on probability paper, Fig. 6, will give approximately the whole comparison as follows:

	Test	Normal production
n	309	500
$\bar{X}$	36.8	44.1
σ	4.5	8.0
Per cent defective	1.0	14.0

The actual yield (per cent good from starting 100 assemblies) showed an increase from 74 to 83. This increase in yield represents a monthly saving of $2500 to $3000, based upon the current production schedules.

[4] Degrees of freedom represent the number of independent values in the comparison.

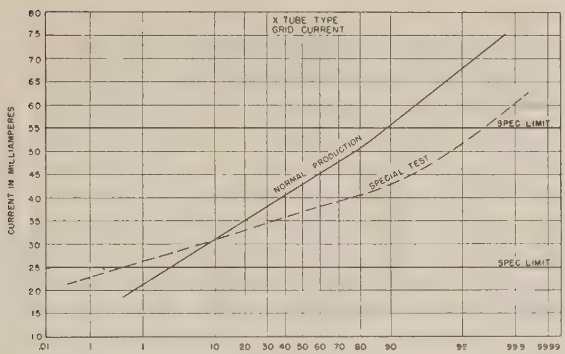

FIG. 6 X-TUBE TYPE GRID CURRENT

The following nomenclature is used in this section:

d = difference between means
X_t = individual value of each special-test reading
X_c = individual value of each control-test reading
$\overline{X}_t$ = average of special-test readings
$\overline{X}_c$ = average of control-test readings
n_t = sample size of special test
n_c = sample size of control test
s_t^2 = variance of special test
s_c^2 = variance of control test
σ = standard deviation

EXAMPLE 2 SPECIAL TEST RUN TO REDUCE HIGH PER CENT DEFECTIVE AS SHOWN BY STATISTICAL CHARTS

On a very critical tube type the per cent defective chart, Fig. 7, indicated a large loss at test due to a plate-voltage characteristic. This characteristic is primarily determined by the relative spacing of certain elements of the tube, which had previously been done by mechanical means. The engineer decided an improvement could be obtained by spacing the tube electrically with a capacitance bridge. This equipment was built for the test and arranged so that a predetermined reading of capacitance could be obtained while the tube was being assembled (the correlation of capacitance and spacing is shown in Fig. 8).

In using this fixture a small lot of tubes was made and the analyzed results indicated so much improvement that a special test was run on 420 tubes. These tubes were made on a completely randomized basis so that a correct comparison could be made with normal production.

Cumulative frequency distributions were plotted and are shown in Fig. 9. The results in the form of per cent defective are tabulated below:

	Normal production	Special test
Plate voltage	15.0	0.5
Capacitance	10.0	0.8
Gassy	3.7	1.4
Shorts	6.6	1.7

The reduction in gassy and shorted tubes was due to the more uniform spacing.

Statistical tests confirmed the differences in plate voltage and capacitance to be significant.

The device was put into use and the control chart in Fig. 7 shows the results in improvement in losses and quality. The over-all yield on this tube increased 49 per cent due to this factor, and the dollar savings amounted to over $7500 per 1000 tubes to stock.

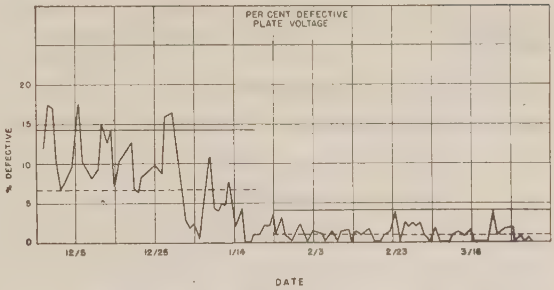

FIG. 7 PER CENT DEFECTIVE PLATE VOLTAGE

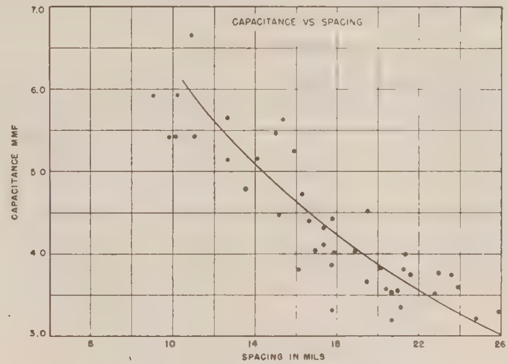

FIG. 8 CAPACITANCE VERSUS SPACING

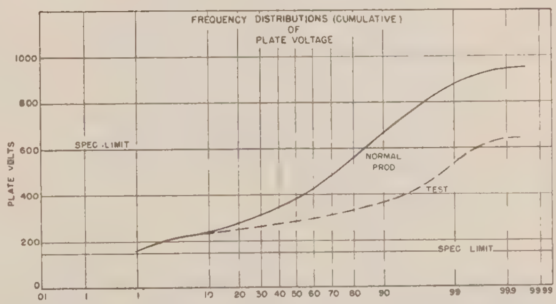

FIG. 9 FREQUENCY DISTRIBUTIONS, CUMULATIVE, OF PLATE VOLTAGE

EXAMPLE 3 COMPARISON OF EXHAUST SCHEDULES THROUGH USE OF L_1 AND F TESTS

Considerable difficulty was encountered in obtaining proper emission on a particular tube type. One of the possible variables which could affect this was the schedule by which the tubes were exhausted.

The engineer ran a special test using four different exhaust schedules. The following results were tabulated:

Exhaust schedule	A	B	C	D
n	16	24	28	19
$\overline{X}$	28	20.2	27	21

From the averages given in the table, schedules B and D look much better than schedules A and C. However, do the averages of these schedules differ significantly among themselves, or do they most likely come from the same homogenous population?

In order to determine this the F test was applied (after applying the L_1 test which showed that the variances of the assumed normal populations from which these samples were drawn were not significantly different).

In the F test we simply segregate the total variances into the variances among schedule means, and the variances within schedule means. We compute the ratio and compare it to the known distribution of F ratio for random samples. In other words, "we compute the ratio of an estimate associated with a suspected 'cause' to the estimate which best defines the error of the experiment. If the probability is small, say, less than 0.05, that this ratio could have occurred by chance in sampling from normal populations of identical means and variances, the hypothesis that such were the populations is rejected."

The following shows the computation of F for the comparison of exhaust schedules:

Source of variation	Sum of squares	Degrees of freedom	Mean square
Among schedules..	$\Sigma(\bar{X}_c - \bar{X})^2$	$K - 1$	$\sigma_1^2 = \dfrac{\Sigma(\bar{X}_c - \bar{X})^2}{K-1}$
	873.7	3	291.2
Within schedules...	$\Sigma(X - \bar{X}_c)^2$	$n - K$	$\sigma_2^2 = \dfrac{\Sigma(X - \bar{X}_c)^2}{n-K}$
	9631.0	83	116.0
Total............	$\Sigma(X - \bar{X})^2$ 10504.7	$n - 1$ 86	

where

$$\Sigma(\bar{X} - \bar{X})^2 = \Sigma\bar{X}_c^2 - \frac{(\Sigma X)^2}{n}$$

$$51080.55 - 50206.9 = 873.7$$

$$\Sigma(X - \bar{X}_c)^2 = \Sigma X^2 - \Sigma\bar{X}_c^2$$

$$60711.50 - 51080.55 - 9631.0$$

$$\Sigma(X - \bar{X})^2 = \Sigma X^2 - \frac{(\Sigma X^2)}{n}$$

$$60711.50 - 50206.9 = 10504.7$$

$$\text{where } \Sigma\bar{X}_c^2 = \frac{(\Sigma X_1)^2}{n_1} + \frac{(\Sigma X_2)^2}{n_2} + \frac{(\Sigma X_3)^2}{n_3} + \frac{(\Sigma X_4)^2}{n_4}$$

$$F = \frac{291.2}{116.0} = 2.501$$

The table of values of F for 3 and 83 deg of freedom produces the ratio of 2.72. Since the value of 2.501 is less than this, we must take it as an indication that the exhaust schedules all come from the same homogenous population and therefore they had no significant effect on the electrical characteristic.

The meaning of terms is as follows:

X = individual value of electrical characteristic
n = sample size
K = number of samples

Example 4 Showing Control Over Test Equipment by Means of Correlation Between Test Sets

One of the methods of maintaining adequate control over test equipment is to check factory sets with standard laboratory sets for all electrical characteristics. Although this does not strictly adhere to the full procedure of running complete special tests in order to make these correlations, the actual testing procedure is considered in the category of a special test.

The usual method is to take a small sample of tubes, test them on the one set, and then test them on the standard set (using the same operator). The results are then analyzed for statistical significance between averages by means of the t test for paired variates. The following is a good example of what can be done with statistical tests of significance in such correlations on a certain tube type:

Electrical characteristic	Factory average	Laboratory average	Difference	Statistical significance
A	183.9	177.6	6.3	Significant
B	4.44	4.35	0.09	Significant
C	4.70	4.62	0.08	Significant
D	0.255	0.268	0.013	Not significant
E	4.28	4.31	0.03	Significant
F	2.11	2.00	0.11	Significant
G	0.322	0.307	0.015	Not significant
H	0.311	0.317	0.006	Not significant
I	0.573	0.423	0.114	Significant
J	0.533	0.428	0.105	Significant
K	21.1	21.5	0.4	Significant

Although many of these differences show statistical significance, only three of them were "practically" significant. The factory sets were recalibrated until these differences were not significant.

The t test of significance is illustrated for the "A" characteristic as follows:

$$t = \frac{\bar{d}}{\sigma/\sqrt{n}}$$

where

$$\sigma^2 = \frac{\Sigma d^2 - \dfrac{(\Sigma d)^2}{n}}{n-1}$$

where

$\bar{d}$ = difference between means
n = sample size
Σd^2 = sum of individual differences squared
$(\Sigma d)^2$ = square of sum of individual differences

$$t = \frac{6.3}{\sigma/\sqrt{21}} = 3.45$$

$$\sigma^2 = \frac{2237 - \dfrac{(133)^2}{21}}{20}$$

$$\sigma = 8.35$$

The Effect of Heat Loss on the Performance of Exchangers With Interconnected Walls

By P. R. TRUMPLER,[1] NEW YORK, N. Y.

Equations are derived for the calculation of exchangers in which the passage walls are bonded to each other, providing substantially uniform wall temperature over any cross section normal to the flow. Results are presented for both countercurrent and cocurrent exchangers and an example illustrating the solution is given.

Nomenclature

The following nomenclature is used in the paper:

h_s = thermal conductance, based on surface A_s, between metal wall and the surroundings at temperature θ_s, Btu hr^{-1} ft^{-2} deg F^{-1}
A_s = reference surface for h_s, sq ft per ft of exchanger length
Q_s = heat flow from metal wall to surroundings, positive for heat flow to surroundings, Btu hr^{-1}
W = fluid-flow rate, lb hr^{-1}
c = specific heat at constant pressure, Btu lb^{-1} deg F^{-1}
h = fluid film conductance, Btu hr^{-1} ft^{-2} deg F^{-1}
A = surface washed by fluid, sq ft per ft of exchanger length
θ_s = temperature of surroundings, deg F
θ = temperature of warm fluid, deg F
T = temperature of cold fluid, deg F
η = temperature of metal wall, deg F
z = length co-ordinate, parallel to fluid-flow directions, positive in direction of flow of cold fluid, ft
L = exchanger length, ft

Subscripts T and θ refer to the fluids having those temperatures
Subscript 0 refers to value at $z = 0$
Subscript 1 refers to value at $z = L$

Introduction

Under certain conditions heat transfer between an exchanger and its surroundings can have an important effect upon the performance of the exchanger. Even a small heat leak may appreciably alter the temperature difference between the two fluids as calculated for adiabatic performance. Heat-loss effects are often appreciable where a small temperature difference between the fluids is required by the necessity for high thermal efficiency in the process, or where the exchanger operates at a temperature far from the ambient. Examples are found in plants for the separation of gases by deep refrigeration, and at the other end of the temperature scale, in the gas-turbine recuperator.

For the case of a double-pipe exchanger the effect of heat loss has been investigated by Nesselmann.[2] The recent development of extended-surface exchangers, particularly for deep-refrigeration processes, has brought practical importance to another case, namely, exchangers of the general type shown in Fig. 1. For purposes of the present analysis this type is characterized by passages bonded together in such a manner that the wall-temperature variation over any cross section normal to the flow is small compared to the temperature difference between the wall and the surroundings.

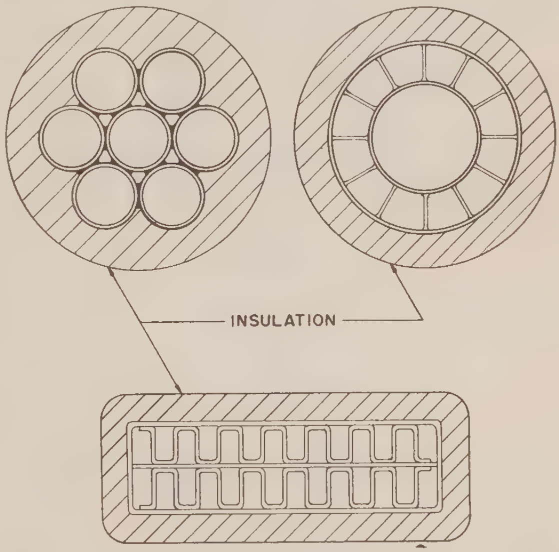

Fig. 1 Typical Heat Exchangers With Interconnected Walls

It will be seen that the results are applicable to exchangers in which the passages are not bonded together, provided the temperature difference between the various walls at a cross section is small. This is generally true of double-pipe or shell-and-tube exchangers in which either (1) the film coefficient of the shell fluid is very much higher than that of the tube fluid or (2) if the two fluids are exchanging heat at a small temperature difference.

Under what conditions should the effect of heat loss be investigated? The equations appear to yield no simple criterion. If, however, a rough estimate of the heat loss shows that the mean temperature difference based on terminal values is appreciably changed, a check for the effect of heat loss should be made.

The performance equations derived in the following section are limited only by the usual assumptions, which require that conductances and specific heats remain constant for the length of the exchanger, and that heat conduction in the metal or the insulation along the length of the exchanger is not important. The effect of heat conduction through fins, wall, bonding material, and fouling films may be taken into account by correcting the individual film coefficients.

Countercurrent Flow

The three basic equations are:

[1] Development Engineer, M. W. Kellogg Company. Jun. A.S.M.E.
[2] "The Influence of Heat Loss From Double-Tube Heat Exchangers," by K. Nesselmann, *Zeitschrift für die Gesamte Kälte-Industrie*, vol. 35, 1928, pp. 62–67.

Contributed by the Heat Transfer Division and presented at the Annual Meeting, New York, N. Y., Nov. 26–29, 1945, of The American Society of Mechanical Engineers.

$$W_\theta c_\theta d\theta = W_T c_T dT + h_s(\eta - \theta_s)A_s dz \quad [1]$$

$$W_T c_T dT = h_T A_T(\eta - T)dz \quad [2]$$

$$W_\theta c_\theta d\theta = h_\theta A_\theta(\theta - \eta)dz \quad [3]$$

Eliminating η from Equations [2] and [3]

$$\frac{W_T c_T dT}{h_T A_T dz} + \frac{W_\theta c_\theta d\theta}{h_\theta A_\theta dz} = \theta - T \quad [4]$$

Eliminating η and z by Equations [3] and [4], Equation [1] becomes

$$\frac{W_\theta c_\theta}{W_T c_T}\left[1 + \frac{h_s A_s}{h_\theta A_\theta}\left(1 - \frac{\theta - \theta_s}{\theta - T}\right)\right] d\theta = \left[1 + \frac{h_s A_s}{h_T A_T}\left(\frac{\theta - \theta_s}{\theta - T}\right)\right] dT \quad [5]$$

The variables may be separated if we make the transformation

$$x \equiv \frac{\theta - \theta_s}{\theta - T} \qquad y \equiv \theta - T \quad [6]$$

$$xy = \theta - \theta_s$$

$$xdy + ydx = d\theta \qquad dT = (x - 1)dy + ydx \quad [7]$$

Substituting also

$$D \equiv \frac{W_\theta c_\theta}{W_T c_T} \quad [8]$$

Equation [5] becomes

$$\frac{dy}{y} = \frac{1 - D - D\dfrac{h_s A_s}{h_\theta A_\theta} + \left(\dfrac{h_s A_s}{h_T A_T} + D\dfrac{h_s A_s}{h_\theta A_\theta}\right)x}{1 + \left(D + D\dfrac{h_s A_s}{h_\theta A_\theta} + \dfrac{h_s A_s}{h_T A_T} - 1\right)x - \left(\dfrac{h_s A_s}{h_T A_T} + D\dfrac{h_s A_s}{h_\theta A_\theta}\right)x^2}\, dx \quad [9]$$

Using Equation [9] to eliminate y from Equation [4] we determine x as a function of z

$$\int_{x_0}^{x} \frac{dx}{1 + (a + D - 1)x - ax^2} = \int_0^z \frac{dz}{K} \quad [10]$$

where

$$\left.\begin{aligned} a &\equiv \frac{W_\theta c_\theta}{W_T c_T}\frac{h_s A_s}{h_\theta A_\theta} + \frac{h_s A_s}{h_T A_T} \\ K &\equiv W_\theta c_\theta\left[\frac{1}{h_\theta A_\theta} + \frac{1}{h_T A_T}\left(1 + \frac{h_s A_s}{h_\theta A_\theta}\right)\right] \end{aligned}\right\} \quad [11]$$

Integration yields

$$x = \frac{1}{2\left(\dfrac{D}{h_\theta A_\theta} + \dfrac{1}{h_T A_T}\right)} \left\{\frac{1}{h_T A_T} + \frac{D}{h_\theta A_\theta} + \frac{1}{h_s A_s}\left(D - 1 + r\frac{R_0 e^{(r/k)z} + 1}{R_0 e^{(r/k)z} - 1}\right)\right\} \quad [12]$$

where

$$\left.\begin{aligned} r &\equiv \sqrt{(D - 1 + a)^2 + 4a} \\ R_0 &\equiv \frac{-2ax_0 + (a + D - 1) - r}{-2ax_0 + (a + D - 1) + r} \end{aligned}\right\} \quad [13]$$

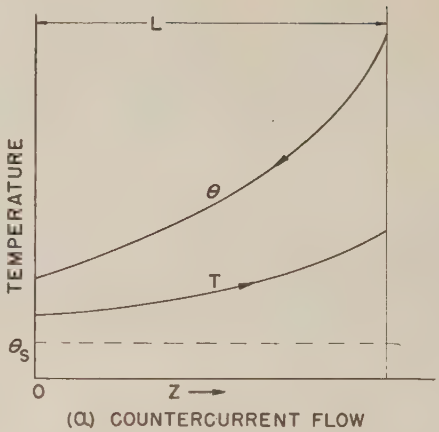

FIG. 2

Integrating Equation [9] and eliminating x by Equation [12] we obtain y as a function of z

$$\frac{y}{y_0} = me^{pz} + ne^{qz} \quad [14]$$

where

$$m \equiv \frac{1}{2r}\left\{r - D + 1 - h_s A_s(1 - 2x_0)\left(\frac{D}{h_\theta A_\theta} + \frac{1}{h_T A_T}\right)\right\}$$

$$n \equiv \frac{1}{2r}\left\{r + D - 1 + h_s A_s(1 - 2x_0)\left(\frac{D}{h_\theta A_\theta} + \frac{1}{h_T A_T}\right)\right\}$$

$$p \equiv \frac{U_\theta A_\theta}{2W_\theta c_\theta}\left\{r - D + 1 - h_s A_s\left(\frac{D}{h_\theta A_\theta} - \frac{1}{h_T A_T}\right)\right\}$$

$$q \equiv \frac{U_\theta A_\theta}{2W_\theta c_\theta}\left\{-r - D + 1 - h_s A_s\left(\frac{D}{h_\theta A_\theta} - \frac{1}{h_T A_T}\right)\right\}$$

$$\frac{1}{U_\theta A_\theta} \equiv \frac{1}{h_\theta A_\theta} + \frac{1}{h_T A_T}\left(1 + \frac{h_s A_s}{h_\theta A_\theta}\right)$$

$$r \equiv \sqrt{(D - 1 + a)^2 + 4a}$$

$$a \equiv h_s A_s\left(\frac{D}{h_\theta A_\theta} + \frac{1}{h_T A_T}\right)$$

$$D \equiv \frac{W_\theta c_\theta}{W_T c_T}$$

Equations [12] and [14] completely define the exchanger performance. Two special cases will be noted.

$h_s A_s = 0$

Then

$$a = 0 \qquad r = D - 1 \qquad n = 1$$

$$m = 0 \qquad p = 0$$

$$q = \frac{U_\theta A_\theta}{W_\theta c_\theta}\left(1 - \frac{W_\theta c_\theta}{W_T c_T}\right)$$

and

$$y = y_0 exp\left[\frac{U_\theta A_\theta}{W_\theta c_\theta}\left(1 - \frac{W_\theta c_\theta}{W_T c_T}\right)z\right] \quad [15]$$

which is the equation of the adiabatic exchanger.

$h_sA_s \to \infty$ with other film coefficients finite

$$a \to \infty \qquad r \to \infty$$

$$\frac{r}{h_sA_s} = \frac{D}{h_\theta A_\theta} + \frac{1}{h_TA_T}$$

and Equation [14] becomes

$$y = (\theta_0 - \theta_s)exp\left(\frac{h_\theta A_\theta}{W_\theta c_\theta}z\right) - (T_0 - \theta_s)exp\left(-\frac{h_TA_T}{W_Tc_T}z\right) \ldots [16]$$

Exchanger Length. The calculation of exchanger length is of prime importance to the heat-transfer engineer. The length may be determined by the following procedure:

From Equation [4]

$$\frac{W_Tc_T}{h_TA_T}\int_0^1 dT + \frac{W_\theta c_\theta}{h_\theta A_\theta}\int_0^1 d\theta = \int_0^L (\theta - T)dz \ldots [17]$$

or

$$\frac{W_Tc_T}{h_TA_T}(T_1 - T_0) + \frac{W_\theta c_\theta}{h_\theta A_\theta}(\theta_1 - \theta_0) = \int_0^L (\theta - T)dz \ldots [18]$$

Also

$$\int_0^L (\theta - T)dz = \int_0^L ydz = y_0\frac{m}{p}(e^{pL} - 1) + y_0\frac{n}{q}(e^{qL} - 1) \ldots [19]$$

Three of the terminal temperatures must be given in the statement of the problem. There are four possible combinations of the three temperatures, and the solution for each case will be given.

Case 1. Given θ_0, θ_1, and T_0:

From Equation [14]

$$\theta_1 - T_1 = y_0me^{pL} + y_0ne^{qL} \ldots\ldots\ldots\ldots [20]$$

Substituting Equations [19] and [20] into Equation [18]

$$\frac{W_Tc_T}{h_TA_T}\left(\frac{\theta_1 - T_0}{\theta_0 - T_0}\right) + \frac{W_\theta c_\theta}{h_\theta A_\theta}\left(\frac{\theta_1 - \theta_0}{\theta_0 - T_0}\right) + \frac{m}{p} + \frac{n}{q} = m\left(\frac{1}{p} + \frac{W_Tc_T}{h_TA_T}\right)e^{pL} + n\left(\frac{1}{q} + \frac{W_Tc_T}{h_TA_T}\right)e^{qL} \ldots\ldots [21]$$

Equation [21] fixes the value of L.

Case 2. Given θ_0, T_1, and T_0:

Substituting θ_1 from Equation [20], the solution is

$$\frac{W_Tc_T}{h_TA_T}\left(\frac{T_1 - T_0}{\theta_0 - T_0}\right) + \frac{W_\theta c_\theta}{h_\theta A_\theta}\left(\frac{T_1 - \theta_0}{\theta_0 - T_0}\right) + \frac{m}{p} + \frac{n}{q} = m\left(\frac{1}{p} - \frac{W_\theta c_\theta}{h_\theta A_\theta}\right)e^{pL} + n\left(\frac{1}{q} - \frac{W_\theta c_\theta}{h_\theta A_\theta}\right)e^{qL} \ldots\ldots [22]$$

Case 3. Given θ_0, θ_1, and T_1:

The solution may be readily obtained by changing the direction of the z-axis and interchanging subscripts 0 and 1 of the terminal temperatures. Note that this requires changing x_0 to x_1 in the equations defining m and n. The solution is

$$\frac{W_Tc_T}{h_TA_T}\left(\frac{\theta_0 - T_1}{\theta_1 - T_1}\right) + \frac{W_\theta c_\theta}{h_\theta A_\theta}\left(\frac{\theta_0 - \theta_1}{\theta_1 - T_1}\right) + \frac{m}{p} + \frac{n}{q} = m\left(+\frac{1}{p} + \frac{W_Tc_T}{h_TA_T}\right)e^{-pL} + n\left(+\frac{1}{q} + \frac{W_Tc_T}{h_TA_T}\right)e^{-qL} \ldots [23]$$

Case 4. Given θ_1, T_1, and T_0:

The solution is found as in Case 3

$$\frac{W_Tc_T}{h_TA_T}\left(\frac{T_0 - T_1}{\theta_1 - T_1}\right) + \frac{W_\theta c_\theta}{h_\theta A_\theta}\left(\frac{T_0 - \theta_1}{\theta_1 - T_1}\right) + \frac{m}{p} + \frac{n}{q} = m\left(+\frac{1}{p} - \frac{W_\theta c_\theta}{h_\theta A_\theta}\right)e^{-pL} + n\left(+\frac{1}{q} - \frac{W_\theta c_\theta}{h_\theta A_\theta}\right)e^{-qL} \ldots [24]$$

Calculation of Heat Loss:

Case 1. Given θ_0, θ_1, and T_0, or θ_0, T_1, and T_0:

T_1 or θ_1 may be calculated from y_1 where

$$y_1 = y_0me^{pL} + y_0ne^{qL}$$

Knowing the terminal temperatures, the heat loss may be calculated

Case 2. Given θ_0, T_1, θ_1, or T_0, T_1, θ_1

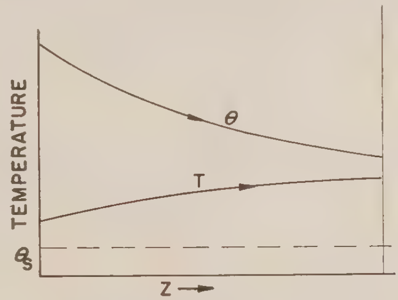
T_0 or θ_0 may be calculated from

$$\frac{\theta_0 - T_0}{\theta_1 - T_1} = me^{-pL} + ne^{-qL} \ldots\ldots\ldots\ldots [25]$$

Note that x_0 must be changed to x_1 in the equations defining m and n.

Parallel Flow

The three basic equations for parallel flow are



(b) PARALLEL FLOW

FIG. 3

$$-W_\theta c_\theta d\theta = W_Tc_TdT + h_s(\eta - \theta_s)A_sdz \ldots\ldots\ldots [26]$$

$$W_Tc_TdT = h_TA_T(\eta - T)dz \ldots\ldots\ldots\ldots\ldots\ldots [27]$$

$$-W_\theta c_\theta d\theta = h_\theta A_\theta(\theta - \eta)dz \ldots\ldots\ldots\ldots\ldots\ldots [28]$$

By a treatment similar to that for countercurrent flow the solution is found to be

$$x = \frac{1}{2\left(\frac{1}{h_TA_T} - \frac{D}{h_\theta A_\theta}\right)}\left\{\frac{1}{h_TA_T} - \frac{D}{h_\theta A_\theta} - \frac{1}{h_sA_s}\left(D + 1 + r_c\frac{R_{c0}e^{(r_c/k)z} + 1}{R_{c0}e^{(r_c/k)z} - 1}\right)\right\} \ldots [29]$$

where

$$r_c \equiv \sqrt{(D + 1 - a_c)^2 + 4a_c}$$

$$R_{c0} = \frac{2a_cx_0 + (D + 1 - a_c) - r_c}{2a_cx_0 + (D + 1 - a_c) + r_c}$$

$$a_c \equiv h_sA_s\left(\frac{1}{h_TA_T} - \frac{D}{h_\theta A_\theta}\right)$$

and

$$\frac{y}{y_0} = m_c e^{p_c z} + n_c e^{q_c z} \quad \text{................} [30]$$

where

$$m_c \equiv \frac{1}{2r_c} \left\{ r_c - D - 1 - h_s A_s (1 - 2x_0) \left(\frac{D}{h_\theta A_\theta} - \frac{1}{h_T A_T} \right) \right\}$$

$$n_c \equiv \frac{1}{2r_c} \left\{ r_c + D + 1 + h_s A_s (1 - 2x_0) \left(\frac{D}{h_\theta A_\theta} - \frac{1}{h_T A_T} \right) \right\}$$

$$p_c \equiv \frac{U_\theta A_\theta}{2W_\theta c_\theta} \left\{ r_c - D - 1 - h_s A_s \left(\frac{D}{h_\theta A_\theta} + \frac{1}{h_T A_T} \right) \right\}$$

$$q_c \equiv \frac{U_\theta A_\theta}{2W_\theta c_\theta} \left\{ - r_c - D - 1 - h_s A_s \left(\frac{D}{h_\theta A_\theta} + \frac{1}{h_T A_T} \right) \right\}$$

If $h_s A_s = 0$

$$y = y_0 \, exp \left[- \frac{U_\theta A_\theta}{W_\theta c_\theta} \left(1 + \frac{W_\theta c_\theta}{W_T c_T} \right) z \right] \quad \text{.......} [31]$$

If $h_s A_s \to \infty$

$$y = (\theta_0 - \theta_s) exp \left(- \frac{h_\theta A_\theta}{W_\theta c_\theta} z \right) - (T_0 - \theta_s) exp \left(- \frac{h_T A_T}{W_T c_T} z \right) [32]$$

Exchanger Length. The equation corresponding to Equation [18] is

$$\frac{W_T c_T}{h_T A_T} (T_1 - T_0) - \frac{W_\theta c_\theta}{h_\theta A_\theta} (\theta_1 - \theta_0) = \int_0^L (\theta - T) dz \quad \text{..} [33]$$

$$\int_0^L (\theta - T) dz = \int_0^L y dz = y_0 \frac{m_c}{p_c} (e^{p_c L} - 1)$$

$$+ y_0 \frac{n_c}{q_c} (e^{q_c L} - 1) \quad \text{........} [34]$$

Case 1. Given θ_0, θ_1, T_0:

$$\frac{W_T c_T}{h_T A_T} \left(\frac{\theta_1 - T_0}{\theta_0 - T_0} \right) - \frac{W_\theta c_\theta}{h_\theta A_\theta} \left(\frac{\theta_1 - \theta_0}{\theta_0 - T_0} \right) + \frac{m_c}{p_c} + \frac{n_c}{q_c}$$

$$= m_c \left(\frac{1}{p_c} + \frac{W_T c_T}{h_T A_T} \right) e^{p_c L} + n_c \left(\frac{1}{q_c} + \frac{W_T c_T}{h_T A_T} \right) e^{q_c L} \quad \text{.....} [35]$$

Case 2. Given θ_0, T_1, T_0:

$$\frac{W_T c_T}{h_T A_T} \left(\frac{T_1 - T_0}{\theta_0 - T_0} \right) - \frac{W_\theta c_\theta}{h_\theta A_\theta} \left(\frac{T_1 - \theta_0}{\theta_0 - T_0} \right) + \frac{m_c}{p_c} + \frac{n_c}{q_c}$$

$$= m_c \left(\frac{1}{p_c} + \frac{W_\theta c_\theta}{h_\theta A_\theta} \right) e^{p_c L} + n_c \left(\frac{1}{q_c} + \frac{W_\theta c_\theta}{h_\theta A_\theta} \right) e^{q_c L} \quad \text{.....} [36]$$

Case 3. Given θ_0, θ_1, T_1:

$$\frac{W_T c_T}{h_T A_T} \left(\frac{\theta_0 - T_1}{\theta_1 - T_1} \right) - \frac{W_\theta c_\theta}{h_\theta A_\theta} \left(\frac{\theta_0 - \theta_1}{\theta_1 - T_1} \right) + \frac{m_c}{p_c} + \frac{n_c}{q_c}$$

$$= m_c \left(+ \frac{1}{p_c} + \frac{W_T c_T}{h_T A_T} \right) e^{-p_c L} + n_c \left(+ \frac{1}{q_c} + \frac{W_T c_T}{h_T A_T} \right) e^{-q_c L} . [37]$$

Note that x_0 becomes x_1 in m_c and n_c.

Case 4. Given θ_1, T_1, T_0:

$$\frac{W_T c_T}{h_T A_T} \left(\frac{T_0 - T_1}{\theta_1 - T_1} \right) - \frac{W_\theta c_\theta}{h_\theta A_\theta} \left(\frac{T_0 - \theta_1}{\theta_1 - T_1} \right) + \frac{m_c}{p_c} + \frac{n_c}{q_c}$$

$$= m_c \left(+ \frac{1}{p_c} + \frac{W_\theta c_\theta}{h_\theta A_\theta} \right) e^{-p_c L} + n_c \left(+ \frac{1}{q_c} + \frac{W_\theta c_\theta}{h_\theta A_\theta} \right) e^{-q_c L} . [38]$$

Note that x_0 becomes x_1 in m_c and n_c.

Example

An exchanger of the type shown in Fig. 1 is employed to exchange heat between two air streams. Stream θ with a flow of 10,000 lb per hr is to be cooled from 1000 F to 350 F by 9500-lb per hr air entering at 300 F. Each air stream has a surface of 50 sq ft per ft of exchanger length and a corrected film coefficient of 20. The exchanger is lightly insulated, and the outside conductance, based upon a surface of 5 sq ft per ft of exchanger length, may be considered uniform at 1 Btu per hr per sq ft per deg F. Consider the specific heat of the air for each stream as constant and equal to 0.25 Btu per lb. Surroundings are at 100 F. Calculate the outlet temperature of the cold stream and the required exchanger length.

Solution. (Countercurrent exchanger)

$$D = \frac{10{,}000}{9500} = 1.053$$

$$h_s A_s = 5 \qquad x_0 = \frac{\theta_0 - \theta_s}{\theta_0 - T_0} = \frac{350 - 100}{350 - 300} = 5$$

$$h_\theta A_\theta = 1000$$

$$h_T A_T = 1000$$

$$a = 5 \left(\frac{1.053}{1000} + \frac{1}{1000} \right) = 0.010265$$

$$r = \sqrt{(0.053 + 0.010265)^2 + 0.04106} = 0.212$$

$$m = \frac{1}{0.424} \left\{ 0.212 - 0.053 - 5(1 - 10)(0.002053) \right\} = 0.593$$

$$n = \frac{1}{0.424} \left\{ 0.212 + 0.053 + 5(1 - 10)(0.002053) \right\} = 0.407$$

$$U_\theta A_\theta = \frac{1}{\dfrac{1}{1000} + \dfrac{1}{1000} \left(1 + \dfrac{5}{1000} \right)} = 498$$

$$p = \frac{498}{2 \times 10{,}000 \times 0.25} \left\{ 0.212 - 0.053 - 5 \left(\frac{1.053}{1000} - \frac{1}{1000} \right) \right\}$$

$$= 0.01583$$

$$q = \frac{498}{20{,}000 \times 0.25} \left\{ -0.212 - 0.053 - 5 \left(\frac{1.053}{1000} - \frac{1}{1000} \right) \right\}$$

$$= -0.0264$$

$$\theta_0 = 350 \qquad \theta_1 = 1000 \qquad T_0 = 300$$

$$\frac{\theta_1 - T_0}{\theta_0 - T_0} = \frac{1000 - 300}{350 - 300} = 14 \qquad \frac{\theta_1 - \theta_0}{\theta_0 - T_0} = \frac{1000 - 350}{350 - 300} = 13$$

Using Equation [21]

$$\left(\frac{9500 \times 0.25}{1000} \times 14 \right) + \left(\frac{10{,}000 \times 0.25}{1000} \times 13 \right) + \frac{0.593}{0.01583}$$

$$+ \frac{0.407}{-0.0264} = 0.593 \left(\frac{1}{0.01583} + \frac{9500 \times 0.25}{1000} \right) exp(0.01583L)$$

$$+ 0.407 \left(- \frac{1}{0.0264} + \frac{9500 \times 0.25}{1000} \right) exp(-0.0264L)$$

Simplifying

$$2.26 = exp(0.01583L) - 0.372 \, exp(-0.0264L)$$

By trial and error

$$\underline{L = 54 \text{ ft}}$$

Cold Gas Outlet:

$$\frac{y_1}{y_0} = 0.593\ exp(0.01583 \times 54) + 0.407\ exp(-0.0264 \times 54) = 1.491$$

$$\frac{1000 - T_1}{350 - 300} = 1.491$$

$$\underline{T_1 = 925\text{ F}}$$

For Adiabatic Exchanger:

$$10{,}000 \times 650 = 9500(T_1 - 300)$$

$$\underline{T_1 = 984\text{ F}}$$

Mean temperature difference = L.M. of 50 and 16 = 30 deg F
$U = 10$

$$\text{Exchanger length} = \frac{2500 \times 650}{30 \times 10 \times 50} = 108\text{ ft}$$

TABLE 1 COMPARISON OF EXACT AND ADIABATIC VALUES

	Exact	Adiabatic
Outlet temperature, cold gas, deg F...............	925	984
Temperature difference, hot end, deg F...........	75	16
Exchanger length required, ft.....................	54	108

ACKNOWLEDGMENT

The writer wishes to express his appreciation to the M. W. Kellogg Company for permission to publish this paper.

Discussion

R. S. Leigh.[3] In reviewing this paper, mathematics and discussion of the author's derivation are to be omitted, since the writer agrees with this method as being one of several equally accurate methods available for use, although a much simpler method will now be given.

For the better understanding of the problem two sets of curves have been drawn, Figs. 4 and 5 of this discussion, based on varying lengths and varying degrees of insulation, with all other factors as in the paper. Case 1 is set up as a completely insulated exchanger where the loss through the insulation is taken as zero. Case 2 is a moderately insulated exchanger with the over-all coefficient from either the gas side or the air side to the outside equal to 0.214 Btu hr^{-1} ft^{-2} deg F^{-1}. This corresponds to 2 in. of 85 per cent magnesia. Case 3 is the lightly insulated exchanger as used in the example by the author, where the over-all coefficient equals 0.952 Btu hr^{-1} ft^{-2} deg F.$^{-1}$

After calculating the exchanger, taking lengths of 27, 54, 81, and 108 ft, we find that the losses through the insulation and out the stack result in the curves shown in Fig. 3. In any heat-transfer apparatus or part of a heat cycle, the item of interest is the over-all efficiency. In this case, it may be seen that for a lightly insulated (case 3) exchanger, there is a maximum efficiency at about 65 ft of length. To equal the efficiency of a 54-ft-long (case 3) exchanger, the moderately insulated exchanger (case 2) would be only 37 ft long and the (case 1) perfectly insulated exchanger would be 35 ft long. Naturally, the lightly insulated exchanger would have the lower gas temperature leaving, but this would be due to losses, not to greater efficiency.

Fig. 5 illustrates the various gas and air temperatures obtainable with varying amounts of insulation and varying exchanger lengths. Of interest is the fact that the log-mean-temperature difference is fixed for any length, regardless of the amount of insulation. The quantity of heat actually transferred from the gas to the air divided by the over-all coefficient, 10 Btu hr^{-1} ft^{-2}

[3] Project Engineer, Development Department, Chase Brass & Copper Company, Waterbury, Conn.

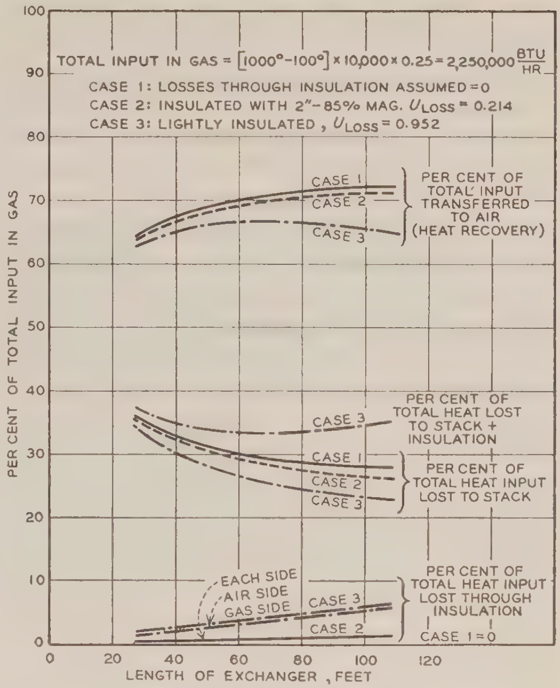


Fig. 4 Heat Balance

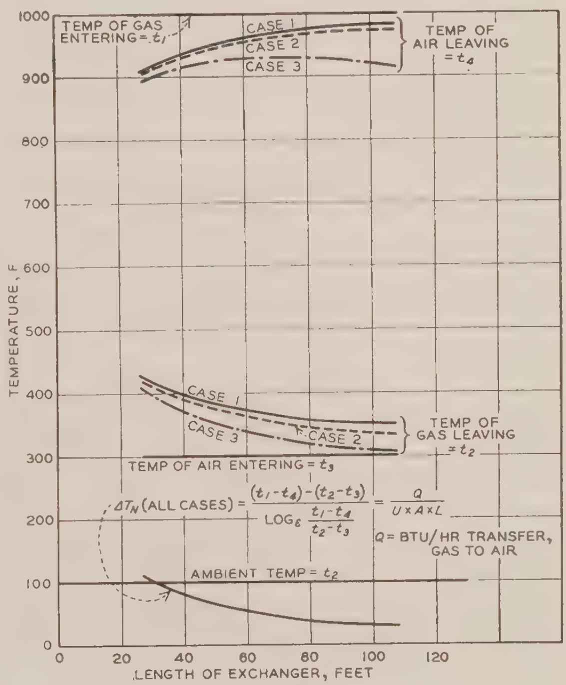

Fig. 5 Gas and Air Temperatures

deg F^{-1} times the area per foot of length times the length in feet equals the log-mean-temperature difference and is also constant for any given length. A solution based on this should give a simpler derivation than that in the paper. The amount of heat removed from the gas is simply this given amount plus the losses on the gas side. The amount of heat leaving the exchanger in the air is equal to this given amount minus the losses on the air side.

The solution in which the insulation is neglected (case 1) is simple to calculate. From this calculation the number of Btu per hour actually transferred may be determined, as well as the log-mean-temperature difference for any given length. To this quantity of heat add the gas-side losses and divide by pounds of gas per hour times the specific heat, to obtain the gas temperature drop. Then subtract the air-side losses from the given quantity of heat transferred and divide by pounds of air per hour times the specific heat, to obtain the air temperature rise.

Of interest is the slight difference between a moderately insulated (2 in. of 85 per cent magnesia) exchanger, case 2, and a completely insulated exchanger, case 1, indicating that the results obtained in the paper were exceptional only because the losses were allowed to be excessive.

The effect of the friction should be included in any problem such as this, since the friction on either the gas or air side tends to increase the leaving temperature slightly. This gain would tend to offset the loss through the insulation.

The use of standard symbols and nomenclature should be encouraged and every effort bent to this end.

Author's Closure

The author is not aware of any other methods to solve the heat-loss problem, other than a tedious step-by-step integration. Unfortunately, no references are given in the discussion. The author cannot agree with Mr. Leigh that his method offers a solution to the problem. It should be obvious that the logarithmic mean cannot be used as the mean temperature difference in a nonadiabatic exchanger.

Contrary to Mr. Leigh's statement, the effect of frictional work on a fluid in a heat exchanger usually has negligible significance on the fluid temperature. This is true because the change in temperature with change in pressure, under adiabatic conditions (Joule-Thomson coefficient), is very small except for a gas near the critical region. For a perfect gas the Joule-Thomson coefficient is zero. If one wishes to take the effect into account the result is almost always a cooling, not a heating, of the fluid.

The author regrets that, through ignorance, standard symbols were not used in the paper.

Temperature Uniformity in Heating-Up Processes

By M. P. HEISLER,[1] NEW YORK, N. Y.

The treatment of temperature-uniformity problems by the method first introduced by Paschkis is extended and enlarged. It is shown that uniformity calculations can be reduced to the solution of a simple trigonometric relation which can be readily solved and analyzed. Standard Gurney-Lurie charts for cylinders and spheres are given in a more complete form than is available at present. A chart is included for determining temperature history in plates subjected to two-dimensional heat flow. Finite cylinders are discussed and three-dimensional heat-flow problems are briefly considered.

Introduction

A temperature-uniformity problem results when a body is to be heated to a given surface and a given center temperature. Such a problem cannot be directly solved by means of the standard heating charts because the furnace temperature and the heating time required to produce the specified uniformity are not known. The possibility of applying the simple heating and cooling charts of Groeber, Hottel, Schack, Newman, and others to temperature-uniformity calculations was first recognized by Paschkis.[2] He prepared a set of curves from the Groeber charts and thereby introduced a fundamentally new parameter, which he called the "temperature-uniformity factor." This temperature-uniformity factor, which he defined as (surface temperature — center temperature)/(surface temperature — temperature of surroundings), was obtained by eliminating the furnace temperature from the standard dimensionless temperature ratio Y, used in all of the charts mentioned. By eliminating the furnace temperature Paschkis was able to derive a new set of curves from which, given only the final surface and center temperatures to which the workpiece was to be heated, the unknown furnace temperature and heating time could be found, provided that the following conditions prevailed:

1 Workpiece was of a simple shape; plate, cylinder, or sphere.

2 A suddenly impressed and thereafter constant furnace temperature was used.

3 Workpiece had constant thermal properties, i.e., properties were temperature-invariant.

4 There was constant boundary resistance throughout the heat period.

5 Uniform surface temperatures existed, e.g., on opposite sides of a slab or plate.

Unfortunately, these conditions are never met in practice, although in particular cases they may be approached. In general, the use of constant average thermal properties in place of the true temperature-varying properties results in relatively slight error. The assumption of simple shape introduces an error proportional to the degree to which the actual shape approximates the assumed one, but it is difficult to measure the exact degree of approximation. The influence of boundary resistance is even more difficult to gage, because boundary resistance is, among other things, a function of the temperature difference existing between furnace and surface of stock and therefore is subject to wide variations during the heating cycle.

In fuel-fired furnaces, constant furnace temperatures are virtually nonexistent. If the charge and furnace are heated-up together, the cold walls and charge will lower the initial furnace temperature. Even after the walls and charge are heated up there will still be temperature fluctuations caused by the temperature control. It may be argued that these latter temperature fluctuations are never very large, yet if they are compared with the temperature differences encountered in the stock at the end of the heating period it will be seen that they may have considerable influence on the temperature uniformity. Similar arguments can be made for cases where the cold charge is suddenly introduced into the hot furnace.

Finally, uniform surface temperatures seldom prevail, whether the charge be heated from one or from all sides. Skids, hearth, contact with neighboring stock, corners, edges—all tend to produce unequal temperature distributions on the surface. Nevertheless, for the sake of obtaining some numerical values average conditions are generally assumed. Very often, even though only approximate, analytical methods yield valuable results.

Of these factors the relative boundary resistance m is of particular importance because the accuracy of the analytical solution depends largely upon how accurately m is known. It has become standard practice to use an average surface heat-transfer coefficient in calculating the relative boundary resistance, the proper choice of the average value leaning heavily upon practical experience. In many instances the engineer has little to use as a guide and the boundary resistance used in his calculations may then largely be the result of concentrated wishful thinking.

In general, surface heat transfer occurs mainly by radiation from some constant furnace temperature to a lower varying surface temperature. It is suggested here, as an initial step in placing the determination of a suitable average boundary resistance on a rational basis, that an average surface temperature be used in calculating the surface heat-transfer coefficient. For example, consider a slab, initially at 70 F, heated in a 2000 F furnace. If it can be assumed that heat transfer takes place largely by radiation, then the conditions illustrated in Table 1 exist. In the table, column 1 shows various surface temperatures of the slab; column 2 shows h values for black-body radiation from 2000 F to the given surface temperature; column 3 shows h

TABLE 1 HEATING-UP DATA FOR SLAB IN 2000 F FURNACE

Surface temperature, deg F	h Btu/(sq ft)(hr)(deg F)	$h/102$	Temperature (deg F)/2000
0	31.2	0.306	0
200	35.0	0.344	0.1
400	38.8	0.390	0.2
600	43.3	0.425	0.3
800	49.0	0.481	0.4
1000	54.8	0.537	0.5
1200	62.0	0.608	0.6
1400	70.0	0.686	0.7
1600	80.0	0.785	0.8
1800	90.0	0.883	0.9
2000	102.0	1.0	1.0

expressed as a fraction of its value at 2000 F; and column 4 the surface temperature expressed as a fraction of the final value of 2000 F. It can be seen that h is directly proportional to the surface temperature over a large part of the temperature scale, the proportionality becoming better as the temperature increases. This latter fact is particularly important because the surface will be at high temperatures for a considerably longer time than it will be at low temperatures. It is evident, then, that a time average of the surface temperature will be nearly proportional to a time average of the boundary resistance m. A relatively simple method for determining the time-average surface temperature will be given later.

In most instances the workpiece is heated to a center temperature that will be as near to the final surface temperature as an economical heating time will permit. In problems of this type two m values must be used. One based upon the time-average surface temperature, to find the heating time; and the other based upon final surface temperature, to find the temperature at the center. To make this clear consider two identical slabs, one at the temperature of the surroundings, the other at a uniform temperature of 1000 F. The slabs are put into a 2200 F furnace at the same instant and are kept there until the surfaces reach a temperature of 2180 F. It is evident that when the surfaces of the slabs reach 2180 F (at different times, of course) their respective center temperatures will, for all practical purposes, be very nearly identical. However, if the center temperatures are calculated in the customary manner from heating and cooling charts, they will not appear to be the same because the average boundary conductances will be based in one case upon initial radiation from 2200 to 1000 F, and in the other case on initial radiation from 2200 F to the temperature of the surroundings. What actually happens is the following:

As the final surface temperature is approached there is little change in the boundary resistance because of little change in surface temperature. As a result, the center temperature which originally lagged considerably behind the fast-changing surface temperature, has time to catch up to the now slowly changing surface temperature and assumes values determined, not by the time-average surface temperature, but by the actual surface temperature at the end of the heating cycle. It is evident then that in any heating to a high degree of uniformity the center temperature should be determined from the boundary conductance at the end of the heating cycle. This can then be adjusted to take care of the slight lag which will still exist between center temperature and surface conductance.

A temperature-uniformity problem therefore resolves itself into determining average and end boundary conditions. The first will yield the heating time, the second the furnace temperature. The determination of the latter is the simpler and will be considered first.

Nomenclature

m = relative boundary resistance, (conductivity)/(surface heat-transfer coefficient) (half thickness)

m_x = relative boundary resistance for two-dimensional heat flow, based upon half thickness in direction of x-axis

m_y = relative boundary resistance for two-dimensional heat flow, based upon half thickness in direction of y-axis

t' = furnace temperature or temperature of hot ambient

t = surface temperature

t° = center temperature

t_b = uniform base temperature of solid

t_a = time-average surface temperature

t_x = temperature in solid at distance x from center

t^* = edge temperature of long rectangular rod

X = dimensionless time (diffusivity)(time)/(half thickness squared)

X_0 = value of dimensionless time when surface has reached final temperature

X_x = dimensionless time for two-dimensional heat flow, based upon half thickness along x-axis

Y_x = dimensionless temperature ratio at distance x from center of solid (furnace temperature—temperature at point x)/(furnace temperature — base temperature)

Y = dimensionless temperature ratio at surface of solid (furnace temperature—temperature of surface)/(furnace temperature—base temperature)

Y° = dimensionless temperature ratio at center of solid, (furnace temperature—center temperature)/(furnace temperature—base temperature)

Y_a = dimensionless temperature ratio for finding average surface temperature (furnace temperature—average surface temperature)/(furnace temperature—base temperature)

One-Dimensional Heat Flow

It was pointed out that in furnace calculations it is customary to make use of dimensionless parameters, m, X, and Y. Many charts by Newman, Hottel, Bachmann, Gurney-Lurie, etc., have been plotted which give the temperature history of simple shapes like semi-infinite plates, infinite cylinders, and spheres. All of these charts, with the exception of Bachmann's, are plotted as functions of m, X, and Y.

Some modifications must be made in these standard charts before they can be used for temperature-uniformity calculations, because neither the furnace temperature nor the heating time is known. However, once the surface and center temperatures of the workpiece are specified and the relative boundary-resistance factor m is determined, the furnace temperature and the heating time are fixed. To see that this is true consider the following equation, which applies to the heating-up of semi-infinite plates

$$Y_x = \frac{t' - t_x}{t' - t_b} = \sum_{k=1}^{\infty} \frac{2(\sin w_k)(\cos w_k x) \exp(-w_k^2 X)}{w_k + (\sin w_k)(\cos w_k)} \quad [1]$$

where w_z is defined by the characteristic number equation $mw = \cot w$, and

t_x is temperature, varying with distance x and dimensionless time X

t' is temperature of hot ambient—furnace temperature

Y_x is relative temperature at position x and time X

t_b is initial temperature of slab

Now, it is a fact that in the expansion all terms after the first can be neglected for X in the neighborhood of 0.2, since for values of X larger than 0.2, these terms rapidly vanish. To illustrate the extreme rapidity of convergence, consider the first two roots of $mw = \cot w$ when m is equal to 1. The first root is $w = \cot w = 0.8603$; the second root is $w = \cot(w + \pi) = 3.4256$. Suppose X is equal to 1. Then, for the first root $\exp(-w^2X)$ becomes 0.477, and for the second root 0.0000076. Thus if only the exponential factor is considered, it is obvious that the second term in the expansion becomes insignificant; the trigonometric factor serves to reduce the numerical value even more. Since the values of X encountered in temperature-uniformity calculations are generally very much greater than 0.2, Equation [1] can be reduced to

$$Y_x = \frac{2(\sin w)(\cos wx) \exp(-w^2X)}{w + (\sin w)(\cos w)} \quad [2]$$

where the first root of $mw = \cot w$ determines w. In the derivation of Equation [1] it was assumed that the origin was at the mid-plane of the slab. Therefore at the surface $x = 1$ and at the center $x = 0$, and

$$\text{(surface)} \quad Y = \frac{t' - t}{t' - t_b} = \frac{2(\sin w)(\cos w)\exp(-w^2X)}{w + (\sin w)(\cos w)} \quad [3]$$

$$\text{(center)} \quad Y^\circ = \frac{t' - t^\circ}{t' - t_b} = \frac{2(\sin w)\exp(-w^2X)}{w + (\sin w)(\cos w)} \quad [4]$$

where t is the surface temperature and t° the center temperature of the slab. Dividing Y by Y° gives

$$Y/Y^\circ = \cos w = (t' - t)/(t' - t^\circ) \quad [5]$$

Equation [5] is plotted in Fig. 1 as a function of m; and since m, t, and t° are known, the unknown furnace temperature t' can be found. To find t', enter Fig. 1 with the known m as abscissa, go vertically to the curve for the plate and thence horizontally and read the ordinate. The ratio $(t' - t)/(t' - t^\circ)$ will hereafter be called the relative-temperature-uniformity ratio, since it is a measure of the relative temperature uniformity existing between stock and furnace at the end of the heat period.

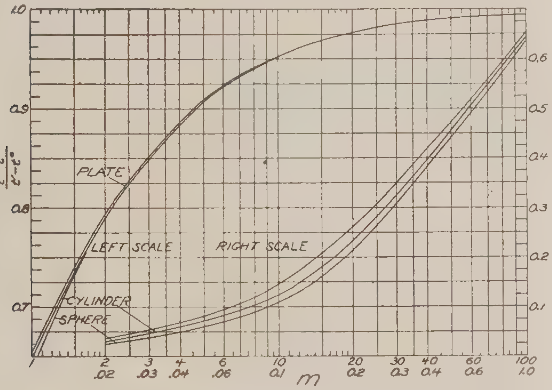

FIG. 1 CHART FOR DETERMINING RELATIVE TEMPERATURE-UNIFORMITY RATIO

Equation [5] shows that the furnace temperature is a function only of the relative boundary-resistance factor m and the given surface and center temperatures. If it were possible to have an infinite heat-transmission coefficient h, m would become zero, $\cos w$ would also become zero, and the surface temperature would equal the furnace temperature. For any given surface and center temperatures m is a direct measure of the required furnace temperature. If m is large, which, other things being equal, is tantamount to having poor surface heat transmission, $\cos w$ approaches 1. This means that a high furnace temperature is necessary to produce the desired uniformity. Conversely, if m is small the furnace temperature approaches the surface temperature as a minimum. The equation clearly shows that lower furnace temperature and better temperature uniformity within a given time are obtained by increasing surface heat transmission from flame to stock.

By comparison with the Gurney-Lurie-type charts it can be seen that small m's also imply low heating times. The relation of furnace temperature and heating time to boundary resistance is shown in Fig. 2. The curves were obtained from Fig. 1 and illustrate how heating times and furnace temperatures increase with boundary resistance. The curves shown hold for a slab

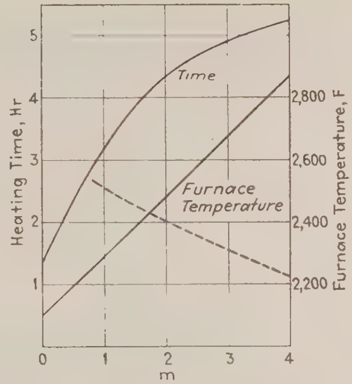

FIG. 2 VARIATION OF HEATING TIME AND FURNACE TEMPERATURE WITH RELATIVE BOUNDARY RESISTANCE

heated to a surface temperature of 2100 F and a center temperature of 2000 F. The dimensions and thermal properties of the slab are not given because the curves are intended to show trends only. For the sake of illustration no distinction was made between average and end boundary conditions.

In the introduction it was pointed out that the relative boundary resistance m is a function of the furnace temperature. Since the furnace temperature is not known, the relative boundary resistance cannot be directly determined, and inversely, since the boundary resistance is not known the furnace temperature and heating time cannot be calculated. One of the necessary calculations in furnace design is a plot showing the relation of the surface heat-transmission coefficient to furnace temperature. This chart must be calculated from the various flame characteristics, such as thickness of flame, composition of the hot gases, amount of dissociation, luminosity of the flame, emissivity and temperature of the surface, and the like. From this chart the surface heat-transmission coefficient can readily be converted into the relative boundary resistance m. Since the furnace temperature increases with increasing h, it will decrease with decreasing m. Suppose that the broken line in Fig. 2 is this calculated temperature versus end m relation for the given flame properties. Then the intersection of the broken temperature line with the solid temperature line (determined from Fig. 1) gives the value of m and the furnace temperature that will, approximately, produce the desired temperature uniformity.

The heating time is determined from the same heat-transmission curve from which the furnace temperature was determined, but in this case an average m is used. To illustrate, suppose such a heat-transmission chart is available and that the time-average surface temperature over the heat period is known. With this average surface temperature the average surface heat-transfer coefficient can be read directly and therefore the average m is determined. With this m, the heating time can be found from the standard heating-cooling charts. The average surface temperature is found as follows:

$$Y_{\text{avg}} = \int_0^{X_0} \frac{YdX}{X_0}$$

where X_0 is the value of the dimensionless time when the final surface temperature is reached. Therefore

$$Y_{\text{avg}} = \int_0^{X_0} \sum_{k=1}^{\infty} \frac{2(\sin w_k)(\cos w_k)\exp(-w_k^2X)dX}{X_0(w_k + \sin w_k \cdot \cos w_k)}$$

$$= \sum_{k=1}^{\infty} \frac{2(\sin w_k)(\cos w_k)[1 - \exp(-w_k^2 X_0)]}{w_k^2 X_0(w_k + \sin w_k \cdot \cos w_k)}$$

Since X_0 is greater than 0.2 this can be simplified to

$$Y_{avg} = \frac{Y\,[\exp(w^2X_0) - 1]}{w^2X_0} = \frac{t' - t_a}{t' - t_b}$$

where t_a is the average surface temperature during the interval of exposure. Eliminating Y, this can be written

$$\frac{t' - t_a}{t' - t} = Y_a = \frac{\exp(w^2X_0) - 1}{w^2X_0} \quad \ldots\ldots\ldots\ldots [6]$$

Values of w^2 can be read from Fig. 3 and values of Y_a from Fig. 4. The use of the charts will become clear from the following example: A 6-in. steel slab of diffusivity 0.5 sq ft per hr, conductivity 25 Btu/(ft)(hr)(deg F) is to be heated to a surface temperature of 1970 F in a furnace at 2070 F. The temperature of the surroundings is 70 F. Heat transfer is assumed, for simplicity, to take place by radiation only, although it should be noted that the method will apply to any heat transfer for which a curve can be drawn. What is the average surface temperature over the interval? What will be the temperature at the center at the end of the heat period?

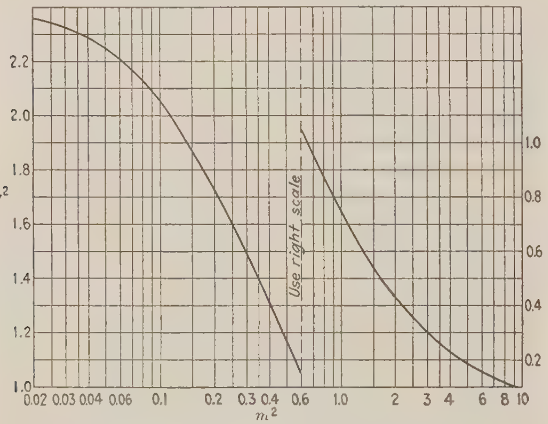

FIG. 3 CHART FOR DETERMINING SQUARE OF CHARACTERISTIC NUMBER w

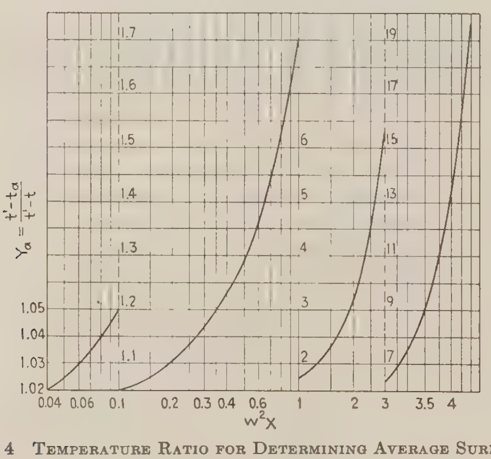

FIG. 4 TEMPERATURE RATIO FOR DETERMINING AVERAGE SURFACE TEMPERATURE OF SLAB

The temperature-time curve of the surface is reasonably parabolic. Therefore assume an initial average surface temperature of (2/3)(1970) = 1315 F. From radiation charts,[3] for radiation between two infinite parallel plane surfaces, one at 2070 F and the other at 1315 F, the surface heat-transmission coefficient h is found to be 70 Btu/(sq ft)(hr)(deg F). Therefore m = (25)/(70)(3/12) = 1.43. From standard cooling charts,[3] for m = 1.43 and Y = (2070 — 1970)/(2070 — 70) = 0.05, X_0 is found to be 4.9. From Fig. 3, when m is equal to 1.43, w^2 is 0.565. Therefore w^2X_0 = 4.9 × 0.565 = 2.77. From Fig. 4, Y_a = 5.45 = (2070 — t_a)/(2070 — 1970). Solving this, t_a is found to be 1525 F.

The procedure is now repeated with the new t_a. For t_a = 1525, h is 80 Btu/(sq ft)(hr)(deg F). Solving for m, we find it to be 1.25. From this X_0 = 4.35 is obtained and also w^2 = 0.628. From Fig. 4, for w^2X_0 = 0.628 × 4.35 = 2.73, Y_a is read as 0.53. Solving, it is found that the average surface temperature is 1540 F. This is sufficiently close to the previous value and further refinement is unnecessary.

To find the center temperature proceed as follows: For radiation between 2070 and 1970 F, McAdams[3] gives an h of 110 Btu/(sq ft)(hr)(deg F). From this m is 0.91 and from Fig. 1 $(t' - t)/(t' - t_0)$ is 0.629. Solving for t_0 gives t_0 = 1875 F.

The difference between average and end-boundary-resistance ratios is pronounced, and it is evident that quite different center temperatures will be obtained with both m values. Strictly speaking, neither temperature will be exact, but that obtained from the final boundary conditions will certainly be more correct than that obtained from average boundary conditions.

The foregoing analysis was carried through for a semi-infinite plate. Equations similar to Equation [5] are derived in the Appendix for infinite cylinders and for spheres. It is sufficient here to remark that the curves shown in Fig. 1 for cylinders and spheres can be used in the manner described for the semi-infinite plate. Average surface-temperature equations can be easily derived. One restriction is placed on all these curves; they apply only for values of X equal to or greater than 0.2. However, this does not detract from their applicability because, as is shown, values of X encountered in temperature-uniformity calculations are always far greater than 0.2.

Figs. 5 and 6 are included here because no standard heating-cooling charts of the Hottel type are available for cylinders and spheres, and temperature-uniformity calculations frequently require the use of curves which give small temperature ratios accurately. Only the center temperatures are given. To find the surface temperatures, multiply the ordinate from Fig. 5 or 6 with the corresponding ordinate from Fig. 1. Figs. 5 and 6 give $Y° = (t' - t°)/(t' - t_b)$, and Fig. 1 gives $(t' - t)/(t' - t°)$. The product gives $(t' - t)/(t' - t_b)$, from which the surface temperature can be found. A more complete discussion is given in the Appendix and the relation is extended to include all in-between points.

It should be emphasized that the relative temperature-uniformity ratio and the uniformity factor are not single-valued parameters and do not in themselves determine a unique solution of the problem. To see that this is true consider the uniformity factors 1 — (1900/2000) and 1 — (3800/4000). The factors are numerically equal and give the same heating times, based upon the Paschkis charts,[2] but they will not result in the same furnace temperatures. Similarly, a given relative temperature-uniformity ratio has an infinite number of dimensionless time ratios X. The system is uniquely determined only by the parameters Y, m, and X. The relative temperature-uniformity ratio and the uniformity factor are auxiliary parameters which show certain

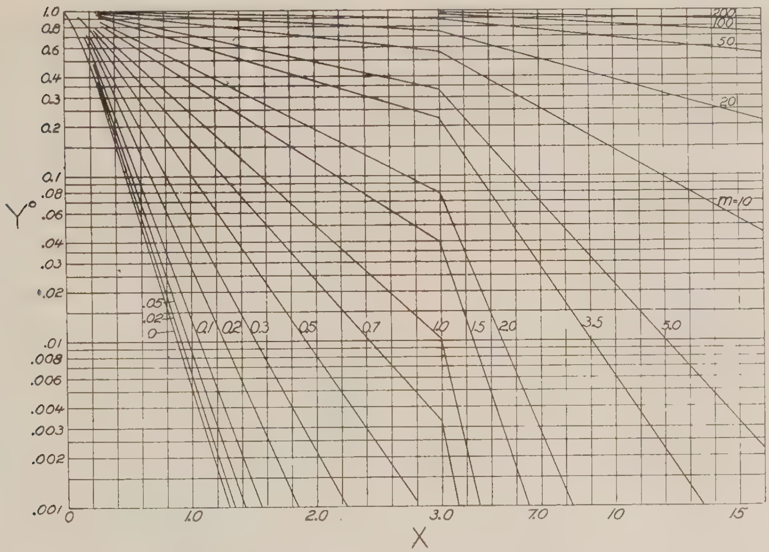

Fig. 5 Chart for Determining Temperature History at the Axes of Cylindrical Bodies

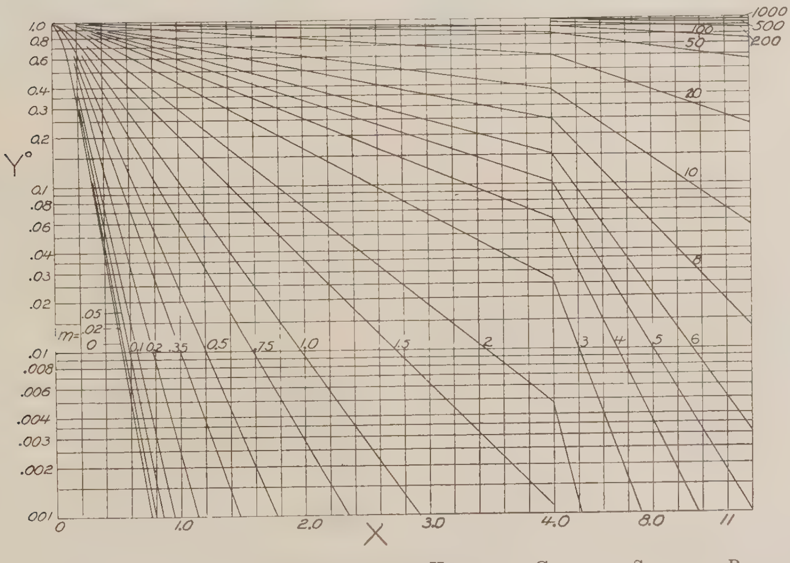

Fig. 6 Chart for Determining Temperature History at Center of Spherical Bodies

relations that exist among the different variables; the former ties in the furnace temperature and the latter the heating time with boundary resistance and surface and center temperatures. Each depends upon the other; if taken together they eliminate the necessity for using the standard cooling charts, but they cannot be combined into a single chart.

Summary. In the preceding paragraphs simple equations have been presented which enable uniformity calculations to be made readily. It is pointed out that the simplicity of the relations derived makes it a comparatively easy task to determine the mutually dependent furnace temperature and relative boundary resistance. Temperature-time-space curves are given to supplement and add to those available at present.

Two-Dimensional Heat Flow

The definition of temperature uniformity is based upon maximum surface and minimum mid-plane temperatures. In two-dimensional heat flow maximum surface temperatures occur at the edge. In the heating of a plate infinite in one direction only, for example, a long rod, or a short plate insulated on two opposite faces, if the origin of a rectangular system of co-ordinates is thought of as placed at the geometric center of the plate, Fig. 7, it is shown in the Appendix that edge, center, and furnace temperatures are related by

$$(t' - t^*)/(t' - t^\circ) = (\cos w)_x(\cos w)_y \qquad [7]$$

where as before t' and t° are furnace and center temperatures,

respectively; t^* is the edge temperature; $\cos(w)_x$ and $(\cos w)_y$ are found from Fig. 1 by calculating the relative boundary resistances m_x and m_y for heat flow in the x- and y-directions, respectively, just as is done for one-dimensional heat flow. Since t^* and t° are given by the specifications and m is assumed for the present to be known, the furnace temperature t' can be found

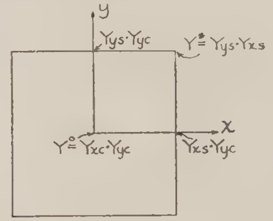

Fig. 7 Y-Factor Relations for Two-Dimensional Heat Flow in Plate

A chart similar to Fig. 1 can be plotted, but in place of a single curve there will be a family of curves with either m_x or m_y as abscissa and m_y or m_x as parameter. In general m_x will not be equal to m_y.

If the sides of the body are of equal length, $(\cos w)_x$ will equal $(\cos w)_y$ and $(t' - t^*)/(t' - t^c)$ will equal $(\cos w_x)^2 = (\cos w_y)^2$, since the two will be numerically equal. In this case the solution can be obtained from Fig. 1 and the standard heating-cooling charts. For example, let $m_x = m_y = 1$, and let the surface temperature be 2100 F and the center temperature be 2000 F. From Fig. 1 and Equation [2]

$$(t' - t^*)/(t' - t^\circ) = (0.654)^2 = 0.428$$

Therefore $t' = 2172$ F. From Equation [18] of the Appendix the temperature ratio at the center is

$$\sqrt{(2172 - 2000)/(2172)} = \sqrt{0.0781} = 0.2795$$

From the cooling curves for $m = 1$, X is found to be 1.88.

When the sides are not of equal length, the cooling charts for one-dimensional heat flow cannot be used. As yet only a few two-dimensional charts have been prepared (an unpublished work by Rohsenow and his co-workers at Yale University, under direction of Professor Wohlenberg). To cover completely all conditions requires an inpracticably large number of such graphs. In the second section of the Appendix it is shown that the system, in so far as temperature-uniformity problems are concerned, can be completely defined by the six parameters m_x, m_y, x/y, X_x, $1 - t^\circ/t'$, and $1 - t^*/t'$. X_x is the dimensionless time ratio, with thickness squared being the square of the length of the smallest side; x/y, a shape factor, is the ratio of the lengths of the sides. The other parameters have already been described. To cover completely all practical combinations of these variables would require (for 15 values of m_y and 5 of x/y) 75 charts of conventional form for each of the two temperature ratios, or 150 charts in all. Such a presentation is obviously out of the question. If an intersection chart is substituted, however, it is possible, by imposing a few restrictions which will be considered later, to cover in a single chart most of the cases met in practical applications. A chart of this type, applying to plates only, is shown in Fig 8.

The chart is somewhat more difficult to use than the simple cooling charts, but some sacrifice in simplicity must be made in order to obtain generality. For temperature-uniformity calculations m_x, m_y, x/y, and Y° will be known (Y° having been found from Fig. 1) and the unknown will be the relative heating time X_x. To find X_x:

1 With the given m_y as abscissa go to the first quadrant and locate the intersection of the vertical from m_y with the curve of constant m_x. From the point of intersection proceed horizontally to the second quadrant and locate the point of intersection with Y°.

2 With the given x/y as abscissa enter the fourth quadrant, go horizontally to m_y; from m_y proceed perpendicularly to m_x and thence horizontally to X. The intersection of this horizontal with a perpendicular from the value of Y° located in the first step determines X.

As an example, the case of the square bar, solved previously by using the one-dimensional cooling chart, is shown (dotted line in Fig. 8). In this case enter the fourth quadrant at $x/y = 1$ and the first quadrant at $m_x = 1$. The intersection in the third quadrant gives $X_x = 1.88$.

Fig. 8 is not restricted to temperature-uniformity calculations, but can be applied to heating and cooling problems in general. However, in any problem neither X_x nor X_y should be less than 0.2 for values of m equal to zero. For larger m values, X less than 0.2 may be used, a simple criterion being to refer to the Gurney-Lurie charts and find for what value of X the lines of constant m have not begun to curve.

In the terminology of this paper X_y will always be less than X_x, because $X_y = X_x(x/y)^2$. Therefore for small values of x/y, X_y should always be calculated to find out if it is within the imposed limit. In general, though, small values of x/y will mean that heat flow in the y-direction is of negligible influence; therefore these cases can be treated as one-dimensional problems, using the standard charts. Fig. 8 can be applied to nearly all problems that cannot be treated one-dimensionally.

Appendix

Infinite Cylinders. Bodies having circular symmetry can be treated in a manner similar to that used for plates. The equation, in dimensionless form, for the heating-up of an infinite cylinder, or a short cylinder insulated at both ends, can be written

$$Y(x,X) = \sum_{k=1}^{\infty} \frac{2J_1(u_k)J_0(u_kx)\exp(-u_k^2X)}{J_0^2(u_k) + J_1^2(u_k)} \cdot \frac{1}{u_k} \quad [8]$$

where u_k is defined by $J_0(u) = muJ_1(u)$.

It is true also for cylinders that the values of X encountered in temperature-uniformity calculations are such that in the expansion all terms after the first become negligible. Therefore Equation [8] can be reduced to

$$\text{(surface)} \qquad Y = \frac{2J_1(u)J_0(u)\exp(-u^2X)}{J_0^2(u) + J_1^2(u)} \cdot \frac{1}{u} \quad [9]$$

$$\text{(center)} \qquad Y^\circ = \frac{2J_1(u)\exp(-u^2X)}{J_0^2(u) + J_1^2(u)} \cdot \frac{1}{u} \quad [10]$$

Proceeding as before

$$Y/Y^\circ = J_0(u) = (t' - t)/(t' - t^\circ) \quad [11]$$

Equation [11] is plotted in Fig. 1 (see curve for cylinder). The furnace temperature is found in the same manner as was prescribed for the plate. The heating-up time can be found from the cooling chart for the cylinder, Fig. 5. Charts other than the Gurney-Lurie type are not suited for temperature-uniformity calculations because they do not have accurate readability in the small temperature ratios. Charts are given only for center temperatures because, as was pointed out previously, temperatures for the surface can be found from the relation $Y^\circ(Y/Y^\circ) =$

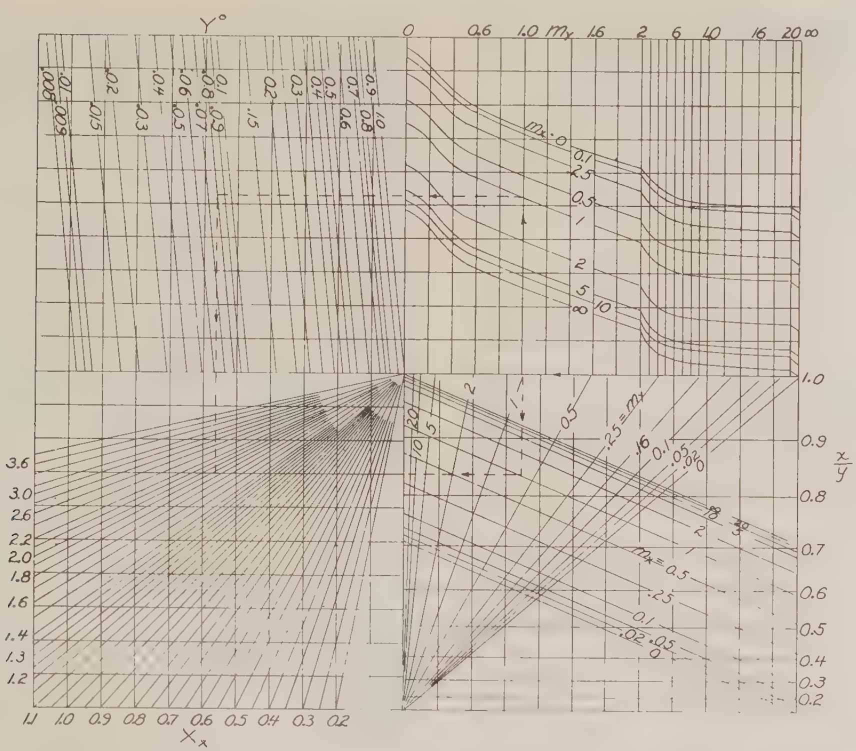

FIG. 8 CHART FOR DETERMINING TEMPERATURE HISTORY AT MID-PLANE OF PLATE SUBJECTED TO TWO-DIMENSIONAL HEAT FLOW

Y. This relation is exact for all values of Figs. 5 and 6 in which the temperature curves are straight lines and this covers practically the entire range of the charts. Little is lost by not being able to use this relation in the small remaining portion of the charts because Gurney-Lurie type charts are not suited for temperature ratios at small values of X; these can be found best by charts derived from short-time expansion formulas.

Spheres. The equation for the sphere is

$$Y(x,X) = \sum_{k=1}^{\infty} 2\frac{(\sin v_k - v_k \cos v_k)\exp(-v_k^2 X)}{v_k - (\sin v_k)(\cos v_k)} \cdot \frac{\sin(v_k x)}{v_k x} \quad [12]$$

and the corresponding characteristic number equation is $mv = (m - 1)\tan v$. Again, in temperature-uniformity calculations, all terms after the first can be neglected and the equation reduced to

$$\text{(surface)} \quad Y = 2\frac{(\sin v - v \cos v)\exp(-v^2X)}{v - (\sin v)(\cos v)} \cdot \frac{\sin v}{v} \quad [13]$$

$$\text{(center)} \quad Y^\circ = 2\frac{(\sin v - v\cos v)\exp(-v^2X)}{v - (\sin v)(\cos v)} \quad [14]$$

From the equations for the surface and center

$$Y/Y^\circ = (\sin v)/v \quad [15]$$

Summary. In the preceding paragraphs it has been shown that by eliminating the dimensionless time from the heat equations for plates, spheres, and cylinders, simple equations result which relate surface, center, and furnace temperatures to boundary resistance. From these elemental relations dimensionless temperature ratios can be formed which make it possible to use standard heating-cooling curves to find the time required to obtain the desired temperature uniformity. In addition, the simple temperature and boundary-resistance relations make it comparatively easy to determine the unknown boundary resistance.

Temperature-time-space curves for cylinders and spheres are given to supplement those available at present. These curves are given for center temperatures only, but can be readily extended to surface temperatures by the use of Fig. 1, and to all in-between points by forming the products $Y^\circ \cos(wx)$, $Y^\circ J_0(ux)$, and $Y^\circ(\sin vx)/v$ for plates, cylinders, and spheres, respectively. In all instances these relations are restricted to values of X equal to or greater than 0.2.

TWO-DIMENSIONAL HEAT FLOW

Supplementing the nomenclature previously given, the following additions will be used:

Y° relative temperature for center $= (1 - t^\circ/t')_x, (1 - t^\circ/t')_y$

Y^* relative temperature for edge of a finite plate $= (1 - t/t')_x, (1 - t/t')_y$

Y_{ys}, Y_{xs} relative temperatures at surfaces perpendicular to x- and y-axes, respectively, when body is considered as a semi-infinite solid $= (1 - t/t')_x, (1 - t/t')_y$

Y_{yc}, Y_{xc} relative temperatures at mid-planes perpendicular to x- and y-axes, respectively, when body is considered as a semi-infinite solid $= (1 - t^\circ/t')_x, (1 - t^\circ/t')_y$

x distance from vertical mid-plane to surface

y distance from horizontal mid-plane to surface

d diffusivity

θ time (not dimensionless)

t_b assumed to be zero

Finite Plate. In two-dimensional heat flow essentially the same methods are applied as in one-dimensional heat flow. The heat-flow equation must now satisfy the differential equation

$$\frac{\partial t}{\partial \theta} = d\left(\frac{\partial^2 t}{\partial x^2} + \frac{\partial^2 t}{\partial y^2}\right) \qquad [16]$$

where x and y are rectangular co-ordinates indicating the direction of heat flow, and d is the diffusivity. Newman[4] showed that if Y_x was the solution of

$$\partial t/\partial\theta = d(\partial^2 t/\partial x^2)$$

and its boundary conditions, and Y_y was the solution of

$$\partial t/\partial\theta = d(\partial^2 t/\partial y^2)$$

and its boundary conditions, then $Y_x Y_y$ was a solution of Equation [16]. McLachlan,[5] following the method of Newman, showed that in the heating of solids the partial differential equation is satisfied by a solution of the form $1 - Y_x Y_y$, where Y_x is the expansion part of Equation [1] and Y_y is the expansion part of the same equation with y introduced in place of x. The corresponding heating-up temperatures are $H_x = 1 - Y_x$ and $H_y = 1 - Y_y$.

In two-dimensional heat flow the maximum temperatures will occur at the edges of the body and the minimum temperature at the center. The desired temperature uniformity will be given in terms of the edge and center temperatures t^* and t°, respectively, and the following relations (see Fig. 7) then hold

(edge) $\qquad Y^* = 1 - t^*/t' = Y_{ys}Y_{xs} = 1 - H^*$

(center) $\qquad Y^\circ = 1 - t^\circ/t' = Y_{yc}Y_{xc} = 1 - H^\circ$

To simplify the form of the equations let

$$a_x = 2(\sin w)/(w + \sin w \cos w)$$

$$b_x = \cos(wx)$$

$$e_x = \exp(-w^2 X_x)$$

for heat flow in the direction of the x-axis. For heat flow in the direction of the y-axis, use the same notation but replace the subscript x by y. Then

(edge) $\qquad Y^* = (abe)_{xs}(abe)_{ys} \qquad [17]$

(center) $\qquad Y^\circ = (ae)_{yc}(ae)_{xc} \qquad [18]$

Dividing Equation [17] by Equation [18] gives

$$(t' - t^*)/(t' - t^\circ) = (\cos w)_x(\cos w)_y \qquad [19]$$

Solution of this equation yields the furnace temperature. The heating time requires a solution of

$$Y^\circ = 1 - t^\circ/t' = (2\sin w)_x(2\sin w)_y\{\exp -X_x[w_x^2 + (w_y x/y)^2]\}/(w + \sin w\cdot\cos w)_x \cdot (w + \sin w \cdot \cos w)_y$$

This equation is plotted in Fig. 8. Only center temperatures are plotted. The surface temperatures can be found from Y°, Fig. 1, and the following relations, Fig. 7:

(vertical mid-plane) $\qquad Y_{ys}Y_{xc} = Y^\circ(\cos w)_y \qquad [20]$

(edge) $\qquad Y_{ys}Y_{xs} = Y^\circ(\cos w)_x(\cos w)_y \qquad [21]$

(horizontal mid-plane) $\qquad Y_{xs}Y_{yc} = Y^\circ(\cos w)_x \qquad [22]$

Finite Cylinders. The handling of finite cylinders is the same as for finite plates. If the axis of the cylinder is taken in the direction of the x-axis, it follows, from the similarity between the heat-flow equations for bodies having circular symmetry and those for plates, that

$$(t' - t^*)/(t' - t^\circ) = J_0(u)(\cos w)_x$$

Values of $(\cos w)_x$ and $J_0(u)$ can be obtained from Fig. 1; from their product the furnace temperature can be calculated. As in the case of two-dimensional heat flow in slabs, the solution of the heating time is dependent upon the preparation of the requisite temperature-time-space charts. A chart similar to Fig. 8 can be prepared, or perhaps other methods of plotting, more convenient in form, may be evolved. Equations for determining temperatures at points other than at the edge and center, for example, equations similar to Equations [20], [21], and [22] can be readily derived, the only restriction being that neither dimensionless time ratio be less than 0.2.

The treatment of three-dimensional heat-flow problems follows directly from the methods given for one- and two-dimensional heat flow.

In two- and three-dimensional heat flow an additional complication enters in determining the average boundary resistance, because of the variation of surface temperature from edge to center of the face. Not only will a time average of surface temperature have to be determined, but also a space average, since the faces do not have uniform temperature distribution, and therefore do not have uniform boundary resistances.

Comment. In the preceding discussion only homogeneous solids have been considered. In the case of laminated solids in which the thermal conductivity may be different along the various axes, the value of thermal diffusivity may be correspondingly adjusted for the different directions, and the calculation carried out as usual. If the surface heat-transmission coefficient is different at the various faces, these different values of h may be used, the only limitation being that of maintaining symmetry; the values of m must be the same for any pair of parallel faces.

Acknowledgment

This paper is largely an extension of the work on temperature uniformity originally initiated by Dr. Victor Paschkis, head of the Heat and Mass Flow Analyzer Laboratory at Columbia University. The author is indebted to him for having brought the subject to his attention.

Discussion

F. S. Bloom.[6] To the engineer who is familiar with practical furnace design and operation, the paper would appear to offer some difficulty, because of the necessary assumptions which the author was forced to make in obtaining a practical solution.

However, he has developed from his mathematical analysis certain facts which agree with test observations of heating furnaces. Some of these statements are worth while emphasizing. For instance, the author states, "As the final surface temperature is approached, there is little change in the boundary resistance, because of little change in surface temperature. As a result, the center temperature, which originally lagged considerably behind the fast-changing surface temperature, has time to catch up to the now slowly changing surface temperature."

[4] "Heating and Cooling Rectangular and Cylindrical Solids," by A. B. Newman, *Industrial and Engineering Chemistry*, vol. 28, 1936, pp. 545–548.

[5] "Complex Variable and Operational Calculus," by N. W. McLachlan, Cambridge University Press, 1939; also The Macmillan Company, New York, N. Y., 1942.

[6] Bloom Engineering Company, Pittsburgh, Pa.

By this statement he approaches the conclusions of Williams and Allen, who have previously stated that center temperatures, or temperatures under the surface of the material, follow the pattern of the surface temperature, and ultimately increase or decrease at the same rate as the surface temperature. From this we can conclude that a temperature history or curve of center temperature will follow, at some later time, the temperature history of the surface. In other words, if we plot surface-temperature history for a piece being heated, we can approximate the history of the center temperature.

If we go further in this analysis, we approach the conclusion that temperature uniformity "center to surface" must be considered with time.

The center temperature knows nothing about what happens to surface temperature at any specific time, although it is similarly affected after some delay. This delay or time lag is a factor dependent upon material size, but is constant regardless of speed of heating, that is, a 6-in. square can be heated in 20 min or 6 hr, but still the time for center temperature to equal surface temperature is the same. The magnitude of temperature difference is very large with fast heating, but after the proper equal time interval, temperature uniformity is the same. We do not produce temperature uniformity by slow heating.

The author's work as expressed in this paper stresses temperature uniformity. The writer does not think he intended to convey this impression. Let us face this problem. We heat a slab to a surface temperature of 2300 F, center temperature 2250 F. It is taken from the furnace and lies on the mill table for 15 sec. The surface cools down while the center continues to increase. We end up in the mill with a mixture of temperatures which cannot be equalized. So why demand or think of perfect uniformity.

Temperature-uniformity data are lacking. What we need is a complete study of temperature differences "surface to center" as related to specific industrial-mill operation. The author's method of calculation could be used for such a study. As is quite general, we get the "cart before the horse." Similarly, we get ourselves involved in calculations which get nowhere except to scare engineers into being cautious where it is not necessary. Let us find out the temperature uniformity demanded by the process.

The author also states, as his conclusion of the calculations, that a lower furnace temperature and better temperature uniformity can be obtained by higher heat transmission. He means luminous flames, thick flame blanket, and greater wall area, which in turn means ample roof height. This factor has been seen time and again on many billet-heating furnaces where a heavy luminous flame produces a better scale condition and a better working piece in the mill operation.

He touches gently on temperature control with which the writer fully agrees. There is no use soaking steel if the surface temperature is changing up and down. A 50-deg F temperature difference is easy to produce with such conditions. Good temperature control on heating furnaces is a necessity for uniform temperature distribution. It should be operated by measuring surface temperature, and in this manner a complicated heating-furnace operation can be reduced to the normal temperature-control problem.

The author has presented an outstanding theoretical paper. It is too complicated for the writer fully to comprehend. He must be pretty close to the right answer, because his conclusions seem accurate. It is suggested that he study mill and furnace conditions and then calculate from surface temperature and mill data the permissible out-of-balance temperatures which mill operations can stand.

Victor Paschkis.[7] The author is to be congratulated for a valuable piece of research. He refers to some previous work of the writer.[2] It may be interesting to compare the two methods of determining the temperature uniformity as follows:

In order to obtain a desired uniformity expressed either by the "temperature-uniformity factor" or by the "relative temperature-uniformity ratio," a definite furnace temperature and a definite heating time must be applied. Both should be expressed in dimensionless units. The determination from the temperature-uniformity factor or the relative uniformity ratio compare as follows:

	Heisler	Paschkis
Unknown	Determines the unknown from	
X	Gurney-Lurie charts	$\frac{t - t_0}{t - t_b} = f(m, x)$
t'	$\frac{t' - t}{t' - t_0} = f(m)$	Gurney-Lurie charts

The writer does not see a particular advantage of the new method above the known one and wonders what advantages can be claimed for it.

The most important part of the paper, as far as one-dimensional problems are concerned, is that dealing with the dual relationship between surface temperature, furnace temperature, and m value.

The recommendation that the heating time should be calculated with the time average m lacks proof, and it would be interesting to obtain definite proof. Incidentally, the step-by-step method described for finding t_a could be conveniently replaced by a procedure similar to that used in Fig. 2 of the paper.

It seems regrettable that the paper does not contain curves for cylinders and spheres, similar to those presented in Figs. 3 and 4, for slabs; also that the curves for the relative temperature-uniformity ratios for rectangular bodies are not developed. Only if curves are available can it be hoped that functions such as those presented in this paper will be widely used in industry. It is hoped that the author will develop such curves and present them at a later time. The author seems to exclude from consideration convection-type furnaces which today certainly gain in importance.

W. Trinks.[8] While the author presents an excellent mathematical study, it is, however, too involved and obscure for the average engineer and will, for that reason, not be appreciated. Many an engineer will spend a couple of hours on it and will then lay it aside. With a few changes the usefulness of the paper could be vastly increased.

A sketch of the temperature distribution in a solid with notation of the temperature differences which are sought would be of great value.

In the "Introduction," condition No. 6 should be added; namely, that at the beginning of the heating process the work blank has uniform temperature throughout.

What is meant by the "time average" of boundary resistance m? This question is asked in view of the author's statement that boundary resistance is to be constant. It may be advisable to define boundary resistance and to give the units. Several definitions of boundary resistance are current.

The writer is at a loss to understand how the heat-transfer coefficient h is obtained when both the surface temperature and the flame temperature are alike. Can there be any heat transfer in that case?

The author does not say how Equations [1] and [8] were obtained. It is surmised that J_0 and J_1 are Bessel's functions. If so, that fact should be stated.

[7] Head, Heat and Mass Flow Laboratory, Columbia University, New York, N. Y.

[8] Consulting Engineer, Pittsburgh, Pa. Mem. A.S.M.E.

In modern heating practice, we do not bring the surface of the work blank up to furnace temperature and soak it a long time. We do something else. We heat the work blank quickly to a surface temperature which is above the desired final temperature and then soak it in a somewhat cooler furnace section, where the surface temperature drops and the center temperature rises. It would be wonderful if the author could solve, with Bessel's functions, the final temperature distribution which we obtain with that heating method.

Author's Closure

In the text the author has mentioned that Roshenow and coworkers' charts for two-dimensional heat flow have not yet been published. These charts have since appeared in the February, 1946, issue of the transactions of the A.S.M.E.

Both Mr. Bloom and Mr. Trinks stressed the desirability of solving problems involving step temperature functions. Mr. Bloom mentioned the case of a hot slab cooling on a mill table, and Mr. Trinks that of a slab heated quickly to a surface temperature which is above the final desired temperature and then soaking in a somewhat cooler section of the furnace. Many problems of a similar nature arise in metal heating. For example, in some types of heating operations, after the charge is brought to a given surface temperature, the furnace is turned off, and both charge and furnace are allowed to cool together. Another case occurs in surface hardening by high-frequency induction heating followed by internal quenching. Numerous others could be cited. Though the thermal operations involved are entirely unrelated physically, yet all of them are decidedly similar when considered in a mathematical sense. For instance the problem mentioned by Mr. Trinks is mathematically identical to the problem of surface hardening by high-frequency induction heating followed by an internal quench. Both of these can be readily solved by means of existing temperature charts, such as those shown in Figs. 6 and 7. In general all the problems mentioned simply involve relaxing from an initial known temperature distribution. The author is at present preparing a paper on the general solution of problems of this type.

Mr. Bloom points out that center temperatures can be approximated when surface temperatures are known, because of the constant time lag between equal surface and center temperatures. The magnitude of the time lag for any given surface-center temperature can be found from

$$t = \frac{-L^2 \log_e (\cos w)}{d\, w^2}$$

where

r = time lag in hours.
d = diffusivity in sq ft per hr
L = half thickness of slab in feet
w = first root of $m\, w = \cot w$

Values of w^2 are plotted in Fig. 3 and cos w in Fig. 1. Obviously, the time lag varies directly as the square of the thickness and inversely as the diffusivity. Because of the factor w, it also depends on the boundary resistance, decreasing as the boundary resistance increases.

Regarding the "time-average" of boundary resistance, mentioned by both Mr. Trinks and Mr. Paschkis: It is true that in the mathematical problem boundary resistance is considered to be constant. However, in actual heating-up processes boundary resistance varies throughout the heating cycle. Therefore, in applying mathematical formulas to actual thermal problems, it is necessary to estimate in some way or other the average value of the boundary resistance over the heating period, substitute this average value into the formulas, and solve as though the boundary resistance were constant. This average boundary resistance can be based on various thermal concepts. The author has suggested basing it on a time-average surface temperature. Even though, as Mr. Paschkis points out, this method lacks proof, it is nevertheless based on what appears to the author to be much more reasonable assumptions than those which are usually made. In fact, to the author's knowledge, it is the only method advanced so far which is not based on hit or miss guessing.

In regard to Mr. Paschkis' query as to the advantages of the present method of solving temperature-uniformity problems over that previously used: The two methods are in fact complementary. In the previous method heating times and in the present furnace temperatures can be found directly without resorting to Gurney-Lurie type charts. The present method covers a wider range of variables and requires just one simple chart, Fig. 1, in place of the three—each with a family of curves—which are required in the method of Paschkis.

Mr. Trinks is at a loss to understand how the heat-transfer coefficient h can be obtained when both the surface temperature and the flame temperature are alike. By definition, for black-body radiation

$$h = 0.173\,\frac{[(T_a/100)^4 - (T_s/100)^4]}{T_a - T_s}$$

where

T_a = flame temperature in degrees Rankine (F + 460)
T_s = surface temperature in degrees Rankine
h = Btu per sq ft, hr, F

After factoring $T_a - T_s$ from the numerator, this reduces to

$$h = \frac{0.173}{(100)^4}(T_a^2 + T_s^2)(T_a + T_s)$$

and when T_s is equal to T_a

$$h = \frac{(0.173)\ (4)\ (T_a)^3}{(100)^4}$$

Although h is finite, there can be no net exchange of heat because no temperature difference exists.

Dynamic Behavior and Design of Servomechanisms[1]

By G. S. Brown[2] and A. C. Hall,[3] Cambridge, Mass.

This paper aims to set forth the criteria that are important in the design of certain servomechanisms and to show how certain analytical procedures can be applied to almost any problem to define quantitatively the properties that the control should have in order to make the servomechanism perform in the manner desired. The nomenclature used is essentially that proposed by Draper (1).[4] It is used in the treatment of the problem of synthesizing a controller for a servomechanism whose controlled member is to be rotated and can be defined in terms of inertia plus viscous and coulomb friction, plus a load torque. The broad objective of the designer is assumed to be that of designing a controller which will keep the dynamic error in controlled angular position of the controlled member a minimum under certain operating conditions. The transient and steady-state error for certain forms of motion, the criteria for stability, the effects of viscous friction, coulomb friction and load torques on the desired performance, and other related matters are treated. Several nondimensional charts and tables are included in the paper and show quantitatively the performance of any particular servomechanism with a controlled member of the kind treated, when the system has the various forms of control.

1 Introduction

Servomechanisms (2) or, more generally, closed-cycle automatic-control systems have become during the past decade exceedingly important elements in, for example, manufacturing, the process industries (3, 4), the steering (5) and operation of ships and aircraft, and many important scientific devices (6). As the applications have been increased in number, the demands imposed on the reliability, precision, and speed of operation of the mechanisms have also been increased. Fortunately, many of these demands have been satisfied because of developments in the various branches of engineering and physics that have taken place simultaneously with the growth of automatic control, but at the same time the complexity of the mechanisms has often been increased. The result of all this has been that the design of servomechanisms or automatic-control systems has now become almost a science, so that for the skillful and straightforward design of a high-caliber system one requires, (*a*) a clear appreciation of the fundamental principles involved in the correct functioning of an automatic-control system, and (*b*) an accurate knowledge of the properties of the mechanisms of which it is composed.

The purpose of this paper is to set forth in fairly simple terms the criteria that are important in the design of servomechanisms and to show how certain simple analytical procedures can be applied to almost any system to define the properties that the control should have in order to make the mechanism perform in the manner demanded.

2 Factors That Characterize a Servomechanism

A servomechanism is a power-amplifying automatic-control system characterized by the presence of a control element that is actuated by some function of the "difference" between the response desired of the system and its actual response. In other words, the system is error-sensitive, and the control is some function of the "error" in the behavior or state of the system. Usually a continuous change in the actuating quantity or the input signal is to be followed by a continuous action of the controller. The input signals usually come from low-power sources and may be random with time, but are preferably continuous. Systems of this kind are closed-cycle continuous-control systems, and it is this closed-cycle property that identifies them as servomechanisms. Their component elements generally tend to be complex, and because of the dependence of the operation of their control upon the result of the control operation, their design must conform to certain basic principles.

Because of widespread application of servomechanisms the actuating and controlled quantities are found in diverse forms. In the servomechanisms used for the automatic steering of ships or aircraft the actuating quantity or input signal is given by a low-power device sensitive to the course setting on a magnetic or gyro compass, and the output or controlled quantity is the direction in which the ship is headed. In servomechanisms used for the control of an automatic die-cutting machine, for example, the cutting head might be required to follow automatically a pattern laid out on a master pattern, or the contour of an existing member, as in replica production. An application such as this would probably result in maintaining the angular position of a shaft operating at a high-power level automatically in synchronism (or in step) with the angular position of a shaft as established by a low-power mechanism. The input signal might be the angular position of a cam-operated shaft, and the controlled quantity or output might be the angular position of the lead screw carrying the cutting head. In practice the angular positions of the two shafts are compared by one of several means common in the art, a measuring device detects the error in the position of the output and establishes a control signal, a controller is actuated by this control signal and operates either directly on the shaft of the high-power member or through some accessory device to bring the output shaft into the desired position.

Confusion occasionally exists among those working in automatic control, concerning the designation of a servomechanism

---

[1] The first portion of this paper was prepared during the summer of 1940, for the Subcommittee on Machine Design, Machine-Shop Practice Division of the A.S.M.E. At the request of the N.D.R.C. it was withdrawn from open publication and privately printed for restricted release. Sections 1 through 9 are substantially as originally written. Sections 10 through 12 have been added for this printing. Sections 13 through 19 have been adapted from an M.I.T. doctorate thesis by A. C. Hall and published for restricted distribution by the Technology Press.

[4] Numbers in parentheses refer to the Bibliography at the end of the paper.

Contributed by the Instruments and Regulators Division and presented at the Annual Meeting, New York, N. Y., Nov. 26–29, 1945, of The American Society of Mechanical Engineers.

and a servo. In this paper the entire array of apparatus beginning with the input member and going through to the high-power output member and including all measuring and control equipment is called a servomechanism. In particular, the torque, force, or power-producing member that is actuated by the control to restore the equilibrium condition is called a servo, or servomotor.

3 Basic Design Problem

Since a servomechanism should perform in a manner that meets a certain specification, the design of the system should be carried out only after an analysis that yields performance data for each component mechanism, in a form readily subject to quantitative interpretation for design purposes, has been concluded. The component elements can be described in terms of certain quantities, and the analysis should be carried out in a manner that shows the relations that must exist among these quantities in order to provide (*a*) a system that is stable and (*b*) a system whose transient and steady-state operating errors are within the specified limits.

This work is aided by subdividing the system into its essential component mechanisms, for example, the input member, the error-measuring element, the controller, the controlled member, and the output member. With all systems, good judgment is necessary in carrying out this subdivision, and in the more complicated systems a rather detailed subdivision may be desirable (see section 10). A block diagram representative of the manner of interconnection of these component mechanisms is, as a rule, readily drawn. After the analysis has been completed the performance of the mechanisms assigned to the various boxes in the block diagram can be defined, and their design and construction eventually carried out. If the performance specifications are reasonable the designer is limited only by cost, space or weight restrictions, availability of devices having the desired rating and characteristics, and so forth. In other words, the designer's problem is basically that of reducing certain requirements to practice.

To illustrate the procedure for the analysis of a simple mechanism, consider the block diagram shown in Fig. 1. Here the entire system is represented by five elements: namely, the input member, the error-measuring device, the controller, the controlled member, and the output member. Each component element may comprise much apparatus but this is unimportant for the present. For a generalized treatment let the system be defined in terms of the symbols shown in Fig. 2, where

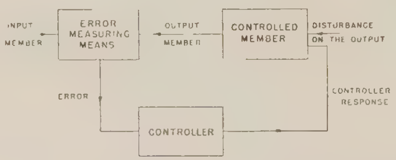

Fig. 1 Block Diagram for a Servomechanism

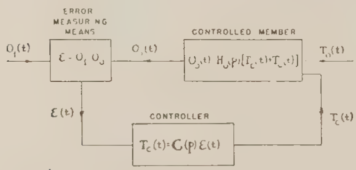

Fig. 2 Block Diagram for a Servomechanism Showing Symbolic Representation of Elements

$\theta_i(t)$ = input disturbance as a function of time
$\theta_0(t)$ = response of output as a function of time
$\epsilon(t)$ = error between desired and actual response as a function of time
$T_c(t)$ = response of controller as a function of time
$T_0(t)$ = any disturbance applied to output as a function of time

Also let these symbols be related in the following manner

$$\epsilon(t) = \theta_i(t) - \theta_0(t) \quad [1]$$

$$T_c(t) = C(p)[\epsilon(t)] \quad [2]$$

$$\theta_0(t) = H_0(p)[T_c(t) + T_0(t)] \quad [3]$$

In Equation [2] $C(p)$ is a differential operator in the form of a polynomial in p, where p represents d/dt. It operates on the time expression for the error and thereby gives the time expression for the controller response. It is called the "controller operator" and is to be determined from the analysis. $H_0(p)$ of Equation [3] is also an operator called the "output member operator." It is characterized by the physical properties of the device or process to be controlled.

Since, in general, the control is intended to keep the error zero, the extent to which the objectives of the control have been achieved is best indicated by deriving the expression for the error in terms of the operators $C(p)$ and $H_0(p)$, the input signal $\theta_i(t)$, and the output disturbance $T_0(t)$. From Equations [1], [2], and [3]

$$\epsilon(t) = \frac{1}{1 + C(p)H_0(p)}[\theta_1(t) - H_0(p)T_0(t)] \quad [4]$$

$$\theta_0(t) = \frac{C(p)H_0(p)\theta_i(t) + H_0(p)T_0(t)}{1 + C(p)H_0(p)} \quad [4a]$$

wherein $C(p)$ is frequently the only design variable. Equation [4] is the basic equation for a closed-cycle control system such as that shown in Fig. 2, and the expression $[1 + C(p)\,H_0(p)]^{-1}$, being an over-all system operator or characteristic equation, summarizes the system behavior. This use of an over-all system operator $[1 + C(p)H_0(p)]^{-1}$ to summarize the theory of design of a closed-cycle system of automatic control originated, to the authors' knowledge, with John Taplin in 1937, while he was a special student in electrical engineering at the Massachusetts Institute of Technology. Taplin no doubt recognized the similarity between the closed-cycle control problem and the feedback-amplifier problem as presented by Black (7) and Nyquist (8).

The applications of automatic control are numerous and varied and it is impossible to say that θ, T, or ϵ always represents any particular quantity. Reference to a few of the applications cited in the literature will show that θ, T, or ϵ may be an angular displacement, a flow, a voltage, a torque, a light flux or any of the physical quantities commonly encountered. However, since interest in an analysis is usually stimulated by speaking in terms of some physical application, the control of an automatic replica-cutting machine is considered as an example. It is assumed that $\theta_i(t)$ is an angular displacement indicated by a delicate cam-operated mechanism which displaces a low-power input shaft in accordance with the motion $\theta_0(t)$ desired of a high-power output shaft. The error $\epsilon(t)$ is assumed to be a voltage made proportional to error angle by any of the commonly used methods. The controller response $T_c(t)$ is assumed as a torque applied to the controlled member. The controlled member is a lead screw carrying a cutting head. Thus the controller, in effect, serves also as the prime mover or servomotor for the lead-screw drive. Fig. 3 shows a schematic arrangement of the essentials of this system.

The output member operator $H_0(p)$ can now be formulated. The cutting-head lead-screw drive of a typical milling machine

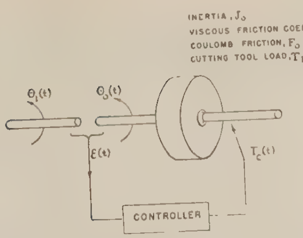

Fig. 3 Schematic Diagram of Servomechanism Used for Illustrative Example

would comprise shafts, screws, gears, and tool holder and could be defined in terms of an inertia J_0, and a viscous-friction coefficient f_0. The output member would be subjected to a coulomb friction torque and a load torque, which jointly can be represented as $-T_0(t)$. On the assumption that the parameters are constant or the system is linear for small ranges of operation, the differential equation of motion for the output member when considered as a single unit is

$$J_0 \frac{d^2\theta_0}{dt^2} + f_0 \frac{d\theta_0}{dt} = T_c(t) - T_0(t) \ldots\ldots\ldots [5]$$

It is expedient now to express $\frac{d\theta_0}{dt}$ by $p\theta_0$ and $\frac{d^2\theta_0}{dt^2}$ by $p^2\theta_0$, and to write Equation [5] as

$$(J_0p^2 + f_0p)\theta_0(t) = [T_c(t) - T_0(t)] \ldots\ldots\ldots [5a]$$

where the expression in parenthesis preceding $\theta_0(t)$ is an operator, which operates on $\theta_0(t)$ as indicated. When solved for $\theta_0(t)$, Equation [5a] gives

$$\theta_0(t) = \frac{1}{J_0p^2 + f_0p} [T_c(t) - T_0(t)] \ldots\ldots\ldots [6]$$

which, by analogy with Equation [3], gives the output member operator as

$$H_0(p) = \frac{1}{J_0p^2 + f_0p} \ldots\ldots\ldots [7]$$

The substitution of $H_0(p)$ from Equation [7] into Equation [4] gives, after some reduction

$$\epsilon(t) = \frac{1}{J_0p^2 + f_0p + C(p)} [(J_0p^2 + f_0p)\theta_i(t) + T_0(t)] \ldots [8]$$

Alternatively, if the input disturbance is a velocity

$$\omega_i(t) = \frac{d\theta_i(t)}{dt} = p\theta_i(t)$$

the error equation becomes

$$\epsilon(t) = \frac{1}{J_0p^2 + f_0p + C(p)} [(J_0p + f_0)\omega_i(t) + T_0(t)] \ldots [9]$$

Expressions typified by Equations [8] and [9] are extremely useful in the design or analysis of control systems since they express the error in terms of the parameters of the system, the input disturbance, the disturbing or load torques on the controlled member, and the controller operator $C(p)$. When any mechanism is to be converted to automatic control, the problem for the designer is the synthesis of the simplest and most practical controller that will have the operator $C(p)$ required to meet the specified operating conditions. The next sections present a generalized treatment of the problem of deriving a form of the operator $C(p)$ required by the various conditions of servomechanism operation commonly encountered in practice.

4 Simple Form of Controller Operator

In any particular application it would be desirable to know the expected form of the input disturbance and to choose the controller operator $C(p)$ on the basis of a certain specified performance under the expected operating conditions. In general, however, the input disturbance is random, so that its description in an analytical form which is of much use in the analysis is usually impractical. It is common practice therefore to evaluate the performance afforded by possible designs on the basis of the nature of the transient and steady-state responses of the respective systems to certain test disturbances.

The well-known transient response of a system defined by Equation [8] or [9] is

$$\epsilon(t) = A + Be^{r_1t} + Ce^{r_2t} + \text{etc.} \ldots\ldots\ldots [10]$$

A direct guide to the simplest form of controller operator that will give a workable system is afforded by a characteristic demanded of the exponents r_1 and r_2 of Equation [10]. For instance, r_1 and r_2 are the roots of the operator $J_1p^2 + f_0p + C(p)$ which may conveniently be a polynomial. Clearly the simplest form of $C(p)$ that will make this operator a polynomial is

$$C(p) = k \ldots\ldots\ldots [11]$$

and for the corresponding simple controller, Equation [2] reduces to

$$T_c(t) = k\epsilon(t) \ldots\ldots\ldots [12]$$

Also, for the system to be stable r_1 and r_2 must have negative real parts, and if they are complex the magnitudes of their imaginary parts must fall within a certain range because of operating restrictions. Hence the magnitude of k is obviously restricted.

A further restriction on k can be deduced from the steady-state operating error given by the quantity A of Equation [10], which can be written down by inspection from Equation [8] or [9]. For a constant input angle θ_i, or a constant input velocity ω_i, and constant load torque, the steady-state error is given by putting the operator p zero everywhere in Equations [8] and [9]. If then $C(p)$ is defined by Equation [11], the steady-state errors become, respectively

$$\epsilon_{ss} = \frac{T_0}{k} \ldots\ldots\ldots [13]$$

for θ_i and T_0 constant; and

$$\epsilon_{ss} = \frac{f_0\omega_i + T_0}{k} \ldots\ldots\ldots [14]$$

for ω_i and T_0 constant.

A controller having an operator as just defined applies torque to the controlled member in proportion to the indicated error. Since this definition makes no allowance for response lag in the controller, which here is assumed to include the servomotor, a perfect element is assumed. Actually, of course, response lags exist in all controller servomotors encountered in practice though frequently the lag is negligible in comparison with the periods of response of the system as a whole. Section 10 discusses the problem of treating the controller synthesis when the servomotor has response lags. Servomechanisms employing controllers characterized by Equation [11] are found frequently in practice. They are called simple-error controller servomechanisms and, as a rule, are confined to the class that involves prime movers rated less than a few watts for reasons that later are made clear.

The problem now to be handled is that of selecting the best value of k. Unfortunately, the selection involves a compromise because from Equations [13] and [14] high precision of operation requires that k be large and f_0 and T_0 small, whereas the stability restriction implied in Equation [10] imposes a limit on the largeness of k or the smallness of f_0, because the entire damping is here supplied by viscous friction in the output. Obviously the restrictions on the magnitude of T_0 are practical operating ones. The answers to these questions are best obtained from an examination of the transient response of the system, which is the subject of the next section.

5 Transient Response of Error-Controlled Servomechanism

The transient response of a servomechanism following the sudden application of a constant disturbance to the input member gives data that are useful (*a*) for appraising the quality of the performance of the system as a whole and (*b*) for proportioning f_0 and k to meet certain performance specifications. The response to this suddenly applied input disturbance completely characterizes the system.

The transient solutions are herein given as dimensionless expressions in a form convenient for engineering use, using the procedure and notation introduced by Draper (1). Coulomb friction and applied torque are neglected during the preliminary analyses since it is unnecessary to include them in order to evaluate the quality of the transient performance. Furthermore, their effects can be readily determined and taken into account by applying the principle of linear superposition of causes to give the total effects.

For identification purposes a servomechanism comprising a simple-error controller defined by Equation [12] is classified herein as type 1. For this controller, and with coulomb friction and load torque neglected, Equation [9] has the following form

$$\epsilon(t) = \frac{1}{J_0 p^2 + f_0 p + k_1}\,(J_0\,p + f_0)\omega_i(t) \qquad [15]$$

where the subscript 1 in Equation [15] and the following indicates that the parameters are for the system with a type 1 controller.

It is convenient now to define certain new symbols ζ_1 and ω_{n1} by the relations (1)

$$\zeta_1 = \frac{f_0}{2\sqrt{J_0 k_1}} \qquad [16]$$

$$\omega_{n1} = \sqrt{\frac{k_1}{J_0}} \qquad [17]$$

and to rewrite Equation [15] in terms of these symbols thus

$$\epsilon(t) = \frac{1}{p^2 + 2\zeta_1\omega_{n1}\,p + \omega_{n1}}\,(p + 2\zeta_1\omega_{n1})\omega_i(t) \qquad [18]$$

In Equation [18] ζ_1 is the damping ratio, that is, the ratio of the actual damping to the damping which would cause aperiodic response of the system. It is a dimensionless parameter and of course equals unity for critical damping; ω_{n1} is the undamped natural frequency of the system.

The response of the system defined by Equation [18] is oscillatory, aperiodic, or overdamped depending upon whether the roots of the denominator of Equation [18] when equated to zero, are conjugate complex, equal reals, or unequal reals, that is, whether ζ_1 is less than unity, unity, or greater than unity. The general form of the expression for the roots is

$$r_1,\ r_2 = -\zeta_1\omega_{n1} \pm j\omega_{n1}\sqrt{1-\zeta_1^2} \qquad [19]$$

$$= -\frac{1}{\tau_1} \pm j\omega_1 \qquad [20]$$

where τ_1 is the characteristic time and ω_1 is the actual angular frequency.

The complete solution of Equation [18] for the case when a velocity ω_i is suddenly applied to the input member with the system at rest and ω_i is afterward maintained constant, and when the roots r_1, r_2 are conjugate complex, is

$$\epsilon(t) = \frac{2\zeta_1\omega_i}{\omega_{n1}}\left[1 - e^{-\frac{t}{\tau_1}}\left(\cos\frac{\sqrt{1-\zeta_1^2}}{\zeta_1}\,\frac{t}{\tau_1} + \frac{2\zeta_1^2-1}{2\zeta_1\sqrt{1-\zeta_1^2}}\,\sin\frac{\sqrt{1-\zeta_1^2}}{\zeta_1}\,\frac{t}{\tau_1}\right)\right] \qquad [21]$$

Equation [21] thus gives the transient response and can be written in a nondimensional form convenient for plotting as

$$\frac{\epsilon(t)}{\epsilon_{ss}} = 1 - \frac{1}{2\zeta_1\sqrt{1-\zeta_1^2}}\,e^{-\zeta_1\omega_{n1}t}\sin\left(\sqrt{1-\zeta_1^2}\,\omega_{n1}t + \phi\right) \qquad [22]$$

where

$$\epsilon_{ss} = \frac{2\zeta_1}{\omega_{n1}}\,\omega_i \qquad [23]$$

and

$$\phi = \tan^{-1}\frac{2\zeta_1\sqrt{1-\zeta_1^2}}{2\zeta_1^2-1} \qquad [24]$$

For the critically damped case Equation [22] reduces to

$$\frac{\epsilon(t)}{\epsilon_{ss}} = 1 - e^{-\omega_{n1}t}\left(1 + \frac{\omega_{n1}t}{2}\right) \qquad [25]$$

where

$$\epsilon_{ss} = \frac{2\omega_i}{\omega_{n1}} \qquad [26]$$

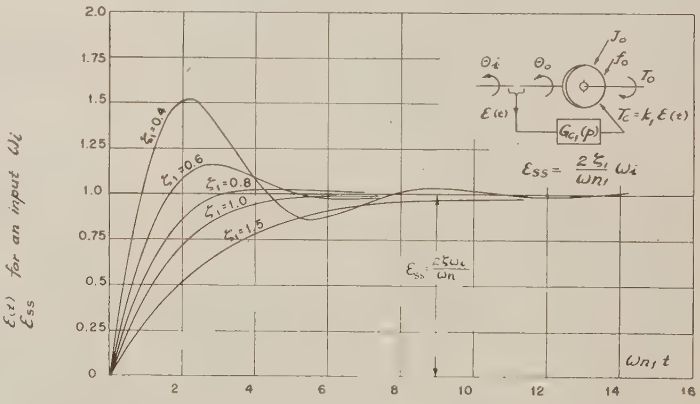

Fig. 4 Dimensionless Transient Error Curves for a Servomechanism With Type 1 Controller When Subjected to Suddenly Applied Input Velocity ω_i

The nature of the transient response is well illustrated by the family of curves in Fig. 4 which shows the dimensionless ratio $\frac{\epsilon(t)}{\epsilon_{ss}}$ as a function of the dimensionless quantity $\omega_{n1}t$ for various values of ζ_1. Load torque and coulomb torque are assumed to be zero. If the viscous-damping coefficient f_0 is assumed to be the only variable in the system, ω_{n1} is constant. Hence when the family of curves is examined with respect to the dimensionless abscissa scale $\omega_{n1}t$, the relative positions of the curves on the plot indicate the relative times of duration of the transient for the particular values chosen for ζ_1.

An inspection of Fig. 4 shows at once: (*a*) that for a type 1 servomechanism with constant ω_{n1} the actual time required for the system to reach substantially its steady-state error is practically independent of ζ_1 when $0.6 < \zeta_1 < 1.0$, whereas the time required for the system to attain any substantial part of its final steady-state error decreases as ζ_1 decreases; (*b*) that the overshoot or tendency to oscillate increases as ζ_1 is decreased; and (*c*) that the steady-following error is proportional to the ratio ζ_1/ω_{n1}. It follows therefore that any design of a type 1 controller is inherently a compromise unless certain specific performance requirements predominate, such for example as a given steady-state error at a given maximum velocity of operation of a given controlled member.

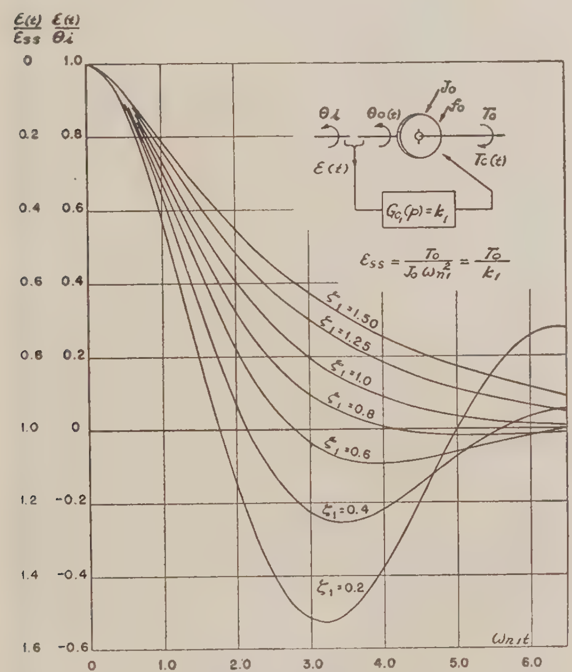

Fig. 5 Dimensionless Transient Error Curves of a Servomechanism With a Type 1 Controller When Subjected to a Suddenly Applied Input Angle θ_i or a Suddenly Applied Load Torque T_0

Fig. 5 shows the dimensionless solutions of Equation [8] for the angle and torque disturbances considered separately. Notice that a single family of curves satisfies both solutions if the ordinate scale for $\epsilon(t)/\theta_i$ for an angle disturbance is inverted to give the ordinate scale $\frac{\epsilon(t)}{\epsilon_{ss}}$ for the torque disturbance.

6 Illustrative Example

The effectiveness with which the foregoing data may be used to direct the path of a typical design, and also the fundamental objection usually leveled at mechanisms with a type 1 controller, are readily demonstrated by the following example:

Suppose a given output member is to be automatically controlled in angular velocity and position and that the controller is to be capable of driving this member at 120 rpm with a steady-state following error, due only to viscous friction, of not greater than π radians. Assume that the moment of inertia of the controlled member plus its connected servomotor is 1 slug ft². Assume also that the system is to be critically damped. Determine the control constant k_1, and the viscous friction coefficient f_0.

From Equation [23]

$$\omega_{n1} = \frac{2\zeta_1\omega_1}{\epsilon_{ss}} = \frac{2 \times 4\pi}{\pi} = 8 \text{ radians per sec} \qquad [27]$$

From Equation [17]

$$k_1 = \omega_{n1}^2 J_0 = 64 \text{ lb-ft per radian} \qquad [28]$$

From Equation [16]

$$f_0 = 2\zeta_1\sqrt{J_0k_1} = 16 \text{ lb-ft sec per radian} \qquad [29]$$

From the curves in Fig. 4 the system reaches the steady-state velocity in a dimensionless time $\omega_{n1}t$ of approximately 5.5, or an actual time t of $5.5/8$ = approximately 0.7 sec.

The design constants and the time of duration of the transient are now known quantitatively. However, when it is realized that the power dissipated in viscous friction at maximum speed is $f_0\omega_i^2$, which in practical units is

$$\frac{16 \times (4\pi)^2}{550} \text{ or } 4.57 \text{ hp} \qquad [30]$$

the objection to a type 1 mechanism is realized. It is clearly apparent that the designer faces a difficult task when he comes to devise means to dissipate this power in viscous friction and to devise a controller that will be essentially instantaneous and linear in operation and develop torques as great as 200 lb-ft. Furthermore, the entire viscous power serves only to damp the system, and serves no real productive purpose.

Smaller damping losses are achieved by resorting to underdamped operation, accepting a larger error, or decreasing inertia. For the same steady-state error and inertia, but with ζ_1 reduced to 0.6, the new constants are

$$\left.\begin{aligned} \omega_{n1} &= 4.8 \text{ radians per sec} \\ k_1 &= 23 \text{ lb-ft per radian} \\ f_0 &= 5.75 \text{ lb-ft sec per radian} \end{aligned}\right\} \qquad [31]$$

The task of the designer has now been eased in proportion to ζ_1^2, and the power dissipated in damping reduced to 1.65 hp. The transient now exists for a dimensionless time $\omega_{n1}t$ of approximately 5, so that $t = 5/4.8$, or about 1 sec, compared with 0.7 sec formerly. The power lost in damping is still appreciable, however, and is the reason why viscous-damped servomechanisms are rarely built for power ratings greater than a few hundred watts.

7 Controllers in Absence of Output Damping

The basic-error equation will now be examined to see whether the controller characteristic can be modified to permit the elimination of output damping power loss. Assume first that substantially all the viscous damping in the output member is eliminated by appropriate modifications to the design. The damping term then disappears from the denominator of Equation [9], the damp

ing ratio ζ_1 becomes substantially zero, the system tends to permit sustained oscillations and hence is impracticable. If by appropriate redesign of the controller, however, a new controller operator $C(p)$ can be obtained which has a term proportional to the time derivative of the error as well as to the error, a damping term is re-established in the denominator. The controller operator then has the form

$$C(p) = k + lp \qquad [32]$$

and for the system to be stable it is necessary only that the magnitude of the coefficient l be such that the roots of the expression

$$J_0{}^2 + C(p) = 0 \qquad [33]$$

have negative real parts.

This method of arriving at a desirable controller characteristic, while perhaps somewhat heuristic, is actually a very useful one because once the need for improvement in servomechanism performance is realized, the possibilities for achieving it by the design of a controller having the appropriate operator $C(p)$ become obvious after relatively little thought.

The use of control coefficients proportional to the derivative of the error is not new. The features which make this so-called derivative control desirable were pointed out by Minorsky (5) as early as 1922, and used by him in experiments on the automatic steering of ships prior to 1930. Later treatments are given by Hazen (6), and Mitereff (23). For purposes of identification a controller whose operator involves only the error and its derivatives is herein classified as type 2. To increase the scope of the analysis both first- and second-derivative control are assumed and the controller operator is written as

$$C_2(p) = k_2 \pm l_2p \pm m_2p^2 \qquad [34]$$

In this expression k_2, l_2, and m_2 are positive real numbers, the subscripts 2 signify control coefficients for a type 2 controller, and the algebraic signs signify the possibility of designing the controller to apply components of torque in a positive or a negative direction for a given error or time rate of change of error. Obviously, there is no choice regarding the algebraic sign before k_2.

The substitution of the expression for $C_2(p)$ in Equation [9] gives, when coulomb friction and load torque are neglected

$$\epsilon(t) = \frac{(J_0p + f_0)\omega_i(t)}{(J_0 \pm m_2)p^2 + (f_0 \pm l_2)p + k_2} \qquad [35]$$

$$= \frac{(J_0p + f_0)\omega_i(t)}{J_2p^2 + f_2p + k_2} \qquad [36]$$

where
